A number of recent morphologic and molecular analyses have addressed phylogenetic relationships both among genera that have been referred to Mustelidae and between mustelids and other extant members of the monophyletic suborder Caniformia, which includes canids (dogs), procyonids, pinnipeds, and ursids. While most of these analyses have supported a traditionally held view that Procyonidae and Mustelidae are sister taxa, and that Ursidae and Canidae represent successive outgroups (Flynn *et al.*, 1988), the position of Pinnipedia has proven more difficult to resolve, with morphological evidence supporting a sister taxon relationship to Ursidae and molecular data tending to support a sister group relationship to Musteloidea (Fig. 2A).

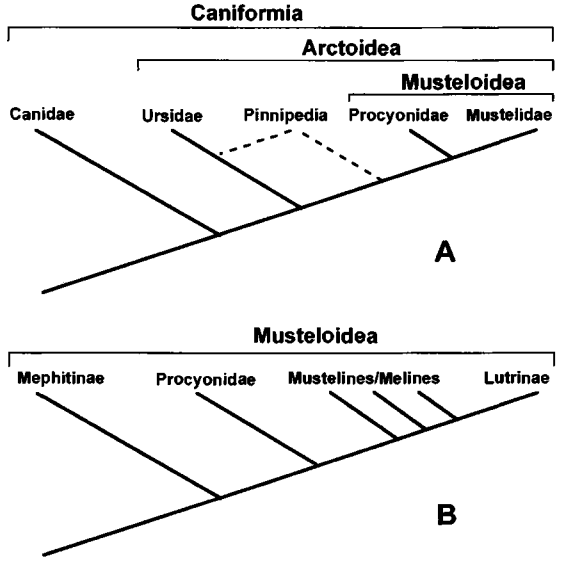

Figure 2 *Cladograms depicting the relationship of mustelids to other extant members of the carnivoran suborder Caniformia (A) and one hypothesis of phylogenetic relationships among musteloids based on molecular data where skunks (Mephitinae) are not part of a monophyletic Mustelidae. Dotted lines (A) show alternative hypotheses for pinniped relationships, and the musteline/meline designation (B) is used to indicate the paraphyletic nature of these subfamilies.*

Among the 23 genera and five subfamilies attributed to Mustelidae, there is strong support, both molecular and morphologic, for the monophyly of otters (Lutrinae) and skunks (Mephitinae), little support for Mustelinae monophyly, and no support for badger (Melinae) monophyly (weasels, martens, wolverines, among others). Lutrinae appears to be nested well within the mustelid clade (Fig. 2B), and several studies have suggested that skunks are the sister taxon to otters (Wyss and Flynn, 1993). Ribosomal protein sequence data (Dragoo and Honeycutt, 1997), however, argue for a phylogenetic position of skunks as sister taxon to Musteloidea (Fig. 2B), implying that characters such as loss of the second molars and upper carnassial notch evolved more than once among musteloids. Consensus on musteloid phylogeny will require more analyses that combine molecular and morphologic data, and that include important fossil taxa such as *Mustelavus* and *Potamotherium*, as well as the early procyonid *Amphictis*.

N

Narwhal

Monodon monoceros

M. P. Heide-Jørgensen
Greenland Institute of Natural Resources, Nuuk

In 1758, Linnaeus used the scientific name *Monodon monoceros* for the whale with one tooth and one horn. Together with the close relative the white whale or beluga, *Delphinapterus leucas*, the narwhal now forms the two-species family of Monodontidae (Fig. 1).

I. External Appearance and Dentition

Newborn narwhals are evenly gray or dark-brownish gray. While nursing for 1–2 years, the coloration changes gradually to a dark background color with white patches that give a mottled appearance. When adult, the animals are completely mottled on the dorsum but with increasing white fields on the ventral side. Old adult males only maintain a narrow dark-spotted pattern on the top of the back, whereas the rest of the body is white. Unlike in other cetaceans, the tail flukes are concave in fully grown narwhals and a low ridge replaces the dorsal fin.

The most conspicuous feature of the narwhal is the up to 3-m-long spiraled tusk. Six pairs of maxillary and two pairs of mandibulary teeth are present in early narwhal embryos, but only two maxillary pairs persist and develop. Of these the two anterior teeth develop into an elongated tooth that is the start of the tusk. The other two TEETH remain vestigial. In males, the left of the two elongated teeth grows and protrudes through the maxillary bones and skin of the rostrum of the whale. During growth the tusk spirals and grooves to the left. In males, the right of the elongated maxillary teeth and in females both maxillary teeth remain inside the SKULL, sometimes just protruding through an opening in the maxillary bone. Irregularities in the development of tusks are frequently seen: females sometimes attain a tusk, males occasionally have no tusk, and narwhals with two tusks (so-called "double tuskers") are not rare.

There is great variability in the shape and dimensions of the protruding tusk. Some are fairly straight and others corkscrew like; some are thin and fragile, whereas others are short and thick. The largest tusk measured was 267 cm, but a full-grown male usually carries a tusk of about 200 cm. Tusks are sometimes broken, and there are records of tusk from another narwhal sitting inside the broken tip. The purpose of the tusk has been much disputed, but because both females and males without tusks thrive, tusks do not seem critical for survival. The tusk is more likely a secondary sexual character that is related to the hierarchy of male narwhals. Displays and crossing of tusks are

Figure 1 *The narwhal,* Monodon monoceros, *occurs in the remote North Atlantic and Arctic Oceans and is conspicuous with a long tusk in males, usually formed from one tooth in the left upper jaw. Pieter A. Folkens/Higher Porpoise Design Group.*

frequently seen on narwhal summering grounds and it is likely that this activity determines social rank.

II. Fossil Records

There are several records of narwhal fragments from Pleistocene deposits in England and Germany. Bones found along the Russian Arctic coasts—both on the mainland and on the Russian Arctic Islands—also suggest a different occurrence of narwhals before or during the most recent glaciation. In Canada, bone remains from early postglacial times have also been found both north (Ellesmere Island) and south (Gulf of Saint Lawrence) of present narwhal distribution.

III. Distribution and Abundance

The main reason the narwhal remained a legendary animal for so long may be because of its preference for remote and inaccessible habitats, usually in areas over deep water that is covered with heavy pack ice during dark winter months. Europeans did not visit most of these areas until the 19th century, and even though Inuit hunters traded the tusks with whalers, precise descriptions were lacking.

The narwhal essentially inhabits the Atlantic sector of the Arctic Ocean with few records of stragglers from the Pacific sector (Fig. 2). During the last glaciation, narwhals were restricted to the North Atlantic but with the retreating ice they inhabited the archipelago of the Canadian High Arctic, northern Hudson Bay, Davis Strait, Baffin Bay, the Greenland Sea, and the Arctic Ocean between Svalbard and Franz Josef Land. Today, low numbers of narwhals are found offshore in deep-water areas of the Eurasian sector of the Arctic Ocean, where they are seen most frequently around Franz Josef Land and Svalbard. The northernmost recordings of narwhals are from the area between 84°N and 85°N northeast of Franz Josef Land at 70–80°E. In the Greenland Sea, narwhals are widely distributed in the pack ice but probably in low numbers. Along the coast of East Greenland, narwhals are found during the open water season in fjords from 65°N to 81°N, with particularly large concentrations in Scoresby Sound and Kangerlussuaq. No complete ABUNDANCE ESTIMATES are available from any of the Northeast Atlantic areas, but in 1983 an estimate of 300 narwhals was derived from a survey in Scoresby Sound.

In West Greenland, narwhals visit coastal areas in northwest Greenland (Inglefield Bredning and Melville Bay) during summer and central West Greenland during autumn (Uummannaq) and winter (Disko Bay). Up to 4000 narwhals have been counted in Inglefield Bredning in August and 3000 in Disko Bay in March. Offshore, narwhals are abundant in the heavy consolidated pack ice in northern Davis Strait and Baffin Bay from late November through May, and the number of narwhals wintering in this area has been estimated at 35,000 whales.

During ice break-up, narwhals move into the Canadian High Arctic through Lancaster Sound and Pond Inlet. They visit the fjord systems of Eclipse Sound, Admiralty Inlet, Prince Regent Inlet, and Peel Sound during the open water season from June to September. The abundance in these areas was estimated at 18,000 narwhals in 1984. With the formation of fast ice in October, narwhals move east toward Baffin Bay and Davis Strait. In northern Hudson Bay and Foxe Basin, an apparently isolated group of 1300 narwhals persists. It is believed that they move south to Hudson Strait in winter.

IV. Migration

Narwhals follow the DISTRIBUTION of the ice and move toward coastal areas in summer when these are ice free. During freeze-up the coastal areas are abandoned and the narwhals move offshore. In winter they stay in very heavy consolidated pack ice, usually in leads or holes in 10/10 of ice. When ice breaks up in the spring, narwhals penetrate north through narrow leads and open water channels.

Movements from summer through winter have been monitored by tracking of narwhals instrumented with satellite-linked radio transmitters attached to the tusk of males. At summering grounds in West Greenland and Canada, narwhals moved back and forth between glacier fronts, offshore areas, and neighboring fjords. When fast ice formed the whales moved out to deeper water, usually up to a 1000-m water depth. In October the whales moved southward toward the edge of the continental shelf where the water depth increases over a short distance from 1000 to 2000 m. This slope was also used as a wintering ground, and even though the whales seemed stationary in this area, they still conducted shorter movements along this steep slope. Narwhals tracked from Canada and West Greenland were within a few kilometers from each other at these wintering grounds at the deep slope at the edge of the continental shelf in central Baffin Bay. The importance of this area as a wintering ground has also been confirmed by aerial surveys. No satellite trackings of whales have been conducted so far in spring and early summer. The mean swimming speed of traveling narwhals is 5 km/hr.

V. Growth in Length and Weight

Length at birth is approximately 160 cm. The tusk erupts at a body length of 260 cm and attains a length of 150 cm at sexual maturity. Body length at sexual maturity is around 360 and 420 cm for females and males, respectively. Mean length and weight at physical maturity are around 400 cm and 1000 kg for females and 475 cm and 1600 kg for males.

No reliable methods are available for estimating the age of narwhals; both the protruding tusk and the embedded teeth contain distinctive growth layers in both dentine and cementum, but with increasing age the growth layers apparently collapse and become unreadable. Also, there is no empirical way to determine how many growth layers are deposited annually. So far, no narwhals have been kept successfully in captivity.

VI. Reproduction

The gestation period of the narwhal is subject to some uncertainty, as mating probably occurs in inaccessible areas in March–May. Calving seems to occur in July–August in both Greenland and Canada, and with a mating season early in spring, this implies a gestation period of 13–16 months. Lactation lasts 1–2 years, and females are generally believed to calve every 3 years, but data supporting this seem inadequate.

Figure 2 *Distribution of the narwhal.*

VII. Feeding

The DIET of narwhals has been studied in Greenland and Canada and they typically prey on high Arctic fish species such as polar cod, *Boreogadus saida*, and Arctic cod, *Arctogadus glacialis;* both are pelagic species that are often associated with the underside of ice. Narwhals also take demersal species that are found at great depths, such as Greenland halibut, *Reinhardtius hippoglossoides;* redfish, *Sebastes marinus;* and bottom-dwelling cephalopods. In some areas the narwhals seem to be feeding exclusively on schools of squids, *Gonatus fabricii,* which can be found at variable depths. Apparently little FEEDING takes place during the open water season in August.

VIII. Population Structure

Narwhals are usually found in small groups of 5–10 whales migrating together. Sometimes larger herds are formed that consist of several smaller groups often all on a directional movement along a coastline or toward the head of a fjord. The narwhal groups are usually segregated with adult males in separate groups and females with calves sometimes together with immature males. Mixed groups occur especially in large herds, but single animals, particularly males, can also be found.

Studies of mitochondrial DNA have revealed a low level of nucleotide and haplotype diversity in narwhals. This is probably the result of a rapid expansion of the population after the last glaciation from a small founding population. Despite the low variation in narwhal mtDNA, there are still genetic differences between narwhals from different areas. Not so surprisingly, narwhals from East Greenland are different from those inhabiting Baffin Bay, but more surprising was the distinctness of narwhals at two summering grounds (Inglefield Bredning and Melville Bay) and one autumn ground (Uummannaq) in West Greenland. Apparently, narwhals have annual fidelity to certain summer and autumn feeding localities, but the extent of mixing on the wintering grounds is unknown.

IX. Diving Behavior

Data on narwhal diving have been collected from whales instrumented with satellite transmitters in both Canada and Greenland. Narwhals are able to dive to depths exceeding 1000 m, and the deepest dive recorded was 1164 m. However, the dives are usually completed within 20 min and never exceed 25 min, so the whales only have a short time at the bottom as ascent–descent rates for deep dives are 2 and 1 m/sec for shallow dives. Narwhals apparently reduce their diving activity during autumn and early winter and make more deep dives.

X. Vocalizations

Narwhals are known to make a variety of noises. Clicks that are believed to be used for echolocation have been measured to have their maximum amplitudes at 48 kHz with rates of 3–10 clicks/sec. Faster click rates of 110-150 clicks/sec had maximum amplitudes at 19 kHz. Whistles or pure tones in frequencies from 300 Hz to 18 kHz have also been recorded and they are suspected to serve as social signals among the whales.

XI. Unicorn Myth and Systematics

The narwhal is the animal behind the legend about the mysterious unicorn: a horse-like creature with a spiraled horn protruding from the forehead. The horn was supposed to have healing abilities, and the wild and shy animal could only be captured with a virgin as bait. Based on narwhal tusks that were brought south from Arctic coasts, this was essentially how narwhals were perceived in western civilization until the 17th century when the first descriptions of a fish-like sea monster appeared.

XII. Human Effects and Interactions

Narwhals have never been a target for commercial WHALING probably because of their skittishness and the difficulties involved in catching them. Inuit hunters in Greenland and Canada hunt narwhals for their valuable tusks and the highly prized skin that is considered a delicacy throughout the Inuit communities. The harvest level was on average 550 and 280 during 1993–1995 in Greenland and Canada, respectively, and it is considered small relative to the population size in most areas; however, depending on the population structure, some subpopulations may be overexploited.

Narwhals have high levels of some organochlorines and heavy metals where at least the first are of anthropogenic origin. Possible effects of these contaminants have not been studied in narwhals.

Because of their prevalence for high-density pack ice, narwhals are susceptible to climatic changes that influence the water currents and thereby ice formation in the Arctic. Whether it is naturally occurring or human-induced climate changes, narwhals may become entrapped or lose access to important feeding areas if ice conditions change.

XIII. Ice Entrapments

A peculiar feature of the natural history of narwhals is their susceptibility to being entrapped in ice. Because of their preference for heavy pack ice, large schools of narwhals are occasionally caught in ice that freezes rapidly during intense cold, thereby preventing the whales from getting enough air to breathe. This happens particularly often in areas where unpredictable ice conditions persist due to the mixing of warm and cold water masses of variable strength, e.g., Disko Bay in West Greenland. Large numbers of narwhals may succumb during such an ice entrapment, and in January 1915, more than 1000 narwhals died in a well-known ice entrapment in Disko Bay. If the whales are discovered, Inuit hunters may also prey upon them, using the word "sassat" for the event.

Neoceti

R. Ewan Fordyce
University of Otago, Dunedin, New Zealand

Neoceti is the taxonomic group containing the two living clades of Cetacea (Odontoceti and Mysticeti), but excluding Archaeoceti. The two living groups are quite disparate, each distinguished by a unique combination of anatomical and ecological attributes. The Odontoceti (toothed whales, dolphins, porpoises) are echolocating macropredators, whereas Mysticeti (baleen whales) are filter feeders. Ancient cetaceans from Oligocene times (25 to 30+ Ma) also show skull structures indicative of ECHOLOCATION in odontocetes and of filter feeding in mysticetes, emphasizing the early divergence of feeding habits. Apart from the feeding apparatus, however, basal odontocetes and mysticetes are much more similar to one another than are their modern descendants. Similarities include some evolutionary novelties (synapomorphies) of the skull, which are not seen in archaeocetes. Thus, odontocetes and mysticetes are regarded as sister taxa, forming a clade variably termed crown group Cetacea, or Neoceti, or Autoceta. Basal odontocetes and mysticetes also show marked similarities with archaic cetaceans (Archaeoceti), pointing clearly to an origin within the archaeocete family Basilosauridae.

I. Changing Concepts of Names

The name Cetacea was first used in a modern sense by Brisson in 1762 for genera and species of living whales, dolphins, and porpoises. Until the mid-1800s, high-level classification was based on superficial features, with no implication that patterns among living cetaceans had arisen by evolution. Formal subdivisions for the living baleen whales and toothed cetaceans were proposed by W. H. Flower for Mysticeti (1864) and Odontoceti (1867), with the implication that these were real groups (in modern terms, clades). The discovery of fossils broadened the concept of Cetacea in the early to mid-1800s. Initially, most fossils were recognized as related to living species, and modern generic names (e.g., *Delphinus, Balaena*) were applied to some of these. The discovery of the archaic Eocene whale *Basilosaurus* in the 1830s eventually led in 1883 to naming of a formal group of archaic cetaceans, the Archaeoceti. Thus, the concept of Cetacea was expanded to include three suborders: one extinct (Archaeoceti) and two living (Odontoceti and Mysticeti).

II. The Monophyly of Odontoceti

Odontocetes include 71–72 living species in the families Physeteridae, Kogiidae, Ziphiidae, Platanistidae, Delphinidae, Phocoenidae, Monodontidae, Iniidae, Pontoporiidae, and Lipotidae. Strictly defined, the Odontoceti comprises the most recent common ancestor of all living species, plus all the descendants of that ancestor. Such an ancestor probably lived in latest Eocene or Early Oligocene times. In practice, fossil and recent odontocetes are distinguished by osteological features, particularly in the skull. For example, above the eye, a large supraorbital process in each maxilla rises posteriorly over the frontal, usually forming a voluminous facial fossa in which open dorsal infraorbital foramina for nerves and blood vessels; in living species, this fossa forms the origin for the nasofacial muscles, which manipulate diverticula or sacs in the soft nasal passages. In turn, the diverticula probably help produce echolocation sounds. Where the rostrum passes into the facial fossa, a vertical antorbital notch forms a path for the facial nerve, which supplies the nasofrontal muscles. Anteriorly, each side of the rostrum in front of the bony nares has a premaxillary sac fossa, premaxillary foramen, and usually premaxillary sulci; in living species, these are also implicated in sound generation in the nasal passages. Below the face, the infraorbital process is vestigial or absent, and the most posterior tooth lies far forward of the antorbital notch. In the ear region on the skull base, the parietal and squamosal roof the periotic so that this ear bone no longer contributes to the floor of the braincase. Finally, all odontocetes that are well-preserved show evidence of a small middle sinus extending laterally from the ear toward the jaw joint in the glenoid cavity.

The only serious challenge to odontocete monophyly has come from recent molecular analyses, which placed the sperm whale, *Physeter macrocephalus,* closer to living mysticetes than to other odontocetes. Such a relationship would make the Odontoceti paraphyletic. Reanalyses, based both on anatomy and on molecules, confirmed that the sperm whale lies within the Odontoceti and that the group is a clade.

III. The Monophyly of Mysticeti

Mysticetes include 13–14 living species in the families Balaenidae, Neobalaenidae, Balaenopteridae, and Eschrichtiidae. Mysticete monophyly has never been in serious doubt (cf. *Physeter* and odontocete monophyly). Strictly, the Mysticeti comprises the most recent common ancestor of all living species, plus

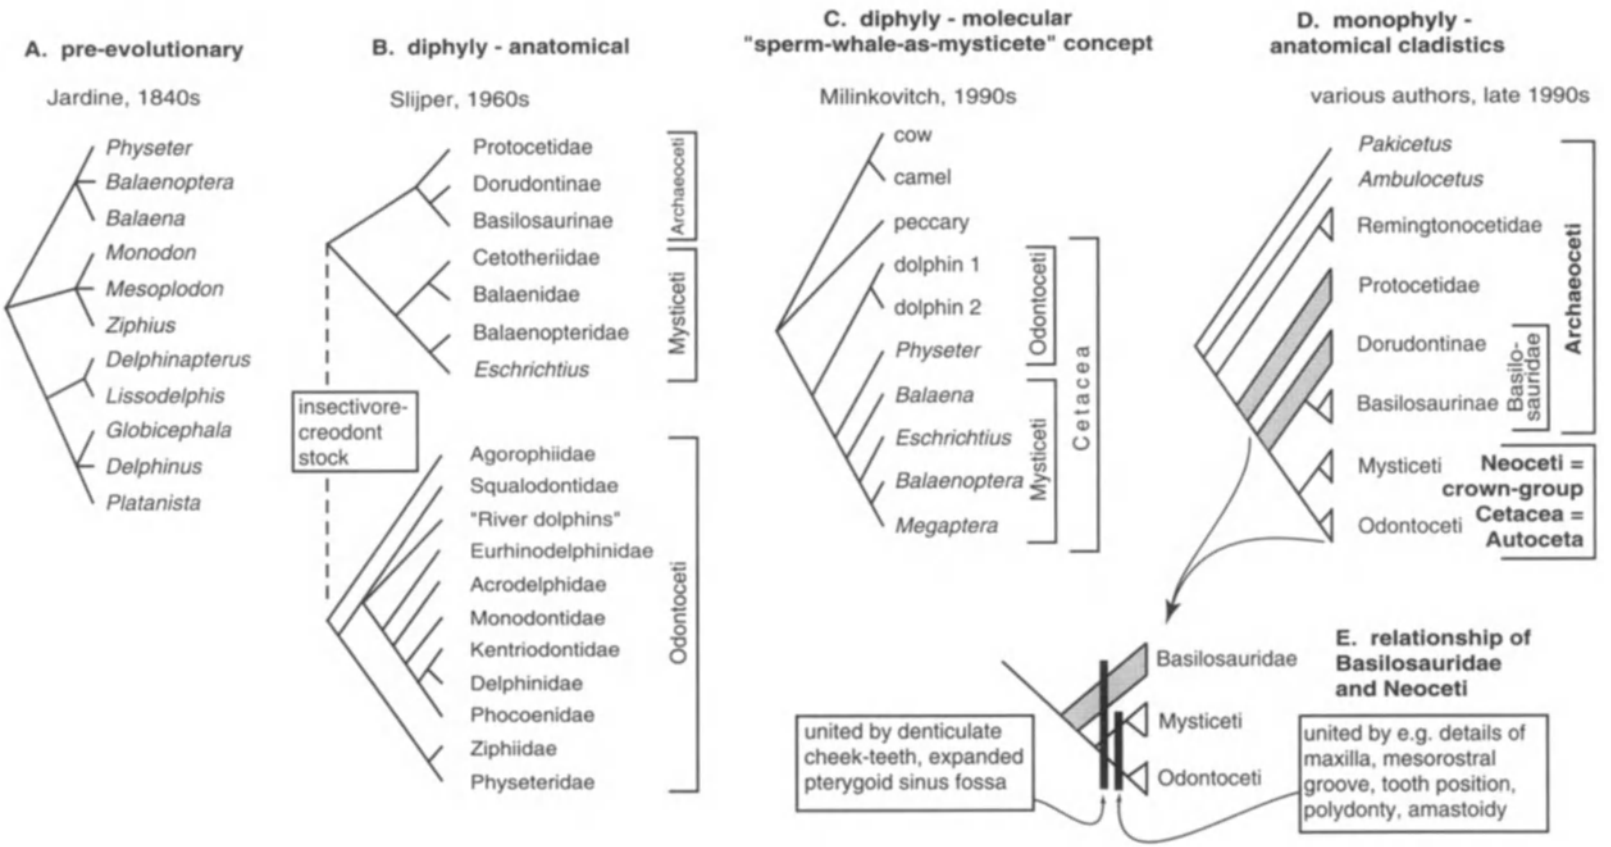

Figure 1 *Changing concepts of the Cetacea. (A) Preevolutionary classification as used by Jardine and others, early to mid-1800s. Species are clustered on the basis of sometimes superficial features. Genealogical relationships are not particularly implied. (B) Widely held concept of cetacean diphyly, as used by Slijper in the 1960s, and supported by many other cetologists (based on Slijper). (C) Widely cited but now abandoned concept of relationships between living Odontoceti and Mysticeti showing the sperm whale,* Physeter macrocephalus, *as more closely related to living mysticetes than to other odontocetes (based on Milinkovitch). (D) Current concept of Cetacea showing crown group Cetacea (Neoceti) with two sister taxa, Odontoceti and Mysticeti, and a cluster of progressively more stemward archaeocete groups (based on Uhen and others). Grade taxa are shown with gray infill. (E) Summary of relationship between later archaeocetes, the Basilosauridae, and Odontoceti + Mysticeti.*

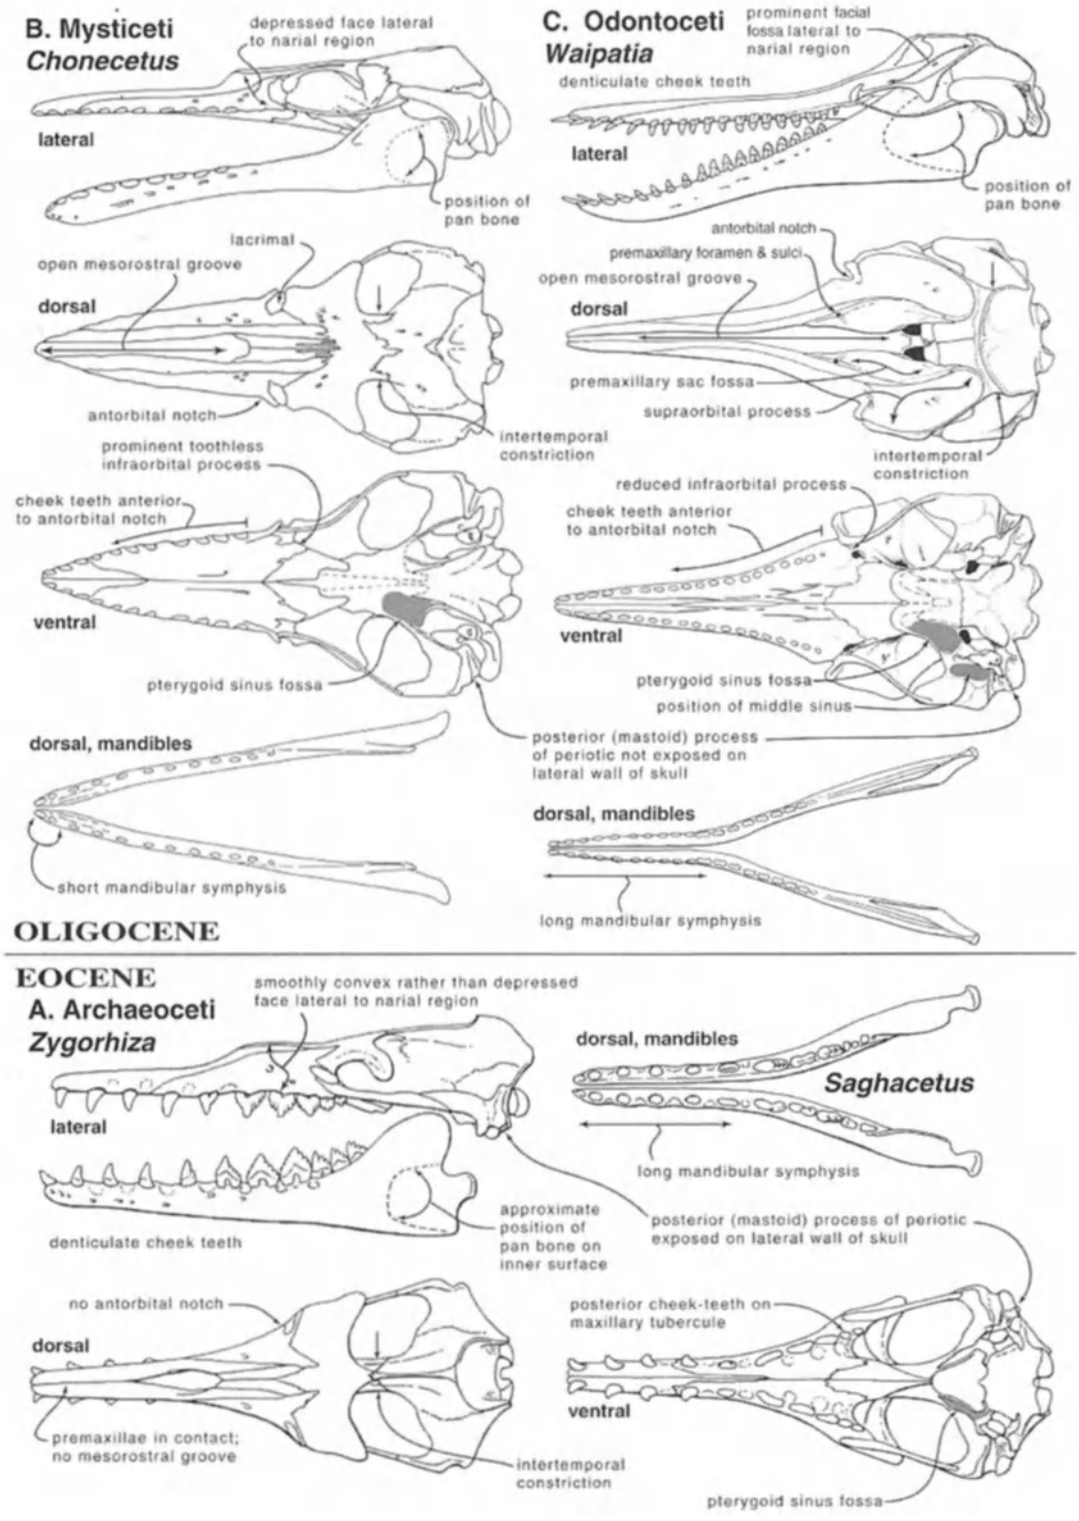

Figure 2 *Morphological similarities and differences among later archaeocetes and basal odontocetes and mysticetes. (A) Archaeocete. Lateral, dorsal, and ventral views of the archaeocete skull show the dorudontine* Zygorhiza kochii *(Basilosauridae: Dorudontinae; Priabonian, latest Eocene), based on Kellogg (1936). Dorsal view of the archaeocete mandible shows the dorudontine* Saghacetus osiris *(Basilosauridae: Dorudontinae; Priabonian, latest Eocene), based on Stromer (1908). (B) Archaic mysticete. Lateral, dorsal, and ventral views of skull and dorsal view of mandible show* Chonecetus geodertorum *(Mysticeti: Aetiocetidae; Chattian, Late Oligocene), based on Barnes* et al. *(1995), with the addition of some features. Figures of teeth are not available. (C) Basal platanistoid odontocete. Lateral, dorsal, and ventral views of skull and dorsal view of mandible show* Waipatia maerewhenua *(Odontoceti, Waipatiidae; Chattian, Late Oligocene), based on Fordyce (1994), with modifications, including the addition of some features. Some teeth are* in situ *on the original fossil, but for simplicity are not shown in other than the lateral view.*

all the descendants of that ancestor. Plausible ancestors of latest Eocene and Early Oligocene age are known. Unlike living species, fossil mysticetes are not recognized by the presence of baleen; although this probably occurred in most extinct species, it preserves rarely. Rather, osteological features, particularly in the skull, distinguish the Mysticeti. The rostrum is relatively large, with thin edges and a flat broad lower surface. The main bones in the rostrum (vomer, premaxilla, and maxilla) are sutured loosely with each other and, posteriorly, with the cranium. The lacrimal is also loosely sutured, between the frontal and a prominent transverse preorbital ridge on the maxilla. Loose sutures between the feeding apparatus and cranium account for the common loss of the rostrum in fossil mysticetes; perhaps such sutures function in skull kinesis during filter feeding. Ventrally, the maxilla is usually toothless, forming an origin for baleen, but in archaic forms the maxilla may have teeth that lie well forward of the orbit (cf. archaeocetes). Posteriorly, the maxilla extends toward the orbit, forming a prominent infraorbital plate below the frontal. Finally, the halves of the mandible are joined by ligaments at a short symphysis. Other putative diagnostic features of the skull are seen in most, but not all, mysticetes, as noted later for archaic forms.

IV. The Monophyly of Odontoceti + Mysticeti

In the later 1800s and indeed until the 1960s, the known archaeocetes and fossil mysticetes and odontocetes seemed rather divergent from one another. Slijper, Kellogg, and other influential cetologists doubted a close relationship between odontocetes and the other two groups and were uncertain about mysticete origins among the archaeocetes. Thus, the two living groups of cetaceans were regarded as diphyletic, of different ancestry. They were sometimes classified as distinct orders.

From the 1970s to 1990s, several major advances overturned the notions of diphyly, and ultimately changed cetacean nomenclature. The fossil record of Eocene archaeocetes and of early (especially Oligocene) odontocetes and mysticetes expanded markedly, helping to bridge the structural and stratigraphic "gap" among the three groups. It became clear that evolution is not always slow and gradual and that major structural change can occur in short geological intervals. Developments in the deep sea drilling project led to much improved geological correlation, helping to date and clarify evolutionary sequences. Molecular and biochemical approaches to phylogeny indicated close relationship between odontocetes and mysticetes. The rise of cladistics (phylogenetic systematics) also clarified many concepts of relationship and nomenclature.

The Odontoceti and Mysticeti are now widely regarded as forming a clade or monophyletic group, equivalent to the Cetacea in the sense of Brisson and, indeed, of many modern systematics. Strictly, this group is crown group Cetacea; it includes all descendants, living and extinct, of the most recent common ancestor of Odontoceti + Mysticeti.

Odontocetes and mysticetes do share bony features not seen in archaeocetes, supporting their sister group relationship. In both, the posterior portion of the maxilla is at least slightly concave, rather than smoothly convex, and carries one or more dorsal infraorbital foramina that open dorsally rather than anteriorly. On the rostrum, an open mesorostral groove extends far anteriorly so that the premaxillae have little or no contact in the midline. The posterior-most teeth in odontocetes and toothed mysticetes lie anterior to the antorbital notch. Most (not all) basal species are polydont, with more than the usual mammalian number of cheek teeth, and a tooth succession is unknown. Compared with basilosaurid archaeocetes, the zygomatic process of the squamosal is more robust and anteriorly produced, with a more delicate jugal. Finally, odontocetes and mysticetes are amastoid, with the posterior (mastoid) process of the periotic not exposed laterally on the skull wall.

Odontocetes and mysticetes are often identified as having a "telescoped" skull in which bone positions have moved dramatically relative to familiar mammalian landmarks such as the nose and eye. However, "telescoping" is a wide-ranging term applied to at least four different functional shifts involving both the facial region and the braincase. It should not be cited to support the monophyly of odontocetes and mysticetes.

V. Primitive Features in Basal Odontocetes and Mysticetes

Some early fossil odontocetes and mysticetes have features similar or even identical to those seen in some basilosaurid archaeocetes. Such fossils include, among odontocetes, species of *Xenorophus, Mirocetus,* and *Archaeodelphis,* whereas mysticetes include species of Aetiocetidae, *Mammalodon, Llanocetus,* and some unnamed taxa. (Perhaps some of these are stem rather than crown group members; e.g., *Archaeodelphis* possibly represents a stem odontocete.) The most obvious basilosaurid-like features of archaic odontocetes and mysticetes are the prominent intertemporal constriction, formed by elongate parietals dorsally on the braincase, and heterodont teeth. In all, the anterior teeth have single roots and simple crowns clearly distinct from two- or three-rooted cheek teeth with complex denticulate crowns. Multiple denticles on the crown are an evolutionary novelty linking basilosaurids, odontocetes, and mysticetes. Further, the posterior mandibular cheek teeth in archaic odontocetes have a distinctive anterior vertical groove, as in basilosaurids. (The loss of the last upper molar, M3, in basilosaurids, has been used to dismiss a basilosaurid origin for odontocetes and mysticetes. However, a widely variable tooth complement in the latter and the likelihood that polydonty involved an increase in the number of mid- to posterior cheek teeth would allow a basilosaurid origin.)

Other parts of the feeding apparatus are revealing. In basilosaurids and basal odontocetes and mysticetes, the mandible has a large mandibular fossa (reduced in more crownward mysticetes), and the temporal muscle has a distinct vertical origin on the frontal. (This origin changes dramatically in most odontocetes, becoming overridden by facial bones and, in mysticetes, migrating over the orbit.)

In all groups, the complex of foramina in the orbit are not tightly clustered (as in living species) but are scattered anteroposteriorly. Ventrally, in the skull base, an enlarged subspherical pterygoid sinus fossa is formed by alisphenoid and ptery-

goid. (Such a fossa is absent in Protocetidae and more basal archaeocetes and becomes more elaborate in more crowned Odontoceti and Mysticeti.) Common features in the ear region include a lack of fusion between periotic and tympanic bulla (fusion occurs in later mysticetes), laterally compressed processes on the periotic (becoming more inflated in many later odontocetes), and a rather low squat tympanic bulla (becoming smoothly rounded in later mysticetes, but more elevated and delicate in later odontocetes). Other basilosaurid features include persistent postparietal foramina in the braincase and prominent exoccipital condyles.

VI. The Paraphyly of Archaeocetes

Because odontocetes and mysticetes (= crown group Cetacea) arose from among basilosaurid archaeocetes, the suborder Archaeoceti is paraphyletic. Archaeocetes form an artificial cluster of cetaceans that lack the features of Odontoceti or Mysticeti. (Many cladists would not recognize archaeocetes as a formal group and would use the term "stem group Cetacea" as an alternative to Archaeoceti.) Note that this expands the concept of Cetacea beyond the crown group, and indeed expands it beyond the concept used by Brisson.

New Zealand Sea Lion

Phocarctos hookeri

NICHOLAS J. GALES
Australian Antarctic Division, Tasmania

hocarctos hookeri (Gray, 1844) is named in honor of Sir James Hooker, who was the botanist with the British Antarctic expedition of 1839–1843. It is monotypic and is one of the world's seven extant sea lions.

New Zealand sea lions, like all otariids (eared seals), have marked sexual dimorphism; adult males are 240–350 cm long and weigh 320–450 kg and adult females are 180–200 cm long and weigh 90–165 kg. At birth, pups are 70–100 cm long and weigh 7–8 kg; the natal pelage is a thick coat of dark brown hair that becomes dark gray with cream markings on the top of the head, the nose, tail, and at the base of the flippers. Adult females' coats vary from buff to creamy gray with darker pigmentation around the muzzle and the flippers. Adult males are blackish-brown with a well-developed black mane of coarse hair reaching the shoulders (Fig. 1).

I. Distribution and Abundance

The New Zealand sea lion is endemic to New Zealand and is one of the most regionally localized and rare of the world's pinnipeds. It is classified as a threatened species by the International Union for the Conservation of Nature (IUCN). Prior to human arrival in New Zealand, *P. hookeri* was more widespread and probably more abundant than today. While the pristine breeding range of *P. hookeri* included almost all New Zealand coastal, island, and subantarctic territory, a combination of subsistence hunting by Maori and commercial sealing by Europeans have virtually reduced the current breeding range to two groups of sub-Antarctic islands. Currently more than 95% of New Zealand sea lion pups are born at three sites in the remote Auckland Islands; the remaining pups being born

Figure 1 *Adult female New Zealand sea lion (right) and subadult male New Zealand sea lion.*

at nearby Campbell Island (Fig. 2). Occasionally, single pups are born at regular sea lion haul-out sites on the South Island of New Zealand (Otago Peninsula) and around Stewart Island. Total pup production during the 1995/1996 breeding season was estimated to be about 2800; estimates of absolute abundance based on this pup production are 12,500 (95% CI: 11,100–14,000) (Gales and Fletcher, 1999). While variations in pup production have been recorded, the population appears to have been stable for the past few decades.

II. Habitat

New Zealand sea lions breed and haul out on a diverse range of terrestrial habitats, including sandy beaches, reef flats, grass and herb fields, dense bush and forests, and solid bedrock. Each site generally has easy access to relatively protected waters (Fig. 3). The sympatric New Zealand fur seal (*Arctocephalus forsteri*) selects rockier, more exposed sites, and the two species rarely interact on land. The marine habitats of New Zealand sea lions have only been described for lactating females from the Auckland Islands. Here they forage on benthic habitats in the waters of the adjacent Auckland Island shelf. Other age and sex classes disperse more widely; in particular, adult and subadult males, tagged at the Auckland Islands, have been seen at Macquarie Island and around the southern parts of New Zealand.

III. Breeding Behavior

The breeding behavior of *P. hookeri* is typical of that of a polygynous otariid. Territorial males begin to assemble and defend physical territories at breeding rookeries in late November. Pregnant females begin to arrive in early December and aggregate into harems of up to 25 animals attended by a single dominant bull. Challenges from peripheral males are regular and the tenure of territorial males is short. There are no published studies to elucidate the behavioral mechanisms by which female movement within the rookeries is determined. Females give birth soon after arrival; the pupping season lasting about 35 days. By mid-January most territorial bulls have departed, the harems break up, and females and pups disperse to occupy surrounding areas.

Postparturient females exhibit estrus 7–10 days after the birth of their pup and are mated by the territorial bull. Soon after they depart on their first foraging trip. Trip durations average 1.7 days, interspersed with an average of 1.2 days ashore feeding the

Figure 3 *Typical breeding aggregation of New Zealand sea lions,* Phocarctos hookeri, *showing pups and adult females in the foreground and adult males fighting in the background.*

pup. Unattended pups gather into groups during maternal absence. At least 10% of pups die during the pupping season. While the causes of this early mortality has not been studied, it is thought to be caused principally by starvation, parasitism, trauma, and disease. INFANTICIDE and cannibalism by bulls have been observed. A high frequency of cows simultaneously nursing more than one pup (6% of observations) has been reported for *P. hookeri* during the first few weeks of pup rearing. This fostering behavior may be associated with kin selection in small populations. Lactation lasts about 10 months (Gales, 1995).

Females are thought to become sexually mature at 3 years or older and produce their first pup a year later. The duration of an assumed embryonic diapause has not been measured. Pregnancy and pupping rates also remain unknown. Males are reported to be sexually mature at 5 years but do not hold territories for a further 3–5 years. Survivorship and longevity have not been measured.

IV. Disease and Predation

Little is known of the normal disease status of New Zealand sea lions. The highly localized distribution of this species makes it particularly vulnerable to the effects of epizootic disease, and indeed in January 1998 an unusual mortality event occurred. At least 53% (n = 1600) of the pups of the year died, as well as many juveniles and adults. A principal cause has not been determined, but it is thought to be the result of bacterial infection. A probable new species of bacteria has been identified that may prove to be the main pathogen. The sea lion population was also found to have been exposed previously to phocine distemper virus, a virus that has resulted in many marine mammal deaths worldwide. An undefined suite of environmental factors (including a strong ENSO event, or El Niño) that stressed the sea lion population and decreased its immunity may have caused the event.

Sharks are likely to be the most significant predator of sea lions; with recent and healed bite wounds being a feature of many animals at the Auckland Islands. Occasional visitors such as leopard seals (*Hydrurga leptonyx*) have been observed to eat small sea lions, and killer whales (*Orcinus orca*) may also be a predator.

V. Foraging Ecology

Sea lions at the Auckland Islands forage on a wide variety of prey, with benthic and pelagic organisms being represented. Thirty-three taxa have been identified from analyses of identifiable remains in scats and regurgitations, with fish comprising 59%, cephalopods 22%, and crustaceans 15% of the remains found. The six most abundant prey items [in decreasing order of abundance: opalfish (*Hemerocoetes* species), octopus (*Enteroctopus zelandicus*), munida (*Munida gregaria*), hoki (*Macruonus novaezelandiae*), oblique-banded rattail (*Coelorhynchus aspercephalus*), and salps (*Pyrosoma* species)] accounted for 90% of the total prey items. The diet of male sea lions on the Otago Peninsula has been found to represent a similar range of prey. Given the problems of bias associated with quantifying diet from scat and regurgitate analysis, further work utilizing newer, more precise tools such as fatty acid analysis would be most instructive.

New Zealand sea lions are the deepest and longest diving of the otariids. At sea they dive at a mean rate of 7.5 dives/hr and spend 45% of the time submerged. They undertake dives to a mean of 123 m (median 124 m, maximum >500 m) and spend an average of 3.9 min (median 4.33 min, maximum 11.3 min) on each dive >6 m. Almost half of the dives exceed the calculated *aerobic dive limit*, leading to a hypothesis that the dive behavior of *P. hookeri* reflects either successful physiological adaptation to exploiting benthic prey or a marginal foraging environment in which diving behavior is close to physiological limits (Gales and Mattlin, 1997). It has been shown subsequently that New Zealand sea lions have indeed equipped themselves physiologically for deep diving by having the largest blood volume of any otariid (Costa *et al.*, 1998). Behavioral adaptations, such as "burst and glide" diving, also appear to be used by this species to maximize the time available for foraging on the benthos, while still maintaining an effective energy budget. They have also been shown to be operating at what is likely to be close to their physiological maximum, as the gains in diving performance have been made with O_2 storage increases but not through a significant decrease in their at-sea metabolic rate (Costa and Gales, 2000).

VI. Interactions with Humans

New Zealand sea lions are subject to incidental drowning in squid and other trawl fisheries that operate around the Auckland Islands. The number of sea lions killed in the squid fishery (estimated to range from 17 to 141 per year for the period 1988–1997) has been the cause of serious concern and has led to a number of management measures. These include the imposition of a 12 nautical-mile marine mammal sanctuary around the Auckland Islands in which commercial fishing is prohibited; the deployment of government observers on trawlers to record the incidence of marine mammal bycatch (7–32% of tows observed each year for 1988–1997; bycatch rate varied from 0.6 to 3.8% of tows during this period); a delay in the opening of the seasonal fishery until February 1 each year; a voluntary code of practice for the industry, which aims to

reduce the chance of bycatch; and the imposition by the New Zealand government of a maximum allowable level of fishing related mortality (MALFIRM), the reaching of which leads to the early closure of the fishery for that season. This MALFIRM (set at the beginning of each season on the basis of an approved model at about 60–80 sea lions) was exceeded each year between 1995 and 1998, and the fishery was closed early in the latter 3 years. In efforts to mitigate the sea lion/fishery interaction, specially designed escape devises are now being tested.

Another identified danger to New Zealand sea lions is tourism (principally sub-Antarctic, but also on the Otago Peninsula). These interactions are regulated via a limited-entry permit system on the sub-Antarctic islands and by behavioral protocols for tourists here and elsewhere. Other impacts, such as POLLUTION, ENTANGLEMENT, and direct killing, are not thought to be significant. There are no *P. hookeri* held in captivity. Under the auspices of a draft population management plan, the New Zealand government aims to monitor and research the sea lion population, mitigate threatening processes and remove the sea lion from its threatened status within 20 years (from 1999).

Noise, Effects of

BERND WÜRSIG
Texas A&M University, Galveston

W. JOHN RICHARDSON
LGL Ltd., King City, Ontario, Canada

When we humans dunk our heads underwater, the ocean seems relatively silent. This misconception occurs because our ears are optimized to hear in air and have poor sensitivity in the much denser medium of water. In reality, the oceans are full of sounds. Natural sources of underwater sound include breaking waves and surf, rain striking the sea surface, ice cracking and groaning in the higher latitudes, and the distant rumble of storms and earthquakes. Besides these physical sources, there is also a rich biological repertoire. There are sounds of snapping shrimp, grunting fishes, squeaking and popping sirenians, and the amazingly varied vocalizations of pinnipeds and cetaceans. Walruses (*Odobenus rosmarus*) display by knocks and mews; bearded seals (*Erignathus barbatus*) emit elaborate trills during their breeding season; toothed whales whistle, send bursts of staccato-like click trains, and echolocate; and large whales moan, groan, and sing for group cohesion, sexual displays, and COMMUNICATION (Tyack, 2000). Some researchers suspect that strong low-frequency sounds of certain baleen whales may also function as active sonar, helping them to navigate across wide open ocean spaces or around ice, or to locate silent conspecifics.

Unfortunately, the industrialized world has created other sources of noise underwater (Fig. 1). There is motorized shipping, underwater blasting, and offshore drilling, dredging, and construction. These activities produce underwater sounds incidentally, not purposefully. Several other types of underwater sounds are created purposefully: fathometers and sonars of many types operating at frequencies ranging from very high to low; air gun pulses for oil and gas exploration; pingers used to locate underwater equipment and to alert marine mammals to the presence of fishing nets; acoustic harassment devices (such as seal bombs) to keep marine mammals away from mariculture facilities; and sounds used for ocean science measurements (such as ATOC). Fish and marine mammals have evolved with the rich physical and biological cacophony of nature and are presumably well adapted to those sounds. However, most anthropogenic (human-generated) sounds first appeared in the past 100 years or so and are increasing in intensity and geographical extent decade by decade (Gisiner *et al.*, 1999; Jasny, 1999).

I. Importance of Sound to Marine Mammals

Marine mammals rely on underwater sound for communicating, finding prey, avoiding predators, and probably navigating. Other senses are available to them, but sound is the most important one at distances or in environments where the senses of touch, taste, and sight are not available. It is unclear how much sea otters (*Enhydra lutris*) and polar bears (*Ursus maritimus*) rely on sounds underwater. However, it is well known that pinnipeds (sea lions, fur seals, seals, and walruses), sirenians (manatees and the dugong, *Dugong dugon*), and cetaceans (dolphins, porpoises, and whales) use sound both passively, when listening to the environment, and actively, when communicating. The toothed whales also echolocate to find prey, detect predators, and maneuver in the environment.

The acoustic frequencies that are most important vary with the type of marine mammal. Baleen whales tend to use lower frequencies of sound: usually below 1 kHz and reaching down into the infrasonic range (<20 Hz) in fin and blue whales (*Balaenoptera physalus* and *B. musculus*). Toothed whale communication is mainly above 1 kHz, and the echolocation sounds of most species are at very high frequencies, above 20 to 30 kHz.

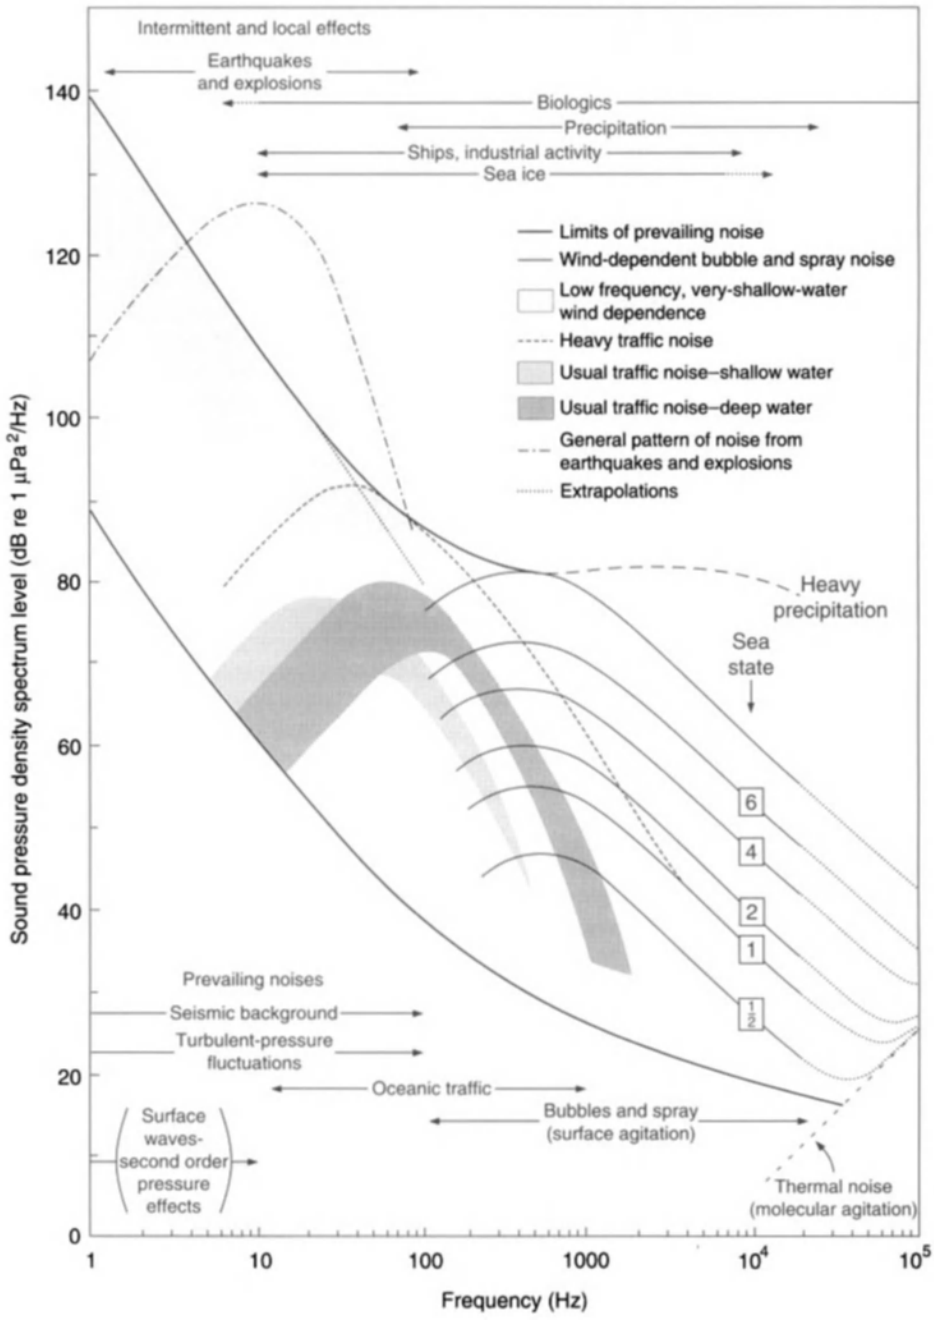

Figure 1 *General types of natural and human-made sounds in the world's oceans (adapted from Wenz, 1962).*

The latter sounds are above the frequency range audible to humans ("ultrasonic"). Pinnipeds and sirenians tend to be intermediate between baleen and toothed whales with respect to the frequencies of their calls (mainly at 0.5–10 kHz) and optimum hearing range. The optimum frequencies for pinnipeds and sirenians are similar to those for humans.

While sounds of sirenians, some pinnipeds, and some small odontocetes are weak and audible only within a few tens of meters, most cetacean sounds are much stronger (Richardson *et al.*, 1995). Received sound levels and maximum detection distances depend not only on the strength of the sound at the source ("source level"), but also on the frequency and on physical properties of the environment through which the sound propagates. Nevertheless, smaller dolphins and porpoises can be heard to several hundred meters. Killer whale (*Orcinus orca*) "screams," social sounds of pilot whales (*Globicephala* spp.) and the staccato click sounds of sperm whales (*Physeter macrocephalus*) reach to several kilometers. Communication sounds of many odontocetes

and mysticetes have source levels of 160 to 180 dB re 1 μPa at 1 m distance. The clicks of bottlenose dolphins and sperm whales can be much more intense, >220 dB in the same units (Au *et al.*, 2000; Møhl *et al.*, 2000). Echolocation clicks of some smaller odontocetes can have similarly high peak levels, but are very brief and do not contain much energy. In a few species of seals, e.g., bearded and Weddell seals (*Leptonychotes weddellii*), the males appear to use complicated tonal sounds as advertising displays to warn off other males (and possibly to attract females); these sounds can also be quite intense. These seals, which defend underwater territories (or "maritories"), are exceptional among the pinnipeds, however.

A. Potential Types of Noise Effects

Anthropogenic sounds can result in a variety of effects whose consequences to marine mammals can range from nil to severe, depending on the type and received level of the sound:

Tolerance (No Overt Response): Mammals exposed to audible levels of man-made sounds often exhibit no obvious responses, continuing their normal activities without moving away. A marine mammal hearing a sound does not always react overtly to it. However, responses can be subtle so a detailed behavioral and physiological study is needed before it is legitimate to conclude that there is no response. Animals might tolerate noise in order to remain in a preferred location, such as a feeding area, even if the noise caused stress or other inconspicuous effects.

Changes in Behavior or Activity: Alterations in behavior are common when marine mammals are exposed to man-made sounds. Sometimes the effects are subtle, discernible only by detailed observation and statistical analysis, e.g., changes in surfacing/respiration/dive cycles. More conspicuous effects include changes in activity, e.g., from resting or feeding to alert, facing toward the noise source, and so on.

Avoidance Reactions: Upon exposure to strong man-made sounds, marine mammals engaged in feeding, social interactions, or other "normal" activities often interrupt those activities and swim away. When migrating whales approach a noise source, they typically deflect a few degrees off their "normal" course and swim to one side or the other of the noise source.

Masking: Masking is the process whereby sounds of interest to a listener are obscured by interfering sounds. If those sounds are important to the listener (e.g., predator calls), masking could have a serious effect (Richardson *et al.*, 1995).

Hearing Impairment: Animals (including humans) exposed to strong sounds can incur a reduction in their hearing sensitivity. This impairment is often temporary, provided the sound levels are not too high or too prolonged. However, repeated exposure to strong sounds, and even a single brief exposure to an extremely strong sound (e.g., nearby explosion), can cause permanent hearing impairment.

Nonauditory Physiological Effects and Stress: In humans, exposure to very strong underwater sounds can cause resonances in lung cavities and other types of nonauditory physiological effects. Chronic exposure to strong noise may also at times cause stress reactions. These phenomena are almost entirely unstudied in marine mammals.

B. Noise Definition, Categories, and Levels

The term "noise" indicates an unintentional or unwanted sound, possibly disagreeable or noxious. We tend to think of noise as sound we do not like, but this is a subjective impression; a sound that is noise to one person (or animal) may be an important signal (or music) to another. For example, the songs of humpback whales (*Megaptera novaeangliae*) are undoubtedly important to them. We do not know whether these strong and—in some areas—seasonally persistent sounds are regarded as "music" or as noise by pilot whales and bottlenose (*Tursiops* spp.), spinner (*Stenella longirostris*), and spotted dolphins (*S. attenuata* and *S. frontalis*) that are attempting to communicate in the presence of this background of whale song. However, industrial sounds are likely to be perceived by marine mammals as noise. Nevertheless, some anthropogenic noises may themselves be important cues to mammals: a boat is approaching, take evasive action; a seismic vessel is active, do not get too close, etc. Thus, noise can have an important signaling function. In human terms, it is probably good that we hear an approaching truck or train while we are on foot or on a bicycle nearby.

Sound strength can be measured near the source or at some greater distance. By convention, source levels usually are reported for a standard distance of 1 m. The received sound level tends to diminish with increasing distance. In interpreting quoted sound levels, it is essential to know whether the value is a source or received level and, for the latter, the distance from the source. The received levels 10, 100, and 1000 m from a source are often about 20, 40, and 50–70 dB less than the corresponding source level. A further complication is that sound levels are measured in many different and sometimes difficult-to-convert units. Decibel (dB) values are meaningless unless the reference level is also specified. This is typically 1 μPa for underwater sound and 20 μPa for airborne sound, but other references are sometimes used, especially in the older literature. Even when the distance from source and the reference level are stated, other complications can make it difficult or impossible to compare acoustical measurements from different studies. For example, simple comparisons of levels in water vs air are usually of doubtful validity.

The levels quoted in this article concern underwater sound measured in dB re 1 μPa and, except for values shown in Fig. 1, are overall broadband levels (i.e., including a wide range of frequencies). In the case of source levels, the levels are standardized to a distance of 1 m.

One way of categorizing anthropogenic noises is whether they are transient or continuous. Transient noises are generated by helicopters or planes passing by, sonar pings, explosions, seismic surveys, and ocean acoustic studies. The source (and received) levels of some of these transient sources can be high (Richardson *et al.*, 1995). However, because these sounds are brief and intermittent, the average sound level over an extended period is lower than the peak level. Transient sounds may have less effect on animal behavior and hearing as compared with continuous sounds having a similar received level.

The strongest transient sounds in the sea come from explosions, which produce shock waves as well as very strong (but brief) underwater sounds. Nominal source levels can be on the order of 270–280 dB—higher than for any other anthropogenic sound. The shock waves from explosions can injure, stun, and even kill nearby fishes, sea turtles, humans, and marine mammals. The distances within which death or injury will occur depend on the size and depth of the explosion, the type of animal, and other factors. Aside from explosions, some of the strongest sources of underwater sound are seismic surveys (typically using air gun arrays to produce low-frequency noise pulses) and military search sonars operating at medium and low frequencies. Air gun arrays and sonars can produce transient sounds with effective source levels of 230 dB or more. Sounds received from these sources diminish rapidly with increasing distance, but often are detectable as much as 100 km away. There are many other types of transient anthropogenic sounds with a wide variety of levels and characteristics.

Continuous sounds are caused by drill ships, dredging, and vessels of all sizes underway. Of these sound producers, large tankers, container ships, and icebreakers working in ice are among the strongest sources. Their source levels are on the order of 200 dB or more. Although not as high as for some transient sources, this level is sustained without gaps. Much of this sound energy is at infrasonic frequencies, which are apparently important to at least some of the baleen whales, but may be irrelevant to dolphins that have little or no hearing sensitivity at those frequencies. Much of the shipping is concentrated along defined shipping lanes, where sound levels will wax and wane as individual ships pass. However, at least in the Northern Hemisphere, the overall din of vessels pervades not only the lanes themselves, but major parts of the ocean basins involved (Fig. 2).

The strongest components of sound from many of the major anthropogenic sources are below 1 kHz, in the same frequency band as is used by most of the baleen whales for their communication calls. For seismic surveys and large ships, most sound energy is below 200 Hz. A recently acknowledged source of strong low-frequency sound is the low-frequency active (LFA) sonar used to detect quiet submarines. The U.S. Navy's LFA projectors produce a beam of intense sound (source level up to about 240 dB) at frequencies in the 100- to 500-Hz band. However, many of the strongest military sonars operate in the midfrequency (a few kilohertz) range. Likewise, the sounds from outboard engines operating at high speed, snowmobiles traveling on ice, and acoustic harassment devices at mariculture facilities are in the low kilohertz range. Sounds at medium and especially at low frequencies tend to propagate for longer distances than sounds at high frequencies (e.g., above 10 kHz). At high frequency, sound is absorbed into seawater, and the absorption rate increases rapidly with increasing frequency. Hence, high-frequency pinger and sonar sounds (including dolphin clicks) generally diminish to low or undetectable levels within 1 km or less and thus do not present potential problems except at close range.

C. Animals of Concern

Because most, if not all, marine mammals rely on underwater sound for various purposes, any strong anthropogenic sounds at relevant frequencies might have an effect. Animals attuned to different sound frequencies will be most affected by different types of sounds. Mid- and high-frequency sounds as produced by small vessels and mid- and high-frequency sonars are likely to affect dolphins, porpoises, pinnipeds, and sirenians. In contrast, large whales are more susceptible to lower frequency sounds such as those from large vessels, drilling operations, and sounds specifically designed to propagate long distances through the water and/or bottom, such as LFA sonar, marine seismic exploration, and ocean tomography (e.g., ATOC).

Although it was once thought that nearshore animals are likely to be most vulnerable because of the concentration of industrial activities in nearshore waters, this is no longer as clear. Marine mammals on the high seas may be affected as well, given the occurrence in deep water of shipping, military operations, acoustic oceanography projects, and (increasingly) oil industry operations. In general, it is probable that mammals of the southern oceans are still affected less often and less intensively by anthropogenic sounds than in the northern oceans, simply because of the preponderance of human occupation, industry, and shipping in the north. However, underwater noise is now everywhere and has the potential to affect all animals that can hear it and that need to communicate through it.

II. Effects on Hearing

Most, if not all, marine mammals have evolved special adaptations to hear well underwater (Au *et al.*, 2000). However, the adaptations that make their ears sensitive to pressure fluctuations in the water may also increase the risk of damage from exposure to strong waterborne sound and shock waves.

The most drastic effects come from shock waves, which can damage not only the ear but also other organs, in extreme cases causing death. Explosions produce mechanical and pressure trauma effects that can cause profound physical injury or direct death of marine mammals. It has also been suggested that some deaths of beaked whales (Ziphiidae) in the Mediterranean Sea, the Bahamas, and elsewhere were attributable to strong noise from sonar trials. The evidence is circumstantial and inconclusive for the Mediterranean. Preliminary accounts of the Bahamas incident indicate that sonar sounds may have caused injury to the auditory system and associated structures, although not enough to kill the animals directly.

Sounds that are not strong enough to cause profound physical injury or outright death may nonetheless impair hearing, resulting in either temporary or permanent threshold shifts (TTS and PTS, respectively). TTS occurs in humans and animals subjected to intense sounds for short periods of time or to less intense sounds for longer times. The temporary loss of hearing acuity by humans listening to a rock concert is the classic example. Mild TTS has been demonstrated in bottlenose dolphins (*Tursiops truncatus*) and beluga whales (*Delphinapteras leucas*) exposed to a single 1-sec pulse of strong sound (192–201 dB) and in dolphins and various pinnipeds exposed to lower sound levels for 20–50 min (Kastak *et al.*, 1999; Schlundt *et al.*, 2000). Hearing thresholds returned to preexposure levels within about 12 hr, and these brief exposures caused no long-term hearing impairment.

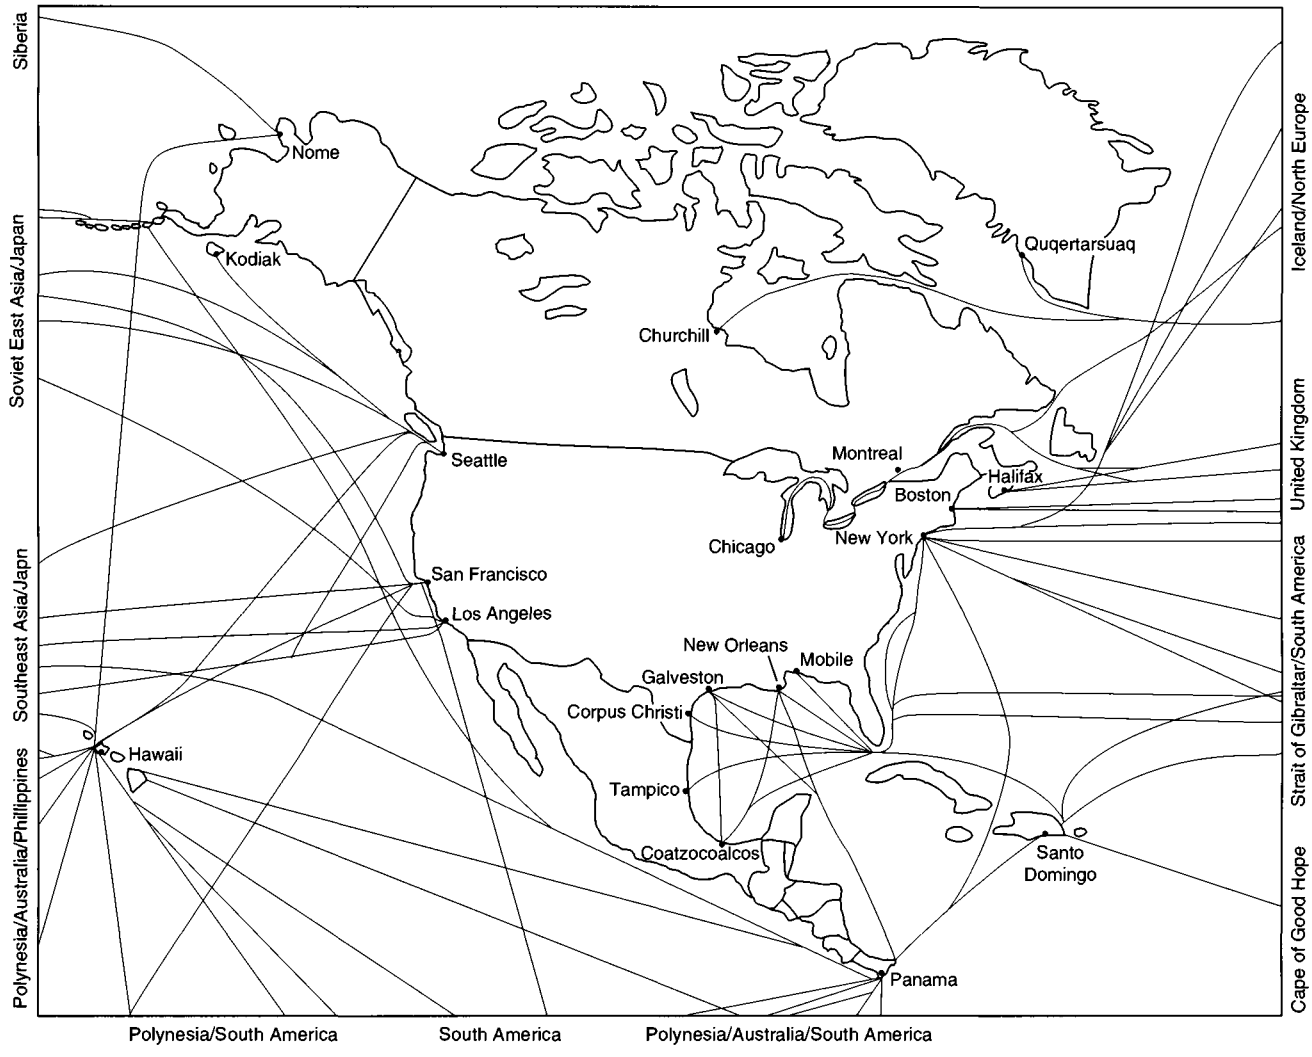

Figure 2 *Major international shipping lanes in North American waters. From Jasny (1999) and U.S. Department of State.*

Temporary hearing impairment could be deleterious to animals that rely strongly on their abilities to detect sound. In addition, data on the sound levels and durations at which TTS begins are useful in identifying situations when there is concern about permanent hearing damage (PTS). However, it is not known how much additional exposure (higher levels and/or longer durations) would be necessary before PTS would occur. In general, permanent damage typically results from a loss of sensory hair cells within the inner ear. The loss is most pronounced in the part of the inner ear responsible for detecting sound at the frequency of the injurious stimulus. In terrestrial mammals, lost hair cells do not grow back, and this is likely the case for marine mammals as well. (Interestingly, at least partial regeneration occurs in birds and fishes.) Older bottlenose dolphins in captivity are known to have reduced hearing sensitivity (especially at the higher frequencies), presumably at least in part because of the cumulative effects of sound (Ridgway and Carder, 1997). This loss is similar to the progressive hearing loss in humans, or presbycusis.

The initial TTS results from small odontocetes confirm that sound levels necessary to cause TTS are correlated with the duration of exposure. More data are needed to quantify this relationship and to determine the TTS thresholds for repeated sounds such as seismic and sonar pulses. Sound levels necessary to cause TTS and PTS in baleen whales and sirenians are entirely unknown.

III. Nonauditory Physiological Effects

Even less is known about potential effects of strong noises on nonhearing physiology than on hearing. Human and animal studies show that strong sounds can affect the vestibular system (and thus sense of balance), air sinuses and adjacent tissues, neural transmission (skin tingling in divers), and reproductive functions. Studies of some terrestrial animals exposed to strong noise have shown reduced sperm production, menstrual irregularities, abortions, and stillbirths. Most of these drastic effects come from intensive low-frequency sounds and

attendant physical vibrations of body tissues. It is not known whether the low-frequency underwater sounds of ATOC, LFA, or seismic exploration could elicit similar effects in marine mammals. If so, these effects would probably be limited to animals close to the sound source.

It is possible that strong sound could cause bubbles to form in blood or tissues, and that animals might succumb to a lodging of these bubbles in the BRAIN and elsewhere (Crum and Mao, 1996). This situation is analogous to bubble formation in human divers when they return too rapidly from depth—the condition known as the bends.

Stress is one possible outcome of exposure to sounds that are disturbing to animals. Stress could, in theory, inhibit normal social interactions, FEEDING, reproduction, longevity, and a host of other important functions (Curry, 1999). However, noise-induced stress is not well understood even in humans and terrestrial mammals, and there are essentially no data on noise-induced stress in marine mammals. Research is needed.

IV. Effects on Behavior

A. General

Short-term behavioral and avoidance reactions to noise have been studied more than damage to hearing and other physiological effects, to the point that there are now at least some data on noise-induced disturbance in every group of marine mammals. For most marine mammals, it is relatively easy to observe some aspects of their DISTRIBUTION and behavior, as they need to come to the surface to breathe. Nevertheless, much of their time is spent below the waves, and our brief glimpses of them at the surface can present a biased view. Also, short-term reactions (or lack thereof) are not necessarily a good indicator of long-term effects, and the latter have rarely been studied directly. This section does not attempt to review the numerous studies on behavioral and distributional responses to underwater noise; for more details, see Richardson *et al.* (1995).

Mammals often appear to become alert to novel sounds when they are of low intensity, but this alertness quickly wanes if there is no danger connected with the sound. Thus, the droning of ships or drilling platforms in the distance often appears to be ignored due to habituation or sensory adaptation. Some mammals may avoid the immediate area around the noise source, but remain within the area where the sounds are at least faintly audible. When sounds are tolerated, it is possible (though unproven) that they may elicit stress or other unseen physiological reactions.

Marine mammals often react more dramatically when received sound levels are high (indicative of a strong or nearby source) or when they are increasing (indicative of an approaching source). Bowhead whales (*Balaena mysticetus*) migrating toward a drill ship or a marine seismic operation typically deflect their course so that their closest point of approach as they pass the noise source is at least 20 km away. At that distance, the received level of the strongest air gun pulses was near 130 dB, averaged over pulse duration. Migrating gray whales (*Eschrichtius robustus*) show similar deflections of their migration route as they approach a simulated seismic operations or LFA sonar, but they seem to tolerate higher sound levels than bowheads. These deflections by bowhead and gray whales are not a sudden fright reaction, but an edging away—analogous to a person walking along a sidewalk, seeing a disturbance ahead, and crossing to the sidewalk on the other side of the road. Also, at least in bowheads, there is a decrease in durations of surfacings and dives, and number of breaths per surfacing. In other words, the whales cycle through their surfacing/dive repertoire more rapidly. There must be at least subtle commensurate changes in activities such as feeding, socializing, or rest.

Cetacean responses to noise are quite variable, depending on the circumstances of exposure and the activities of the animals at the time. There are anecdotal reports from Heard Island in the Southern Ocean, and from the Gulf of Mexico, that sperm whales are sometimes sensitive to air gun pulses at even greater distances than bowheads. In contrast, observers on seismic vessels near the United Kingdom found that sperm whales did not show strong avoidance when the air guns were operating. The beluga whale is another example of a species whose responses to anthropogenic noise are highly variable. Belugas sometimes tolerate exposure to large fleets of fishing vessels, but in other circumstances flee when exposed to faint sounds from approaching ships 35–50 km away (Finley *et al.*, 1990).

A noise that is associated with danger, such as a catcher boat of a whaling fleet or a purse-seine vessel that encircles dolphins to catch the tuna underneath, can trigger strong avoidance reactions at distances of 10 km or more. Reactions may become stronger upon repeated exposure to aversive stimuli; in this case, "sensitization" is said to occur. At least some dolphins seem to distinguish vessels based on their sounds and react differently to boats that habitually harass the animals (such as aggressive tour operators or researchers who tag or collect biopsy samples) vs boats that approach slowly and carefully. In the latter case, the marine mammals may have learned that the vessel is not harmful—a case of behavioral adaptation.

In contrast to the extreme examples just cited, some marine mammals tolerate exposure to high levels of sound. Seals and sea lions attracted to locations where prey fish are concentrated often tolerate exposure to high levels of noise from acoustic harassment devices designed to disperse pinnipeds. Also, during the Heard Island study, hourglass dolphins (*Lagenorhynchus cruciger*) approached to within several hundred meters of a powerful source of low-frequency sound (57 Hz; source level 209–220 dB), whereas pilot (*G. melas*), southern bottlenose (*Hyperoodon planifrons*), and minke whales (*Balaenoptera* sp.) were seen less often during sound transmissions than during silent periods (Bowles *et al.*, 1994). The hearing systems of the small hourglass dolphins probably were not very sensitive to low-frequency sounds; they may have been curious about but not discomfited by the noise. However, it is also noteworthy that, when visible near the surface, they would not have been exposed to levels much above 160 dB given the nature of the sound field around this particular sound source. It is possible that they exhibited a vertical avoidance response, staying near the surface simply because the noise was less strong there.

Marine mammals sometimes approach and tolerate a sound source for their own benefit. Bottlenose dolphins that feed on

prey stirred up by shrimp fishers know the sounds of all aspects of the trawling and net-lifting operations; they move from vessel to vessel according to stage of trawling, even from several kilometers away. Killer whales and several pinniped species of the northeast Pacific similarly react to net lifting like the gong of a dinner bell. Many species of dolphins and some species of sea lions and fur seals approach vessels to bow ride or wake ride near the vessel, apparently "for fun."

While this discussion centers mainly on underwater sounds, in-air noises can affect pinnipeds on land, occasionally with serious consequences. A low-flying aircraft, the sudden honk of an automobile horn, or the noisy approach of humans on foot can cause animals on land to stampede into the water. If this occurs on a birthing/nursing beach, adults sometimes trample pups in their rush to escape the perceived danger; however, it is not always clear whether sound or sight (and, at times, substrate vibration) is more responsible for the stampede and loss of pups.

B. Communication

Because sound is such an important sensory modality for almost all marine mammals, it stands to reason that noise has the potential to disrupt the efficiency of communication (and echolocation). Indeed, there is some evidence for this. Some animals fall silent when they perceive danger (or a novel sound). During the aforementioned Heard Island study, sperm and pilot whales were heard 24% and 8% (respectively) of 1137 min when there was no sound, but none were heard to vocalize during 2202 min with sound transmissions. Although these data suggest a strong effect of noise on communication, they are not yet sufficient to indicate at what received levels the whales became quiet (Bowles *et al.*, 1994).

Acoustic reactions to intense sounds vary among species and with the activity of the animals when they perceived the sound. Belugas are vocally active when they detect ship sounds, but narwhals fall silent. Dusky dolphins (*Lagenorhynchus obscurus*) resting in small groups fall silent when they perceive danger. However, those same dolphins will continue their social whistling and burst-pulse "chatter" when they are engaged in high-energy social and sexual activities. They seem less easily disturbed at these higher energy times.

Masking of sounds useful to animals by stronger anthropogenic noise is another important phenomenon. We humans have the ability to converse with each other even at noisy parties and can separate useful speech from an amazing background din (the well-known "cocktail party" phenomenon). Marine mammals can probably do likewise, for they have evolved in a world where physical and biological sounds other than their own abound. Nevertheless, studies of captive dolphins and pinnipeds have confirmed that, in marine as well as terrestrial mammals, strong man-made noise can physically "drown out" other sounds at similar frequencies. The noise reduces the maximum distance at which one animal can hear calls from another animal or some other environmental sound that may be important (Richardson *et al.*, 1995). There are indications (not fully proven) that gray whales, belugas, and bottlenose dolphins sometimes shift the primary frequencies of their sounds to reduce overlap with the frequencies of background noise. If so, this suggests that some cetaceans may be able to reduce the negative effects of noise masking, but this suggestion needs further study.

C. Social Structure

Marine mammals are generally very social. If noise disrupts social structure, and if the effect is sufficiently strong and long-lasting, then it could be detrimental to the well-being and survival of individuals and perhaps ultimately populations. Noise disturbance can cause some degree of social disruption, but the consequences are largely unknown. When a supply ship comes within 2–4 km of a group of bowhead whales, the whales scatter in all directions. They are "socially disrupted" for as much as a few hours. However, we have no idea how important this disruption may be to the well-being and productivity of the whales. We can guess that they will be harmed if this kind of disruption happens day after day to animals that feed more efficiently when together than when apart. Social disruption also includes the accidental separation of a nursing mother from her pup or calf. When this happens, the probability of pup or calf survival may be reduced substantially.

We do not know to what extent the masking of communication sounds by noise can cause social disruption. Blue whales and fin whales can sometimes hear each other over distances of several hundred kilometers. If there are important social interactions over those long distances (not proven), these interactions may be impeded by the masking effects of background noise, especially if that noise is continuous. For example, these whales may not be able to find each other as efficiently for feeding and mating purposes given the masking effect of the man-made noise. If whale societies are mediated in large part by acoustic contact, as we suspect (Wells *et al.*, 1999; Tyack, 2000), then background noise that diminishes the distances over which whales can communicate also diminishes the spatial scale of their societies.

D. Habitat Use

While short-term disruption of behavior by noise is known to occur, it is less clear how this may translate to overall use of habitat and to long-term disturbance. It was mentioned earlier that migrating bowhead whales "edge away" from seismic exploration and drill ships, in most cases maintaining a minimum distance of about 20 km. It is unlikely that this results in any major harm to the animals. However, if there were a similar and prolonged displacement from a localized area of important feeding habitat, then the potential for harm would be great. At this point, we know that some whales move away from sources of strong noise, but we do not know whether this significantly reduces their yearly food intake or causes other important disruption.

Similarly, human disturbance of island spinner dolphins has affected their use of nearshore bays that appear to be important to them for daytime rest (after feeding in deep water at night). It is possible to argue that this reduced use of safe havens might impact their survivability as individuals and therefore as populations. However, to date, we have no information on such a population-wide effect.

The concept of habitat available vs habitat disturbed is an important one in CONSERVATION BIOLOGY. The purist would argue

that any habitat disrupted is too much, and compromises the natural world. The pragmatist argues that we humans are so overpoweringly disruptive that we must be content with keeping at least a minimum of area available for the animals in question to survive. In the case of marine mammals, that means keeping some critical habitats relatively free of strong noises that create unacceptable disruption in short-term behavior, long-term behavior, aspects of physiology, and hearing. The task is a difficult one and needs further research, monitoring, mitigation, and political enforcement to have a chance of success.

V. Research and Potential Mitigation

The first step in mitigation is to develop a better knowledge base. Detailed discussions of research needs can be found in NRC (1994, 2000) and Richardson *et al.* (1995). We need better information on auditory sensitivity, especially of large whales, and the levels and frequencies of noises that cause TTS, PTS, and nonhearing physiological disruptions in all marine mammals. Researchers have acquired the technical capability to study noise-induced stress and other aspects of physiology, with miniature data loggers and telemetry transmitters attached to animals under field conditions. This is a relatively new avenue of research for marine animals and is likely to grow in the near future. Studies of short-term behavioral disruptions are worthwhile, but it is long-term behavioral, social, communication, and habitat disruption that are of greatest need of study. It is our challenge to monitor the health of marine mammals as related not only to anthropogenic sound pollution, but also to other aspects of habitat degradation.

Potential mitigation avenues are many. Naval vessels are already engineered to reduce sound emissions, e.g., by physical decoupling of rotating machinery from the hull, propeller design, and emission of screens of air bubbles. This knowledge needs to be taken into the private sector, which is responsible for the vast majority of shipping noise. Bubble screening has been shown to strongly decrease the noise from a stationary pile-driving activity in Hong Kong waters, and this technique could be effective in dampening industrial sounds in many other situations (Würsig *et al.*, 2000). A controversial technique that is often employed is "ramping up" of sounds in order to alert animals of impending strong noise, essentially to chase them away from the zone of most influence. This approach probably is effective for some species and situations (e.g., baleen whales vs airguns). However, in other situations it may attract curious marine mammals into a zone of danger. Further study is needed to determine the situations when ramping up is a useful mitigation technique.

In projects where sound is emitted purposefully, e.g., marine seismic exploration, ocean science studies, and navy LFA sonar, refinements in equipment and operational procedures may be possible that will reduce the exposure of marine mammals to noise. Some efforts have already been made to reduce source levels to the minimum that will be effective and to improve beam forming so as to reduce sound radiation in unnecessary directions. Also, these (and some other) noisy activities are amenable to regulation as to where and when they are used, especially as pertains to the seasonal MIGRATION of sensitive baleen whales. It is common for noisy projects to be restricted to certain times of year and/or to certain areas in order to reduce impacts on marine mammals.

It is up to scientists to help provide badly needed information on disturbance reactions and zones of potential influence, and up to politicians and regulators to write and enforce legislation to curb the uncontrolled proliferation of ocean noise. Combined efforts by all will be needed in order to provide adequate protection for marine mammals while avoiding unnecessary restrictions on worthwhile human activities.

North Atlantic Marine Mammals

GORDON T. WARING AND DEBRA L. PALKA
Northeast Fisheries Science Center, Woods Hole, Massachusetts

Marine mammals are a diverse, widespread, and significant component of North Atlantic marine ecosystems. Four of the five commonly recognized marine mammal taxa reside in the North Atlantic: cetaceans (mysticetes, baleen whales; and odontocetes, toothed whales, dolphins, and porpoises), sirenians (manatees), pinnipeds, (seals and walruses), and polar bears (Table I). A fifth taxon (marine and sea otters) and sea lions and fur seals (family Otariidae) have not inhabited the North Atlantic since at least the late Pleistocene. The systematics of marine mammals are still being disputed. However, with the advent of molecular, biochemical, morphological and TELEMETRY studies, the exact number of extant species may be settled. Marine mammals occupy all North Atlantic marine regimes, tropical to polar, although species-specific ranges exist and distribution patterns are not uniform. The large-scale, nonrandom distribution of marine mammals is influenced by oceanographic features, whereas smaller-scale distributions are influenced by factors such as the animal's physiology, behavior, and ecology. Over geologic time scales, the diversity and ecology of North Atlantic marine mammals reflect adaptation to a dynamic aquatic environment. As elsewhere, North Atlantic marine mammal populations have been significantly impacted by human interactions. Some species have been, and continue to be, harvested for subsistence and commercial use and for their cultural value. Overexploitation has resulted in EXTINCTION [e.g., Caribbean monk seal (*Monachus tropicalis*), Atlantic gray whale (*Eschrichtius robustus*)] and significant population declines (e.g., North Atlantic right whale, *Eubalaena glacialis*) and has also likely caused significant ecological "changes" (e.g., reduction of top predators and competitive interactions). Indirect mortality (e.g., fishery bycatch, pollution) has adversely affected numerous species [e.g., harbor porpoise (*Phocoena phocoena*), bottlenose dolphin (*Tursiops truncatus*), beluga whale (*Delphinapterus leucas*), gray seal (*Halichoerus grypus*)].

I. Physical Environment

The physical characteristics of the North Atlantic ecosystem (Fig. 1) critically influence marine mammal distribution. Although the ocean basin provides marine mammals with an open pathway that extends from the equator northward to the Arctic and includes adjacent bodies of water (e.g., Gulf of Mexico, Caribbean Sea, North Sea, Norwegian Sea, and Bay of Biscay), the North Atlantic has many different ecosystems. Some adjacent seas, such as the Baltic and Mediterranean, are more isolated from the open ocean and form separate ecosystems. In open ocean, water masses define tropical to polar ecosystems that are influenced by circulation patterns of the major ocean currents, such as the Gulf Stream, Greenland current, and North Equatorial current. There are broad continental shelf ecosystems defined by basins, banks, channels, ice, submarine canyons, and volcanic islands. Sea mounts and the mid-Atlantic Ridge also define important ecosystems. These types of oceanographic features influence productivity to concentrate prey and create high-use marine mammal habitats.

II. Distribution and Habits

Baleen whales are widely distributed in the North Atlantic, with individual species exhibiting preferences for certain ecosystems. Some preferences are temperature driven. For example, bowhead whales (*Balaena mysticetus*) only occupy polar waters, whereas Bryde's whales (*Balaenoptera edeni*) are only found in tropical waters. Other preferences are more topography driven. For example, right, humpback (*Megaptera novaeangliae*), fin (*Balaenoptera physalus*), and minke (*B. acutorostrata*) whales prefer continental shelf ecosystems, whereas blue (*B. musculus*), sei (*B. borealis*), and Bryde's whales are associated with shelf-edge and deeper oceanic water. Large whales, however, are highly mobile and seasonally may occupy different habitats. Baleen whales, except bowhead and Bryde's whales, undergo the most extensive seasonal migrations of all North Atlantic marine mammals, migrating between warm low-latitude breeding grounds in winter and cold high-latitude feeding grounds in summer. North Atlantic humpback whales exemplify this migratory behavior. In summer, humpback whale stocks feed in Iceland, Greenland, Newfoundland, Gulf of St. Lawrence, and Gulf of Maine/Scotian Shelf and then spend winter on breeding grounds in the Caribbean Sea. Molecular genetic studies indicate that the feeding stocks are matrilineal groups of related individuals. There is little evidence of recent genetic exchange between North Atlantic and South Atlantic populations of baleen whales, due largely to seasonal differences in the migration paths of the two populations.

TABLE I
North Atlantic Marine Mammal Taxa[a]

Scientific name	*Common name*
Order Cetacea	
Suborder Mysticeti (baleen whales)	
Family Balaenidae (right whales)	
Balaena mysticetus	Bowhead whale
Eubalaena glacialis	Northern right whale
Family Balaenopteridae (rorquals)	
Balaenoptera acutorostrata	Common minke whale
B. borealis	Sei whale
B. edeni	Bryde's whale
B. musculus	Blue whale
B. physalus	Fin whale
Megaptera novaeangliae	Humpback whale
Suborder Odontoceti (toothed whales)	
Family Physeteridae	
Physeter macrocephalus	Sperm whale
Family Kogiidae	
Kogia breviceps	Pygmy sperm whale
K. sima	Dwarf sperm whale
Family Monodontidae	
Delphinapetrus leucas	White whale/beluga whale
Monodon monoceros	Narwhal
Family Ziphiidae (beaked whales)	
Hyperoodon ampullatus	Northern bottlenose whale
Mesoplodon bidens	Sowerby's beaked whale
M. densirostris	Blainville's beaked whale
M. europaeus	Gervais' beaked whale
M. mirus	True's beaked whale
Ziphius cavirostris	Cuvier's beaked whale
Family Delphinidae (ocean dolphins)	
Delphinus delphis	Short-beaked common dolphin
Delphinus capensis	Long-beaked common dolphin
Feresa attenuata	Pygmy killer whale
Globicephala macrorhynchus	Short-finned pilot whale
G. melas	Long-finned pilot whale
Lagenodelphis hosei	Fraser's dolphin
Grampus griseus	Risso's dolphin
Lagenorhynchus acutus	Atlantic white-sided dolphin
L. albirostris	White-beaked dolphin
Orcinus orca	Killer whale
Peponocephala electra	Melon-headed whale
Pseudorca crassidens	False killer whale
Sousa teuszii	Atlantic hump-backed dolphin
Stenella attenuata	Pantropical spotted dolphin
S. clymene	Clymene dolphin
S. coeruleoalba	Striped dolphin
S. frontalis	Atlantic spotted dolphin
S. longirostris	Spinner dolphin
Steno bredanensis	Rough-toothed dolphin
Tursiops truncatus	Common bottlenose dolphin
Family Phocoenidae	
Phocoena phocena	Harbor porpoise
Order Sirenia (manatees and dugongs)	
Family Trichechidae (manatees)	
Trichechus manatus	West Indian manatee
Subspecies	
T. m. latirostris	Florida manatee
T. m. manatus	Antillean manatee
Order Carnivora	
Suborder Pinnipedia	
Family Phocidae (true seals)	
Subfamily Phocinae (northern phocids)	
Cystophora cristata	Hooded seal
Erignathus barbatus	Atlantic bearded seal
Halichoerus grypus	Gray seal
Pagophilus groenlandicus	Harp seal
Pusa hispida botnica	Baltic seal
P. hispida hispida	Arctic ringed seal
Phoca vitulina concolor	Western Atlantic harbor seal
P. vitulina vitulina	Eastern Atlantic harbor seal
Subfamily Monachinae (southern phocids)	
Monachus monachus	Mediterranean monk seal
M. tropicalis[b]	Caribbean monk seal
Family Odobenidae	
Odobenus rosmarus	Walrus
Suborder Fissipedia	
Family Ursidae	
Ursus maritimus	Polar bear

[a]From Jefferson *et al.* (1993)
[b]Extinct.

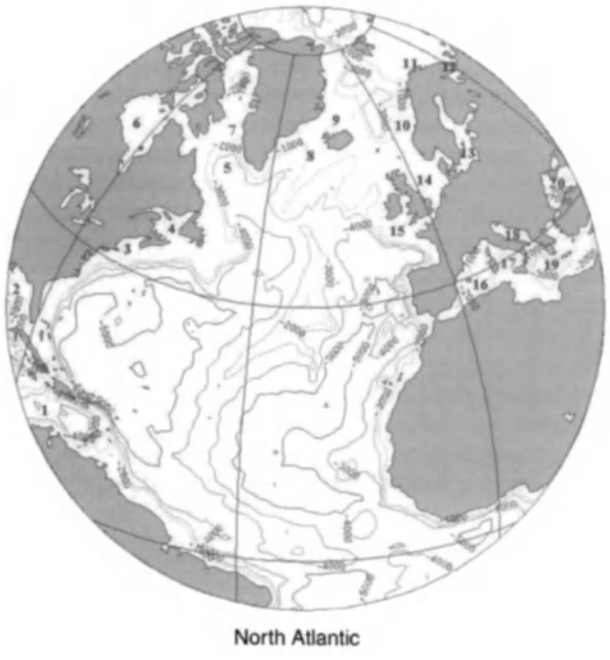

Figure 1 *Bodies of water in the North Atlantic. Depth contours in meters. 1, Caribbean Sea; 2, Gulf of Mexico; 3, Gulf of Maine; 4, Gulf of St. Lawrence; 5, Labrador Sea; 6, Hudson Bay; 7, Davis Strait; 8, Denmark Strait; 9, Greenland Sea; 10, Norwegian Sea; 11, Barents Sea; 12, White Sea; 13, Baltic Sea; 14, North Sea; 15, Celtic Sea; 16, Mediterranean Sea; 17, Tyrrhenian Sea; 18, Adriatic Sea; 19, Aegean Sea; 20, Black Sea. Produced using software written by Dr. Pawlowicz, University of British Columbia, Canada.*

Odontocetes also occupy nearly all marine ecosystems in the North Atlantic, with individual species exhibiting preferences for particular ecosystems. Continental shelf species found in cool temperate to subpolar waters are harbor porpoises, Atlantic white-sided and white-beaked dolphins (*Lagenorhynchus acutus* and *L. albirostris*) and long-finned pilot whales (*Globicephala melas*), and two Arctic species, narwhal (*Monodon monoceros*) and beluga whales. Continental shelf break/pelagic species found in temperate to cooler waters include bottlenose (offshore and coastal forms), short-beaked common (*Delphinus delphis*), Risso's (*Grampus griseus*), striped (*Stenella coeruleoalba*), and Atlantic spotted (*S. frontalis;* coastal form) dolphins, sperm (*Physeter macrocephalus*) and northern bottlenose (*Hyperoodon ampullatus*) whales, and Cuvier's (*Ziphius cavirostris*), Blainville's (*Mesoplodon densirostris*), Sowerby's (*M. bidens*), and True's (*M. mirus*) beaked whales. The range of northern bottlenose and Sowerby's beaked whales extends into sub-Arctic waters. Continental shelf break/pelagic species found in warm temperate to tropical waters are pantropical spotted (*Stenella attenuata*), Atlantic spotted (offshore form), spinner (*S. longirostris*), Clymene (*S. clymene*), rough-toothed (*Steno bredanensis*), Atlantic hump-backed (*Sousa teuszii*), and Fraser's (*Lagenodelphis hosei*) dolphins and melon-headed (*Peponocephala electra*), false killer (*Pseudorca crassidens*), pygmy killer (*Feresa attenuata*), short-finned pilot (*G. macrorhynchus*), pygmy sperm (*Kogia breviceps*), dwarf sperm (*K. sima*), and Grevais' beaked (*M. europaeus*) whales. Within warm-temperate to tropical water mass habitats, bottom topography and frontal boundaries are important characteristics that define cetacean distribution. Unlike baleen whales, only a few odontocetes (e.g., sperm and long-finned pilot whales) are known to undergo long-range seasonal migrations. Stock structure is largely unknown, except for a few nearshore continental shelf species (e.g., harbor porpoise, beluga). Some oceanic odontocetes likely move between North and South Atlantic waters (e.g., pantropical spotted dolphin, Cuvier's beaked whale).

North Atlantic seals (phocids) include both Northern and Southern hemisphere species (Table I). Northern phocids [harbor (*Phoca vitulina*), and gray seals (*Halichoerus grypus*)] are widely distributed in boreal to polar waters. The ice seals [hooded (*Cystophora cristata*), bearded (*Erignathus barbatus*), harp (*Pagophilus groenlandicus*), and ringed (*Pusa hispida*) seals] pup on ice and have seasonal migrations that are strongly associated with seasonal ice fluctuations. Bearded, hooded, and harp seals also utilize pelagic habitats. Ranges change; for example, since the 1990s, the winter/spring distributions of hooded and harp seals extended southward into northeast U.S. coastal waters. Harbor seals are the most widely distributed species, occupying cool temperate to Arctic North Atlantic waters. Gray seals have a discontinuous distribution in cold temperate to sub-Arctic coastal waters. Southern phocids include the Mediterranean (*Monachus monachus*) and Caribbean (extinct) monk seals. The Mediterranean monk seal is primarily found in the Mediterranean, adjacent seas, and along northwestern Africa. The Caribbean monk seal previously inhabited the Caribbean Sea and southern portion of the Gulf of Mexico. Stock structure for North Atlantic seals is well defined.

Cetaceans and phocid seals constitute the largest component of North Atlantic marine mammal fauna. Additional species include walruses (*Odobenus rosmarus*), polar bears (*Ursus maritimus*), and manatees (*Trichechus manatus*). Walruses and polar bears have a circumpolar distribution. Both species are usually associated with ice habitats but also spend time on coastal land areas. The Florida and Antillean manatees have a tropical to subtropical distribution. The Florida manatee is found in coastal waters of the Gulf of Mexico and southeastern United States. The Antillean manatee is distributed from northern Mexico to central Brazil and throughout the islands of the Caribbean.

III. Feeding

The taxonomic division of cetaceans into Odontoceti and Mysticeti reflects their different feeding strategies. Baleen whales are strainers who largely feed on planktonic or micronektonic crustaceans and/or relatively small pelagic fish by using visual or passive acoustic techniques. Toothed whales are graspers who capture fish, squid, and other species by hunting using sight, sound, or active ECHOLOCATION. Pinnipeds and polar bears are carnivores. Pinnipeds consume primarily fish and invertebrates, and some species occasionally eat sea birds, seals, or small whales. Polar bears prey primarily on seals and sometimes feed on fish and other small mammals. In contrast, man-

atees are herbivores, grazing in shallow waters on vegetation using primarily their sense of touch.

IV. Human Impact

Centuries of human activities have affected all North Atlantic marine mammal populations. Prehistoric people hunted coastal marine mammals for subsistence use, and in some areas (e.g., Bequia, Canada, Greenland) aboriginal hunting still exists. Early subsistence hunting, however, was likely insignificant compared to commercial whaling that began in Europe during the 10th century. By the beginning of the 18th century, European whalers depleted bowhead and right whale stocks in the eastern North Atlantic. American whalers also depleted right and humpback whale stocks in coastal waters off the American colonies. Whalers then hunted bowhead and right whales in the western North Atlantic, from Greenland to the Gulf of St. Lawrence. Depletion of these stocks initiated pelagic whaling for sperm and humpback whales in waters as far south as the Caribbean. Modern whaling, as we know it today, began in the late 19th century when Norwegians invented the explosive harpoon and converted from sail to steam vessels. This allowed whaling to expand to the faster swimming blue, fin, and sei whales. By the 1920s the North Atlantic large whales were depleted, and so whaling activities were redirected into Antarctic waters. Commercial whaling depleted most of these stocks as well. In 1946 the International Convention for the Regulation of Whaling was signed to provide for the CONSERVATION of whale stocks. However, North Atlantic whaling continued until the 1987 INTERNATIONAL WHALING COMMISSION moratorium was enacted. Following the moratorium, fin and minke whales were still taken for subsistence in West Greenland, and Norway continued a small minke whale fishery. Recently, Norwegian minke whaling has increased. Despite the many years since whaling of most species has stopped, some of the North Atlantic large whales (in particular the North Atlantic right whale) have not yet recovered. This is probably due to slow growth, low reproductive rates, and other human interactions.

Commercial exploitation of smaller cetaceans began in the 14th century when the Danes initiated organized hunts of Baltic Sea harbor porpoises. Although these hunts ended in the mid-20th century, there are still very few harbor porpoises in the Baltic Sea. In the 1500s, the Faeroese initiated a pilot whale drive fishery that continues to this day. Examples of hunts during the early to mid-1900s include Norwegian hunts of minke, killer, northern bottlenose, and pilot whales, American bounty hunts on harbor porpoises, and Newfoundland pilot whale drives. The Newfoundland fishery had to stop recently due to local depletion. Small-cetacean hunts occurring today are small-scale subsistence fisheries, such as for harbor porpoises in Greenland and belugas in Canada, Greenland, and Russia. It is unknown whether these stocks can sustain these removals.

North Atlantic walrus populations were similarly exploited. In the early 1600s, England initiated walrus hunting around Spitzbergen, Jan Mayen, and Norway. Russian, European, and Canadians jointed in to expand the hunts further northward. As a result, these walrus populations were severely depleted by the 19th century and they have not yet recovered.

Seals were first commercially hunted for oil and blubber in Europe and Newfoundland. In these areas, large-scale commercial hunts for seal skins started in the early 18th century, focusing on harp and hooded seals, although bearded, ring, gray, and harbor seals were also taken. By the late 1800s, hunting expanded to Greenland for harp, hooded, and ringed seals. During the World Wars, hunting slowed down, allowing some populations to recover. However, sealing resumed immediately afterward. During the 1960s, killing methods raised public opinion against sealing, which then prompted MANAGEMENT actions and quotas to reduce hunting. The largest reduction began in 1983, particularly in Canadian waters, when the European community enacted a ban on the importation of seal skins. However, since 1996, the level of Canadian harp sealing has resumed to pre-1983 levels because new markets for skins and meat have opened up.

Long-standing conflicts between humans and seals have occurred because seals impact economically valuable fishery resources. Impacts include seals preying on fish species, and seals, particularly gray and harbor seals, infecting many North Atlantic fish species with seal (or cod) worm, *Pseudoterranova decipiens*. These issues have initiated seal bounty programs in Europe and North America, which resulted in regional extirpation (e.g., northeast United States, Baltic Sea), of some gray and harbor seal stocks. Although bounty programs have either ended or been greatly reduced, ecological interactions between seals and fisheries remain a management challenge in the North Atlantic.

Following World War II, technological improvements in fishing gear and vessels led not only to the expansion of coastal and high seas fisheries, but to the incidental mortality of thousands of marine mammals and rapid depletion of fish resources. By the 1970s, the elevated levels of marine mammals takes, particularly dolphins in the eastern tropical Pacific tuna purse seine fishery, instigated management and conservation measures that were aimed at reducing incidental takes of marine mammals in fisheries (e.g., U.S. Marine Mammal Protection Act of 1972). Over the past two decades, national and international measures have aimed to improve fish stocks and to monitor and reduce fishery-related impacts on marine mammals (e.g., 1991 U.N. Resolution 46/125, ending high seas driftnet fisheries). Unfortunately, marine mammal mortality still occurring in many fisheries threatens some marine mammal populations in the North Atlantic, such as right whales, bottlenose and common dolphins, harbor porpoises, and Mediterranean monk seals.

Environmental contaminants potentially pose a threat to the health of marine mammals. Contaminant levels can become toxic in marine mammals because most feed at high trophic levels and so accumulate low levels of toxins from their contaminated prey. Numerous studies have documented the presence of organochlorine and heavy metals in tissues of marine mammals. The debate is: are these levels dangerous? Potential deleterious biological effects of these contaminants include immunosuppression, endocrine disruption, and reproductive and pathological disorders. Documented cases of deleterious effects include the reproductive failure that has been linked to organochlorine levels in seals from the Baltic and Wadden Seas and to beluga whales from the St. Lawrence Estuary. It has been suggested that some of the large-scale die-off events that have killed thousands of seals and dolphins in northern Eu-

rope, the Mediterranean, the U.S. east coast, and Gulf of Mexico are due, at least in part, to high levels of organochlorines or toxic metals (e.g., cadmium, mercury). Epizootic events and toxic algal blooms have also caused large-scale die-offs. For example, in 1988 an epizootic in the Kattegat-Skagerrak (body of water bordering Denmark, Sweden, and Norway) killed approximately 56% of the harbor seal population in those waters. In winter 1987/1988, 14 humpback whales died in the vicinity of Cape Cod after consuming Atlantic mackerel containing a dinoflagellate saxitoxin. However, in nearly all cases, it has not been possible to demonstrate a direct link between death and contaminants. Other types of potentially dangerous environmental contaminants include oil spills and acoustic disturbances because these may cause behavioral modifications, prey displacement, or direct mortality.

V. Status

The current status of North Atlantic marine mammal populations is tightly linked to the population's biological characteristics and their long history of interacting with human activities. Most populations are no longer commercially hunted, but some are still severely depleted (e.g., North Atlantic right whales). Human activities, such as hunting, incidental takes, and environmental contaminants, continue to directly and indirectly adversely impact marine mammals. Conservation and research programs, particularly for small cetaceans, are highly variable among countries. Because most marine mammal populations are mobile, the only way to assess the status of and conserve these populations is to ensure that scientific research and conservation programs are effective ocean wide.

North Atlantic, North Pacific, and Southern Right Whales

Eubalaena glacialis, *E. japonica*, and *E. australis*

ROBERT D. KENNEY
University of Rhode Island, Narragansett

ight whales occur in temperate to subpolar latitudes of all of the world's oceans. North Atlantic [(*Eubalaena glacialis* (Müller, 1776)] right whales were the first target of commercial whaling and the first whale species to be se-

riously depleted, and today the two Northern Hemisphere species are the rarest large whales in the world. North Atlantic and North Pacific [(*E. japonica* (Lacépède, 1818)] right whales remain critically depleted even after more than six decades of international legal protection and may still be facing the threat of EXTINCTION. Right whale populations off the eastern United States, Argentina, South Africa, and Australia have been the focus of intensive long-term research and may be some of the most intensively studied large whales. Nevertheless, there are many areas where our knowledge is sadly lacking and where additional research is critically needed.

I. Systematics and Nomenclature

A. Common Names

Conventional wisdom holds that the common name "right whale" comes from English whalers, who designated this as the "right" (i.e., correct) whale to hunt because it occurred near shore, swam slowly enough to be caught from a small boat propelled by sails or oars, floated when dead, and yielded large amounts of valuable oil and BALEEN. Alternatively, it may have derived from the sense of right whale meaning "true whale," as later formally recognized in the Latin generic name *Eubalaena*. Other common names in English include black right whale and black whale.

B. Systematics

While Northern and Southern Hemisphere right whales have long been treated as two species, it was recommended in 1998 that all right whales should be considered as a single species, *Balaena glacialis*. In June 2000, the INTERNATIONAL WHALING COMMISSION's scientific committee reviewed right whale taxonomy. Although morphological differences are nearly absent, the most recent genetic evidence demonstrates that right whales of the North Atlantic, North Pacific, and Southern Ocean possess fixed, unique genetic patterns indicating complete and long-established isolation. Genetic data also show that North Pacific and southern [*E. australis* (Desmoulins, 1822)] right whales are more closely related to one another than either is to North Atlantic right whales, making the traditional combination of North Atlantic and North Pacific animals as "northern right whales" a systematics error. Based on the evidence, the committee recommended that the three populations be considered as separate species. They also recommended retention of the generic name *Eubalaena*, published by J. E. Gray (see the accompanying box) to separate right whales from bowhead whales (*Balaena mysticetus*), the only other living species included in the family Balaenidae. However, while there are no currently accepted genetic criteria for differentiation at the generic level, systematic classifications are scientific hypotheses, subject to revision after further study. The few authors who have looked critically at morphological or molecular differences between right whales and bowheads have concluded that there is little evidence supporting their separation at the generic level and that those differences which do exist are less than those between species of *Balaenoptera*. In addition, the known fossil species of *Balaena* cannot be shown as more closely allied with either right whales or bowheads.

Taxonomic Rules, J. E. Gray, and Right Whale Names

There is a set of very specific rules, the International Code of Zoological Nomenclature, for determining the correct scientific name to apply to any particular taxon. One important aspect of the code is the rule of priority—when determining the valid name for any species (or genus or higher level category), the first published name applied should be used. For example, the original descriptions of all three right whale species included them in the genus *Balaena*, a genus name published by Linnaeus in 1758. If biological evidence continues to support classifying right whales as a distinct genus from bowheads, the name *Eubalaena*, published by J. E. Gray in 1864, is the oldest name available applicable only to the right whales and therefore the valid name by the rule of priority.

John Edward Gray (1800–1875) was an English zoologist and an important figure in the history of cetacean taxonomy. He began his career at about age 15 as a volunteer insect collector, received a temporary appointment at the British Museum in 1824 to catalog reptiles, and was Keeper of Zoology there from 1840 until his retirement only 2 months before his death. In his years at the museum, he published well over 1000 papers, including half of the 200 catalogs issued by the museum during his time. *Eubalaena* is not the only cetacean name he coined; 15 of the 85 currently accepted names of extant cetacean species, 15 of the 40 generic names, and 11 of the 14 family names were authored by Gray. One might conclude that he was particularly knowledgeable about cetacean taxonomy. However, he worked at what was likely the world's most influential museum of his day and apparently had a penchant for creating new species, genera, and higher taxa. He has been called one of the most notorious taxonomic "splitters" of all time. He also authored at least four other generic names for right whales, and in a single publication in 1871 he counted six genera and 14 species of right whales.

II. Description

Right whales have an extremely robust body form, bordering on rotund, with the girth at times exceeding 60% of total body length. The body is mostly black, sometimes with irregular white ventral patches. Some individuals may have a mottled appearance, and calves may sometimes be lighter colored. There is no dorsal fin. The pectoral flippers are large, broad, and blunt, and the flukes are very broad (up of 40% of body length), black on both dorsal and ventral surfaces, deeply notched, and smoothly tapered to the tips. Calves are 4.5–6 m long at birth; typical adults are 13–16 m. North Pacific right whales attain larger maximum sizes than the other species, up to 18 m and over 100 metric tons.

The head is relatively large, comprising about one-quarter to one-third of the total body length. The upper jaw is somewhat arched, and the margin of the lower lip forms a very pronounced curve. There are 200–270 baleen plates on each side

Are Whale-Lice Parasites?

Two species are said to be symbiotic when they live intimately associated with each other, with the exact nature of the relationship depending on the fitness costs and benefits incurred by each species. In the symbiosis involving right whales and cyamids, it can be assumed that the cyamid benefits from the relationship by having a place to live and a ready food supply. If the right whale also benefits, the association is defined as mutualism; if the whale receives neither benefits nor costs, the association is commensalism; and if the whale is harmed, the association is parasitism. Most sources refer to cyamids as parasites or ectoparasites. It is known that they do feed on the whale's skin, however, there is no evidence that their presence or feeding causes any harm to the whale. Similarly, while it is possible to construct various hypotheses for potential benefits provided to the whale by the cyamids, there is no evidence to test or confirm these theories. It therefore seems that the conservative course would be to consider cyamids as ectocommensals of right whales until convincing evidence demonstrating otherwise has been shown.

of the upper jaw. The baleen plates are relatively narrow and 2–2.8 m long, with very fine fringing hairs.

The most conspicuous external characteristics of right whales are the callosities on the head. These are irregular patches of thickened, keratinized tissue, which are inhabited by dense populations of specialized amphipod crustaceans, known as cyamids or "whale lice" (see accompanying box). At least three species of whale lice occur on right whales: *Cyamis gracilis*, *C. ovalis*, and *C. erraticus*. In southern right whales the callosities are also inhabited by barnacles, *Tubicinella* sp. The callosities occur at the tip of the snout (called the "bonnet" by whalers), on the lower lips and chin, above the eyes, and in front of and behind the blowholes. The callosities are congenital and not caused externally, as their beginnings are present in fetuses and neonates, but the pattern is not fully developed and colonized by cyamids until the whale is at least several months old. The callosity patterns are unique to individuals and are therefore extremely useful as a natural "tag," which allows repeated identification of individuals by photographs (Fig. 1).

The closest relative of the right whale is the bowhead whale. Bowheads are somewhat longer and substantially stouter, have relatively larger heads (about 40% of body length) with a more arched appearance, have much longer baleen plates (up to 5.2 m long), and completely lack callosities.

III. Distribution and Abundance

Right whales are found in the middle latitudes of both the Northern and Southern Hemispheres, between approximately 20° and 60°S and N latitudes (Fig. 2). There are three geographically isolated populations currently recognized as separate species: in the North Atlantic, North Pacific, and Southern Ocean. The populations are kept separated by Arctic ice and warm equatorial waters so that there is no interchange between populations, and apparently has not been for millions of years.

A. North Atlantic Right Whales

The historical range of North Atlantic right whales apparently extended as far south as Florida and northwestern Africa and as far north as Labrador, southern Greenland, Iceland, and Norway. The traditional hypothesis has been that there were separate stocks with little interchange on the western and eastern sides of the basin; however, recent evidence is casting some doubt on that model. Analysis of some 19th century whaling specimens in European museums shows that they do not differ genetically from living western individuals, and there have been one or two right whales seen in the eastern North Atlantic in recent years that were known individuals from the western stock. It is possible that the structure of a right whale population is that a particular ocean basin is inhabited by a single breeding population without long-term genetic isolation of stocks, but where return to traditional habitats learned from the mother (matrilineal habitat fidelity) maintains shorter term separation between two or more subsets of the population.

The present range of western North Atlantic right whales, from Florida to Nova Scotia with very occasional occurrence beyond those limits, is much reduced from its historical extent. The best estimate of present abundance is about 300 animals. In the

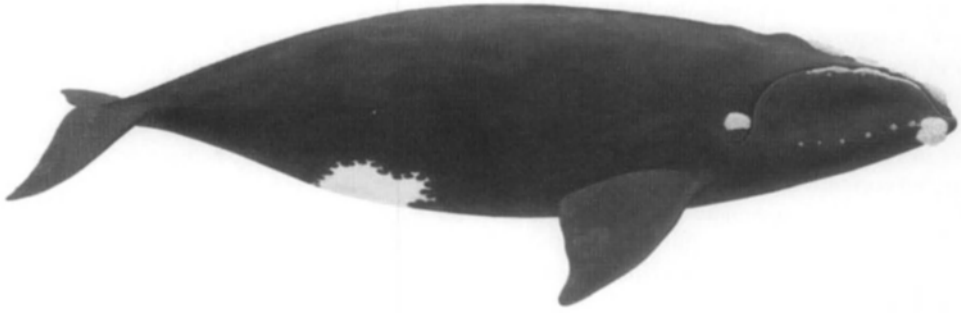

Figure 1 *Right whales are in the genus* Eubalaena *and include three species. Individuals can be identified with varying success using callosity patterns on the head. Southern right whales* (E. australis), *pictured here, are represented by multiple stocks, and some of these stocks appear to be both healthy and increasing, in contrast to the much reduced abundance and distribution of the North Atlantic right whale. Pieter A. Folkens/Higher Porpoise DG.*

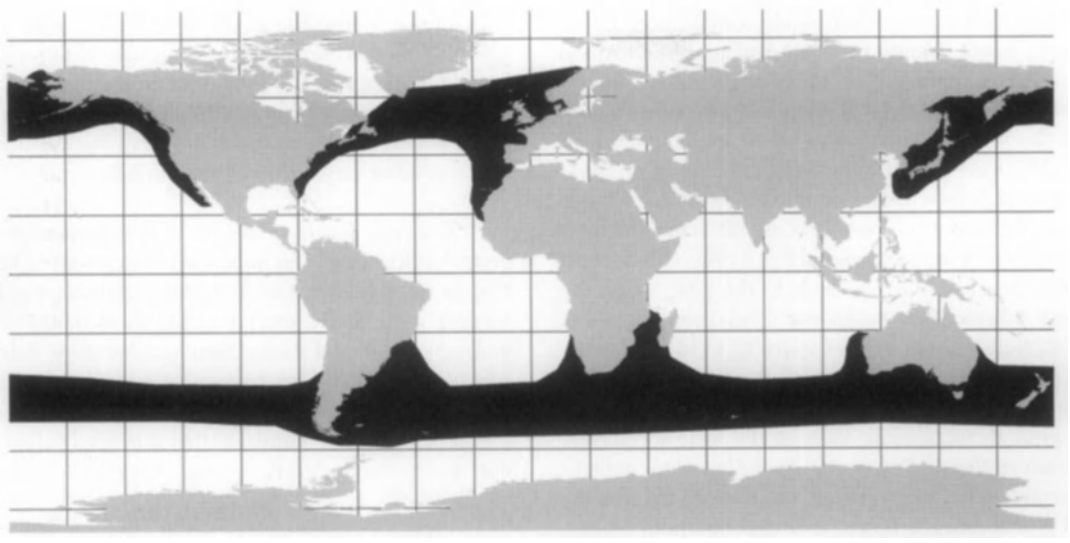

Figure 2 *Worldwide range of right whales* (Eubalaena glacialis, E. japonica, *and* E. australis). *Much of what is shown here is relatively speculative based on sparse historical records of whaling catches and the available recent sightings. Most recent data come from areas relatively nearshore, with few or no data for the pelagic areas between the known coastal habitats.*

eastern North Atlantic, there have been only a handful of right whale sightings in the last few decades. It is not known whether these represent a small remnant eastern stock or whether some or all of them are individuals from the known western population.

B. North Pacific Right Whales

The historical range in the North Pacific was similarly much more extensive than today. Right whales occurred from Japan and northern Mexico north to the Sea of Okhotsk, Bering Sea, and Gulf of Alaska. Recent sightings are extremely rare, primarily in the Sea of Okhotsk and eastern Bering Sea. There are no reliable estimates of abundance, and there may be even fewer whales than in the North Atlantic. There are also insufficient genetic or resighting data to address whether there is support for the traditional separation into eastern and western stocks.

C. Southern Right Whales

Right whales are known from several areas of the Southern Ocean. Multiple stocks have been hypothesized, including Argentina/Brazil, South Africa, east Africa/Mozambique, western Australia, southeastern Australia, New Zealand, and Chile. Additional stocks have been hypothesized for the central Indian Ocean, the Campbell and Auckland Islands in the southwestern Pacific, and Tristan da Cunha in the central South Atlantic. There have also been suggestions of even finer stock structuring, e.g., between Argentina and Brazil in the western South Atlantic or between Namibia and South Africa in the eastern South Atlantic. Preliminary genetic analysis shows incomplete separation between eastern and western South Atlantic right whales. Further genetic studies should shed light on the degree of gene flow and stock separation in southern right whales and on the possible role of matrilineal habitat fidelity in structuring the population.

Right whale populations in Argentina, South Africa, and Australia are presently the largest and the best studied. The total abundance of those three stocks is currently estimated at about 7000 animals, and all three stocks appear to be healthy and increasing at 7–8% annually.

IV. Ecology

A. Prey

Right whales feed entirely on zooplankton, especially on large calanoid copepods (crustaceans approximately the size of a grain of rice). At times they also feed on smaller copepods, krill (larger shrimp-like crustaceans), pteropods (tiny planktonic snails), or the planktonic larval stages of BARNACLES and other crustaceans. The details of their diet likely differ between regions, e.g., it is likely that krill comprise a higher proportion of the DIET in southern right whales. It is also likely that right whales can be somewhat opportunistic, FEEDING on any prey of a size that can be filtered efficiently by the baleen, which does not swim strongly enough to escape, and which is concentrated into sufficiently dense patches to trigger feeding behavior. For example, there have been recent observations of North Atlantic right whales in the Bay of Fundy feeding on aggregations of salps.

B. Habitat

Right whales migrate annually between high-latitude feeding grounds and low-latitude calving and breeding grounds. These are substantial differences in the locations where most research has been conducted between the Northern and the Southern Hemispheres; therefore, there is often a lack of directly comparable information for different populations.

1. Feeding Grounds Right whale feeding takes place in spring, summer, and fall in higher latitude feeding grounds, where ocean temperatures are cooler and overall biological productivity is much higher. The best known right whale feeding grounds are in the western North Atlantic. These habitats are

in nearshore and shelf waters, where some combination of bottom topography, water column structure and stratification, and currents acts to physically aggregate zooplankton into extremely dense concentrations. The densest zooplankton concentrations measured in the North Atlantic were found by sampling near right whales. There are probably also offshore feeding grounds, in locations not yet known, based on historical whaling records and on the fact that some known whales are often missing from the known habitats for months or years at a time. There must also have been other feeding grounds in the past, when the range of North Atlantic right whales was much more extensive.

Feeding grounds for the other species of right whales are much more poorly known. In the North Pacific, based on historical whaling records and the few recent sightings, the principal feeding grounds were most likely in the Sea of Okhotsk, central and eastern Bering Sea, and Gulf of Alaska. All of these feeding areas are much more pelagic or offshore than in the well-studied North Atlantic habitats. In the Southern Ocean, right whale feeding grounds are also apparently mostly in offshore, pelagic regions. Southern right whale feeding grounds are likely to be found associated with areas of extremely high productivity; limited sighting data available show most whales in the regions between the subtropical and Antarctic convergences.

2. Calving Grounds Calving in right whales occurs during winter. Where the calving grounds are known, they are in shallow coastal regions or bays. The only known current calving ground in the western North Atlantic is in coastal waters near Georgia and northeastern Florida. It has been speculated that other coastal areas, including Delaware Bay and Cape Cod Bay, may have been calving grounds before the population was depleted by whaling. It has been noted, for example, that Cape Cod is similar topographically to Peninsula Valdés in Argentina and is located at about the same latitude. In the eastern North Atlantic, Cintra Bay in northwestern Africa is believed to have been a historical right whale calving ground. It is possible that areas near the Azores and Madeira, as well as the Bay of Biscay, were also calving grounds. In the North Pacific, no right whale calving grounds have ever been discovered. In the Southern Hemisphere, shallow coastal waters and bays in many areas are currently known to be southern right whale calving areas or hypothesized to have been calving grounds historically, including Argentina, Brazil, Falkland Islands, Tristan de Cunha, Namibia, South Africa, Mozambique, Kerguelen Island, Australia, New Zealand, Auckland Islands, and Chile.

3. Breeding Grounds Breeding or mating also occurs during the winter. Because of the 3-year female reproductive cycle, breeding can take place geographically distant from calving. In the western North Atlantic, the location of the majority of the population during the winter is not known, and adult males are nearly absent from the calving ground. Breeding must occur wherever the adult population spends the winter, but it is not known whether there are specific, distinct winter habitats or whether the whales are broadly dispersed across wide regions of the North Atlantic.

In southern right whales, at least some mating occurs in or near the calving grounds, although there may be small-scale segregation of breeding adults from females with calves. In Argentina, because females are observed infrequently in these breeding groups in the year prior to calving, it is possible either that the mating which actually leads to conception occurs in some other, unknown habitat or that receptive females only visit coastal waters for very brief periods.

4. Learning and Habitat Use Circumstantial evidence suggests that learning is an important component of habitat selection in right whales. Calves apparently learn the locations of feeding grounds by accompanying their mothers during the first year of life and then return to those same habitats for the rest of their lives. This pattern of matrilineal habitat fidelity seems to be common in migratory whale species; resighting and genetic data demonstrate that it is responsible for population structuring in North Atlantic humpback whales.

C. Predators

Potential predators of right whales include killer whales and large sharks. There have been a few direct observations of killer whale attacks on right whales; more common are records of right whales in the North Atlantic, South Atlantic, and North Pacific with scarring patterns on the flukes that appear to be tooth rakes or missing pieces of the flukes. Predators may be more likely to attack calves or juveniles than adults. Predation may have been one of the selective pressures leading to the evolution of right whales' use of shallow coastal habitats for calving, particularly since at least white sharks are known to often attack their prey from below.

V. Behavior

A. Aerial Behaviors

Right whales are observed to frequently perform highly energetic behaviors at or above the surface of the water. These aerial behaviors include BREACHING (jumping partly or almost completely above the surface), LOBTAILING (violently slapping the surface with the flukes), and flippering (slapping the surface with a pectoral flipper). The functions of these behaviors are not known. They all produce very loud sounds, which may sometimes have a communicative and/or aggressive function. Right whales in Argentina and South Africa have been observed to lift their flukes above the surface, where the flukes act like a sail and allow the wind to push the whale horizontally. This "tail-sailing" behavior has not been reported in other habitats.

B. Feeding Behavior

Right whales are "skimmers" (Fig. 3). They feed by swimming forward with the mouth agape. Water flows into the opening at the front, and out through the baleen, straining their prey from the water. Feeding can occur at or just below the surface, where it can be observed easily, or at depth. At times, right whales apparently feed very close to the bottom, because they are observed to surface at the end of an extended dive with mud on the head. Typical feeding dives last for 10–20 min.

C. Reproductive and Social Behavior

Courtship in right whales often involves aggregations of whales termed "surface-active groups." These are usually centered around

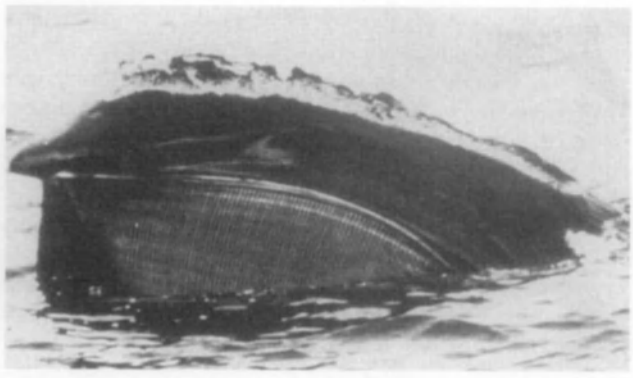

Figure 3 *A "skimming" North Atlantic right whale feeding on plankton near the surface. Photograph by William Watkins.*

a single female and may involve large numbers of males; groups of more than 20 animals have been observed. Often the female is belly-up at the surface, while the males stroke her with their flippers or attempt to push her under. There is some evidence that the female initiates the interaction by vocalizing. In the North Atlantic, surface-active groups are observed in all seasons, even though calving is highly synchronous and restricted to winter. Therefore much of the observed activity does not lead to fertilization and may serve a social function. The female may simply use the interactions to assess male quality for later mating. The interactions between males in the group generally involve very little of the violence and aggressiveness seen in humpback whales. One theory is that right whales engage in sperm competition, where the volume of semen is important in displacing the sperm of other males mating with the same female. Right whale testes may be the largest of any animal, at 2 m long and 500 kg each.

D. Sound Production

Right whale vocalizations are primarily low-frequency moans, groans, belches, and pulses. Most acoustic energy produced is below 500 Hz, with some sounds up to 1500–2000 Hz. The functions of these sounds are not well understood. Hypothesized functions include maintenance of contact between separated individuals, threats or other aggressive signals, and social signals, including their possible involvement in surface-active group behavior.

VI. Life History

A. Age at Maturity

Information on the age at maturity in right whales is not available from whaling data as it is for other whale species taken by 20th century industrial whaling. The information must be derived from photoidentification studies which track known individuals from birth. The youngest mature female in the western North Atlantic was 4 at maturity and 5 at first calving. From both North Atlantic and Southern Hemisphere data, the average age at first calving is closer to 9 or 10 years. Age at maturity is not yet known for males, as there is no external method for identifying paternity. Newer genetic studies may be better able to identify fathers of calves and begin to provide data for age of maturity in males.

B. Growth

Growth in right whales is relatively rapid from birth to weaning at about age 1, by which time the calf approximately doubles in body length to 9–11 m. Available data on growth after age 1 are not entirely consistent. For example, some studies indicate that growth also can be relatively rapid in year 2, by which time total length may reach 12–13 m, and thereafter is much slower. However, South African right whales apparently grow little between ages 1 and 4. Growth after age 1 is likely to be dependent on feeding success. The western North Atlantic female that matured at age 4 remained with her mother well into her second year, possibly growing much faster than the typical rate by nursing for a longer period. Right whales are believed to reach sexual maturity at body lengths of 13–16 m.

C. Life Span

There are very few data on the longevity of right whales. Aging baleen whales is an extremely difficult problem. Japanese attempts to use the wax plug found in the auditory canal from the North Pacific right whales taken for research in 1956–1968 were not successful. The oldest known right whale to date was in the North Atlantic. A mother–calf pair near Fort Lauderdale, Florida, was pursued and shot at by fishermen on March 24, 1935. The calf was killed, but the mother escaped. A photograph of her published in the New York *Herald Tribune* at the time was later matched to photographs taken in Cape Cod Bay (by pioneering right whale researcher William E. Schevill) in April 1959. She was also photographed in 1980, 1985, and 1992. On August 13, 1995 she was photographed offshore, with a large, gaping wound on the head apparently caused by a ship strike. It is unlikely she could have survived that injury. Assuming she was at least 10 years old in 1935, she would have been at least 70 years old in 1995. Recent research on bowhead whales suggests that they may live even longer.

D. Reproduction

The typical reproductive cycle in mature female right whales is 3 years between births. The gestation period is approximately 1 year, and weaning occurs at about 1 year of age. The female then takes a third year to replenish her energy stores, although it is possible for a female who has been especially successful at feeding to skip the resting year and calve after only a 2-year interval (one case observed in the North Atlantic, and at least one in Argentina). An alternative explanation for an observed 2-year interval is calf mortality soon after birth and subsequent avoidance by the mother of the high energetic demands of lactation; documented twice in Australia. This presumes that the mother–calf pair is sighted during the brief interval between birth and death of the calf. Otherwise what would be observed is an apparent 5-year interval, of which 25 were recorded in the North Atlantic between 1980 and 1998. Calving has been observed very rarely; in other instances, known females have been sighted in the calving ground both before and after the calf was born.

VII. Fossil Record

Five fossil species of *Balaena* have been described from deposits of late Miocene, Pliocene, or Pleistocene age (2–10 million years old) from Europe and North America: *B. affinis*,

B. etrusca, *B. montalionis*, *B. primigenius*, and *B. prisca*. The last of these is similar enough to modern bowheads (*B. mysticetus*) that it may, in fact, not be a separate species. There is then a long gap in the balaenid FOSSIL RECORD to *Morenocetus parvus*, the oldest known member of the family, found in early Miocene (23 million years old) deposits in South America.

VIII. Interactions with Humans

A. Whaling

North Atlantic right whales were the first whales to be harvested commercially by the Basques along the Atlantic coast of western Europe as early as the 11th century. The whales were killed primarily for oil, which was sold across Europe, as the technology of the time did not permit preservation and transportation of meat. As populations nearest shore were depleted, Basque whaling expanded to more distant waters, reaching eastern Canada by 1530. Basque whaling in Canada was centered in the Strait of Belle Isle between Labrador and Newfoundland and took 300–500 whales per year at its peak. Catches were declining by 1610–1620 and ended in 1713, by which time they had taken as many as 40,000 whales, including both right whales and bowheads.

Local shore-based right WHALING in North America began soon after the establishment of permanent colonies during the early 17th century. Peak catches were in the early 18th century (e.g., 86 in Nantucket, Massachusetts in 1726; 111 in Long Island, New York in 1707), and right whales in western North Atlantic waters may have been effectively extinct as a basis for a commercial fishery by the middle of the 18th century. The familiar Yankee whaling industry soon developed as a high-seas fishery targeting sperm whales; however, the whalers continued to opportunistically take any right whales encountered. Yankee whaling (including ships from several European nations) spread to the South Atlantic by 1775, into the South Pacific in 1789, and into the North Pacific by 1820. The Japanese had also begun their own shore-based fishery, which took some coastal migrant right whales, in the late 16th century.

The traditional high-seas Yankee whale fishery finally ended in the early 20th century, when it was replaced by modern industrial whaling. Total right whale catches (although records are not complete) were at least 38,000 in the South Atlantic, 39,000 in the South Pacific, 1300 in the Indian Ocean, 15,000 in the North Pacific, and at least a few hundred in the North Atlantic. Some shore-based whaling in the eastern United States persisted into the 1920s, but it was minor, with only 8 taken in Long Island after 1900. In the North Atlantic, the last episode of intensive right whaling was in the late 19th and early 20th century off Norway, Iceland, and Scotland, and the last right whales taken were at Madeira: 1 in 1952 and 2 in 1967. All right whale populations worldwide were protected from commercial whaling in the 1930s by the first International Convention for the Regulation of Whaling. However, the Japanese took 23 North Pacific right whales in the 1940s and 13 more under special scientific research permits between 1956 and 1968, some illegal takes of right whales along the coast of Brazil were reported in the 1950s, there was a significant amount of illegal Soviet taking of right whales in the North Pacific and Southern Ocean into the 1960s, and it is possible that there has been illegal right whaling elsewhere in the world.

B. Ship Strikes

The most significant human-related source of mortality at present in western North Atlantic right whales is collision with large ships. Between 1970 and 1999, 16 right whales were known to have been killed by ships, and 2 others were last seen with serious and probably fatal injuries. There are probably additional mortalities that are never discovered because the carcasses are lost at sea. Ship collisions may be less of a mortality factor in other oceans, where right whales spend less time in nearshore habitats or where the level of industrial development is lower, although at least three probable ship-strike mortalities have been recorded in recent years off the Brazilian coast.

C. Entanglements

The second most important human-related mortality factor in western North Atlantic right whales is incidental capture in commercial fishing gear. The gear involved is fixed gear (set in one location rather than towed behind a vessel), including sink gill nets, drift nets, and a variety of pot and trap fisheries. Since 1970, three right whales are known to have been killed by ENTANGLEMENTS and eight others were seriously injured but disappeared and probably died. It is not always known whether entanglements occur in actively fishing gear or in gear that has been lost, damaged, or moved by storms or vessels (often termed "ghost" gear). There are few data on entanglement mortalities in other populations.

Entanglement seems to be very common in right whales. Many entanglements involve the tail, where the leading edges of the flukes begin, and leave characteristic scars afterward. Over 60% of whales in the western North Atlantic carry such scars, and some individuals have been entangled two or three times. Entanglements are therefore often not lethal. They may be more dangerous in younger animals, who might grow into a relatively benign entanglement until it becomes life-threatening.

D. Climate Change

Right whales are feeding specialists, with a relatively narrow range of acceptable prey species and requiring prey to be concentrated in exceptionally high densities. The development of right whale feeding grounds is closely linked to physical phenomena such as water structure, currents, and temperature. This may make right whales more sensitive than other species to impacts from global climate change. Any possible impacts may be increased because of matrilineal fidelity to their feeding grounds, and possibly a relatively low ability to locate new feeding grounds when conditions change. For example, right whales have never reoccupied the habitat in the Strait of Belle Isle where Basque whaling killed many thousands.

E. Other Human Impacts

There are a number of other potential human impacts on right whales:

1. Habitat loss due to high levels of human activity is mentioned frequently as a possible impact. Right whales no longer occur in Delaware Bay, eastern United States; Table Bay, South Africa; Wellington Harbor, New Zealand; or Derwent River, Tasmania. However, a plausible alternative explanation is that they were extirpated by whaling and have never reoccupied the habitat due to matrilineal habitat fidelity.

2. Pollution is another potential impact that is mentioned frequently but where evidence is sparse. Oil spills may be a bigger threat to right whales than to other baleen whales because their very fine baleen might be fouled more easily. Blubber samples show a presence of toxic contaminants, but at lower levels than in cetaceans that feed at higher trophic levels. A recent concern is that some contaminants may act as hormone mimics, affecting reproduction, or as immune system suppressants.
3. Man-made noise may have the potential for interfering with acoustic communication, particularly since the major noise source, shipping, is also concentrated in the lower frequencies.
4. Effects of intensive commercial fisheries may alter ecosystem structure, increasing the abundance of other species that feed on zooplankton, particularly small fishes with lower economic value than the larger species harvested by FISHERIES.
5. The long-term effects of extreme population depletion by whaling might include reduced genetic diversity and associated health and reproductive problems.

Northern Fur Seal

Callorhinus ursinus

ROGER L. GENTRY

National Marine Fisheries Service, Silver Spring, Maryland

The northern fur seal, *Callorhinus ursinus,* inhabits the North Pacific Ocean and Bering Sea (Fig. 1). *Callorhinus* is the oldest living genus of the family Otariidae, with origins 2–5 million years ago. *Callorhinus* means "beautiful nose," and *ursinus* means "bear-like"; sea bear was a former common name. This species has a short rostrum and therefore lacks the dog-like profile of the other fur seal genus, *Arctocephalus.* Females are small (45 kg) and gray-brown with a light underbelly; males are larger (200–250 kg) and vary from black to reddish (Fig. 2). The young (pups) are generally black with a light belly. About 91% of the northern fur seal population breeds at the Pribilof Islands of Alaska (74%) or at the Commander Islands of Russia (17%). The remainder breeds at the Kurile Islands and Robben Island (Russia), Bogoslof Island (Alaska), and the Farallone and San Miguel Islands (California). The species predates some of the islands on which it now breeds so some past population redistribution has occurred. It is primarily a subpolar species whose adaptations do not preclude breeding at a lower latitude. Bones in kitchen middens suggest that breeding colonies once occurred at several mainland sites in the United States.

Northern fur seals have been studied longer than most other marine mammals. George Wilhelm Steller first described the species in 1749 based on his observations in 1742 when he was a member of Vitus Bering's expedition that discovered the Commander Islands, Russia. Heavy exploitation of this colony (for pelts to be made into garments) began almost immediately after discovery and expanded considerably in 1786 when the Pribilof population was discovered. To protect the populations from overexploitation, the Russians prohibited the killing of females, which was one of the first known wildlife management actions. Despite this protection, major declines in population size occurred three times since 1742, each one associated with killing for pelts or other management actions. After one such decline (1911), the North Pacific Fur Seal Treaty was enacted, which involved four nations (Japan, Russia, United States, and Britain for Canada). It ended permanently in 1985. The population declined from 1956 to about 1983, was apparently stable at about 1.5 million animals until 1990, and declined at 2% per year until 2000.

If the commercial kill for pelts at times affected the population size, it was also responsible for a vigorous research program that made this among the best known marine mammal species. Population records extend back to at least 1865, and data are especially good between 1911 and 1985 when comparative research at the major land breeding sites was carried out under the treaty mentioned earlier. Presently research is conducted under a bilateral environmental agreement with Russia.

I. Natural History

This species is among the most pelagic of pinnipeds; females spend all but about 35 and males all but about 45 days per year at sea. From November to about March each year, the species remains north of the transition zone between the Oyashio and the Kuroshio currents (about 35°N latitude) without coming ashore. In March and April, animals gather along the continental shelf breaks and begin to migrate north to their respective breeding islands, apparently so that females can rear their young while feeding on greater (but more seasonal) food concentrations than are available at lower latitudes. The young

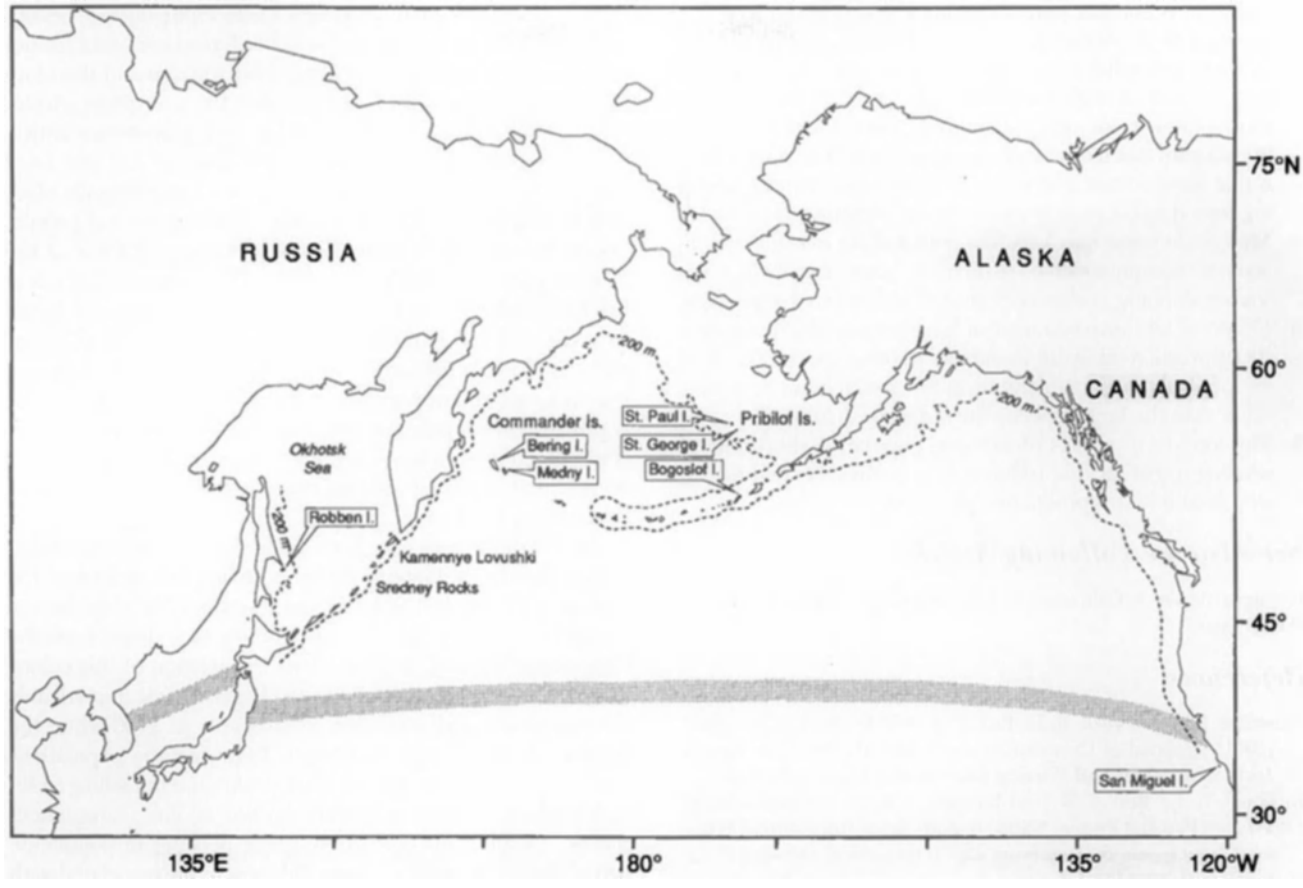

Figure 1 *Distribution of the northern fur seal.*

Figure 2 *Adult male and female northern fur seals. Photo by V. B. Scheffer.*

are born mainly in July, are nursed for about 4 months, wean in October or November just as winter arrives, and begin their southward migration with the rest of the population. The only animals that do not migrate are those that breed at San Miguel Island and the adult males of all other breeding colonies. It may be the larger mass of adult males that allows them to overwinter in cold northern waters unlike smaller animals that migrate to the southern end of the range.

This species is not under intense competition for breeding space by other species of otariids. California sea lions (*Zalophus californianus*) compete with them for space only at San Miguel Island. Steller sea lions (*Eumetopias jubatus*) may rest among northern fur seals (and occasionally eat their young at sea) but do not usually mate on the same sites. The Guadalupe fur seal (*Arctocephalus townsendi*) does not presently share any breeding islands with the northern fur seal. Furthermore, northern fur seals do not often compete with other otariids for food. They take small fish and squid over deep water, unlike California and Steller sea lions. They feed along the shelf break, but not upon the shelf like California sea lions. Guadalupe fur seals probably take many of the same prey items as the northern fur seal, but the Oyashio/Kuroshio transition zone effectively separates the two fur seal species at sea.

Individuals show strong preferences for using specific land sites at particular times of the year. Despite having many square kilometers of suitable land available for giving birth, individual females bear their young within 8–10 m of the same site in successive years. Males will defend only one territorial location for their reproductive lifetime. This tie to specific sites may be an extreme form of philopatry (mating on the site of their own birth). Furthermore, females and males tend to arrive on a date that is specific to them as individuals, despite the fact that pupping and mating in the population occur over a 6-week period. On the beach, the tens of thousands of breeding animals may superficially resemble a large, amorphous mass, but in reality it is composed of individuals each with fairly specific preferences for breeding at a given location and time of year.

In timing and location, the breeding aggregations of this species are highly predictable because of the site fidelity of individuals. Thirty-one BREEDING SITES (formerly called "rookeries") now exist. One of these ("North" breeding site on Bering Island, Commander Islands, Russia) has been occupied yearly since at least 1742. Breeding sites do not change much in size or shape from year to year. Northern fur seals colonize new islands and new beaches at a low rate compared to other fur seals. The onset and duration of the pupping/mating season are quite stable and vary little because of weather or climatic conditions.

The young leave land with modest fat reserves and little foraging experience at 4 months of age. At sea they must immediately learn to find and capture solid food alone while migrating in the appropriate direction. The difficulty of these tasks is reflected in the fact that some 60% or more of the pups born per year fail to survive to age 2 years when their age mates first return to land. Despite this seemingly low survival rate, the species is evolutionary quite successful; it numbered approximately 2.5 million animals at its peak in the mid-1950s.

The ecological role of the species is a high-level consumer, taking a variety of fish, cephalopods, crustaceans, and an occasional bird. Seventy-five different prey species have been identified in northern fur seal stomachs. Juvenile pollock, Atka mackerel, capelin, eulachon, herring, and several species of squid predominate. They take these prey items at relatively shallow depths (100–200 m for females, less than 400 m for males) compared to those species of marine mammals that can dive to a thousand meters or more. Northern fur seals feed mostly at night on prey that migrate vertically. A major component of the northern fur seal's diet is lantern fish (myctophids), which have no commercial value. Northern fur seals are preyed upon by large sharks, killer whales, and (for young only) Steller sea lions.

II. Reproduction

The species is SEXUALLY DIMORPHIC; males are at maximum 4.5 times larger than females. A size difference exists as early in embryonic growth as the sexes can be identified, and it accelerates at the onset of sexual maturity, about 3–5 years of age. Females mate almost immediately after becoming sexually mature and begin to produce one young per year. Males do not become socially mature (large enough to gain a territory among females) until they are 8–9 years old. Like other otariids, the sex ratio at birth of northern fur seals is nearly 1:1, but due to greater age-specific mortality rates in males than in females, and delayed mating in males, mating is polygynous. The average adult sex ratio is about 9 females per male, but it may increase to 60:1 when males are killed for pelts.

Females have the highest pregnancy rates between ages 8 and 13 years, with rates sometimes exceeding 93% of an age class. Females can produce offspring yearly to about age 22 years, although few survive to that age. Contrary to sexual selection theory, older, larger females do not preferentially give birth to male pups, but larger mothers give birth to larger pups. Twinning is rare. For unknown reasons, females in the Commander Islands population have their first pup on average a year younger than females in the Pribilof population.

Females usually enter estrus and mate about 5.3 days after parturition. About 85% of the females have only a single copulation per estrus; the other 15% have no more than two. The reason for this low number of copulations is that the physical act of coitus terminates receptivity. Males can trigger the onset of estrus by interacting with females (the Whitten effect). However, if no male is present, females enter estrus spontaneously and become nonreceptive again after about 36 hr if they fail to copulate. No second estrus occurs that year.

Sexually receptive females mate indiscriminately with any male that approaches them. When no adult males are present (as in captivity), females will mate with a male of any size or age, and they adopt a stereotyped posture indicating sexual receptivity when touched in the pelvic area by humans, other females, or even their pups. Most matings are between adult males and females not because females reject juvenile males, but because adult males exclude them from the breeding areas. In contrast to females, males may mate 115 times or more per year, depending on their size and the location of their territory. The reproductive life span of males averages 1.5 seasons, significantly shorter than for females. Ten seasons is the maximum territorial occupancy recorded for any male northern fur seal.

III. Mating System

Males partition the pupping areas used by females into spaces called territories. They defend the boundaries of these territories (not the females therein) using mainly vocal and postural threats and rarely fighting. Males arrive on territory about 1 month before the females and spend their time maintaining boundaries and fasting. Fasts last on average 38 to 42 days for the population, but uninterrupted fasts of 80 days have been recorded for individuals. Throughout the main breeding season (July), males spend most of their time interacting with females and mating. Each male has exclusive reproductive access to all females in his territory. They abandon their territory in late July and are replaced by large subadult males that perform perhaps 20% of the year's copulations, including with all the virgin females that arrive after pupping has ended. Males are highly specific in the area they will defend, maintaining at least some of the same boundaries from year to year. Very few defend a

territory that is more than 10 m distant from the previous year's territory. Males will persist in defending a territory from year to year even if it contains few females.

Females arrive usually 1 day before parturition occurs. They select a parturition site without apparent regard to the male that defends that site. Most births occur at night. Females remain with the pup in one location and defend it from other females until estrus and mating occur. Usually 1–24 hr after mating they depart on the first of a series of foraging trips. When they return they locate their pups by vocal exchanges and probably smell. Females will not suckle any pup but their own. Orphans and starvelings sneak-suckle, but are often bitten and tend to die of wounds and infection.

Females use the same parturition site from year to year to the greatest extent possible given the number of females on land, date, and other factors. Females prefer the company of other females. They are reluctant to be the sole female in a male's territory probably because such males bite females to keep them from moving. By living in a group, females reduce the number of male/female contacts and thus reduce the risk of injury. Females will abandon a favored birthing site if reaching it means being along in a territory with an adult male.

Despite seeking the close company of others, females are quite aggressive toward near neighbors. They bite and frequently threaten females around themselves, generally do not allow others to lie in full body contact (like sea lions do), and appear to lack identifiable social bonds with any other female. Females are therefore gregarious but not social. This combination allows each animal to enter and leave the aggregation without loss of social status in the usual sense of the term. The largest females win contests over resting sites, but there is no evidence of a stable social hierarchy based on individual identity.

Active female mate choice is not apparent. Females mate at nearly the same site for many years whereas the male defending that site as part of his territory (and having sexual access to all females on it) changes on average every 1.45 seasons. That is, females do not move around in an apparent attempt to find the highest ranking, most fit male. Furthermore, as stated earlier, females appear unable to discriminate high and low ranking males (or even their own species) when they are receptive. Females mate with the most fit males in the population, but by a more indirect means than individual choice. By arriving predictably at a given location and time of year and not deviating from this pattern, females become a predictable resource over which males compete. The winners of this competition remain as potential mates. Females thus indirectly acquire as potential mates the class of males that is highest ranking, but they accomplish this without having made a choice among individual males. This appears to explain why females are uniformly receptive to all males when they are in estrus.

IV. Foraging Behavior

Many aspects of foraging, such as duration of trips to sea, vary according to the local foraging environment. For example, trips to sea are shorter at the Commander Islands, which have a narrow continental shelf, than at the Pribilof Islands, which have a wide shelf. Some aspects of foraging behavior, such as the duration of trips to sea, depth of dives, number of dives per day, and others, change seasonally in response to changes in the behavior of prey and the energy needs of the pup. Other aspects of foraging behavior, such as the duration of the deepest dives and the recovery times from these dives, do not change seasonally and may be determined physiologically. Females tend to specialize in one of three types of dive patterns [shallow (<50 m maximum), deep (100–200 m maximum), and mixed (a combination of the other two)] and to use the same pattern for several years. Furthermore, they tend to feed at about the same location on different trips to sea. Deep dives occur on the shelf and apparently represent feeding near or at the bottom. Shallow divers change depth at dawn and dusk, suggesting that the prey are migrating vertically. Females using the deep and shallow dive patterns have different fatty acids in their blubber, indicating that different prey bases are being exploited.

V. Ontogeny

As in other pinnipeds, the young of northern fur seals are precocial. They can swim on the day of birth but do not voluntarily do so until they are a month old. While their mothers are away foraging, pups withdraw to unoccupied parts of the breeding grounds to avoid being bitten by adult females. There they join other pups in dense "pods" where they sleep and play until their mothers return. Because adult males actively avoid trampling pups, the pups are actually safer from the much larger males than they are from adult females. Intentional infanticide by adult males is unknown in this species. Newborn pups can perform many of the components of adult behavior. For example, a 5-day old male pup can mount a female correctly and make coordinated, pelvic thrusting motions without ever having observed mating BEHAVIOR in adult males.

About 10% of pups die on shore before weaning. Starvation, trauma, hookworm, and several infectious diseases account for most of the deaths.

Males are on average 0.6 kg heavier than females at birth and remain larger until weaning. The growth rate during suckling is slow (1.1–1.3% of maternal mass per day) compared to phocids. The reason is that unlike phocids, northern fur seal pups fast each time their mothers are way foraging, and maintenance metabolism is costly given the cold temperatures, wind, and rain that the pups face. Pups are weaned at about 40% of adult female mass. Most pups wean themselves and depart from land before their mothers.

The migratory pathways, distribution, diet, and behavior of pups at sea are largely unknown because they are small and difficult to instrument and recapture. It is known that they migrate through Aleutian passes into the North Pacific Ocean in November of their birth year and that some of them are seen on the coasts of Washington, British Columbia, and Japan by the following January. Pups return to land during the summer of their second or third year, usually to the island of their birth. Juvenile females usually land on the breeding grounds, but juvenile males are excluded from these areas by adult males and instead come ashore on nearby all-male landing areas. They remain around the breeding island for 80 days or so, during

which time they make periodic feeding trips to sea, visit all the landing areas available, and spend time in play bouts where they perfect the movement patterns used in fighting. Many juvenile males makes brief incursions onto the breeding grounds where they visit sites that some of them will later defend as territories, which suggests philopatry. The landing areas used by juvenile males were the sites where sealers used to stage the kill for pelts. Despite the fact that killing occurred on some of these sites weekly during the breeding seasons for over two centuries, fur seals did not learn to avoid them.

VI. Physiology

The northern fur seal reduces heat loss to cold ocean waters by means of dense underfur that traps small air bubbles. This fur stays dry even when in water. While at sea, and especially after deep dives, fur seals spend long periods grooming the fur and restoring its air content. The variable part of their thermoregulatory system is their naked rear flippers, which are the longest and thinnest of any pinniped. To reduce heat loss to cold water they hold one front flipper and both rear flippers in the air, often in an arch or "jug handle." To increase heat loss on land in warm weather they fan their rear flippers, keep them damp, or pant. The fur is such an effective insulator that snow falling on sleeping animals does not melt or make the animals shiver.

Fur seals are apneustic breathers, meaning they hold their breath on inspiration even in their sleep. This type of breathing is the rule in diving mammals. The longest dive northern fur seals can make without resorting to anaerobic metabolic pathways is about 3.7 min for a 45-kg female. They require about 20 min to recover from such a dive. During the dive their heart rate decreases dramatically as in other diving mammals. While SWIMMING at high speed northern fur seals often leap free of the water to breath, thus making a "porpoising" motion.

Both vision and hearing are highly effective in air and underwater. In bright light their pupil closes to a small pinhole showing a brown iris. In dim light the pupil opens wide to gather more light. An open pupil and a reflective layer in the retina contribute to good visual acuity in dim light where most feeding occurs. The reflective layer is visible as an "eye shine" if a light is trained on animals at night.

North Pacific Marine Mammals

SERGIO ESCORZA-TREVIÑO
Southwest Fisheries Science Center, La Jolla, California

I. North Pacific Marine and Freshwater Biomes

The vastness and diversity of the North Pacific Ocean are reflected in the richness of its marine mammal community. Sixteen of the world's 36 species of pinnipeds, 50 of the 85 species of cetaceans, and 2 of the 5 species of sirenians have been reported to occur in the North Pacific, in addition to the polar bear (*Ursus maritimus*) and the sea otter (*Enhydra lutris*). Most of these species are also found in other parts of the world, as is the case of most balaenids and delphinids, many ziphiids, and some otariids, phocids, and phocoenids. However, a large proportion of the species found in the North Pacific are endemic to its marine or riverine ecosystems: 9 pinnipeds, 10 cetaceans, 1 sirenian, and the sea otter.

The North Pacific Ocean ranges from about 80°W to 130°E, covering about 60% of the earth's circumference, and from the Arctic Ocean to the Equator (Fig. 1). The North Pacific encompasses a great number of peripheral basins, as different as the highly evaporative and relatively small Gulf of California (also known as Sea of Cortés) in the east, the large and epicontinental Bering Sea in the north, or the complex region of small, semienclosed seas and shallow shelves around the Indo-Pacific Archipelago in the west, where the Pacific and the Indian oceans meet. In addition, a number of large, complex river systems exist that extend thousands of kilometers upstream, as is the case of the Yangtze River in China.

The geographic DISTRIBUTION of mammal species in the ocean depends on a number of factors, among which temperature, depth, and productivity tend to be the most important. Some species, such as the killer whale (*Orcinus orca*) or the sperm whale (*Physeter macrocephalus*), are considered cosmopolitan. Others, like the vaquita (*Phocoena sinus*) or the now extinct Steller's sea cow (*Hydrodamalis gigas*), have or had very limited ranges. Many species are circumglobal but limited to particular climatic zones. For example, some species are pantropical, inhabiting low-latitude waters in all the world oceans, whereas others have antitropical (or bipolar) distributions. Species such as the ringed seal (*Pusa hispida*) and polar bear have been sighted as far north as the North Pole. Others can range hundreds of kilometers up the great rivers of both sides of the Pacific Ocean, either permanently or on a seasonal basis.

The North Pacific is dominated by a large subtropical gyre (Fig. 1). This North Pacific central gyre flows clockwise, bounded to the west by the Kuroshio Current, to the north by the North Pacific Current, to the east by the California Current, and along the south by the North Equatorial Current. To the north of the

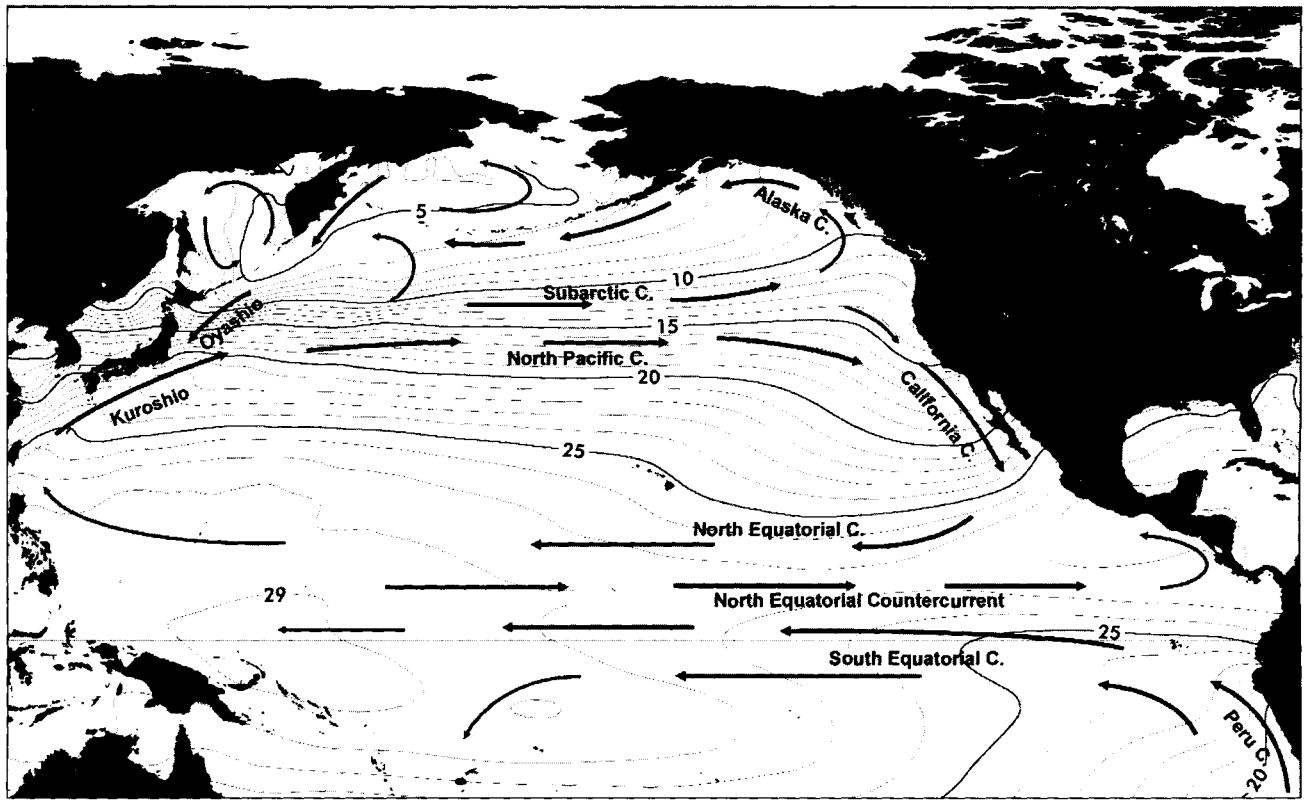

Figure 1 *Annual mean surface temperatures and principal currents of the North Pacific Ocean (graphic by Paul Fiedler).*

North Pacific central gyre, the cold Oyashio Current flows along the Kamchatka Peninsula and forms the western boundary of a counterclockwise subarctic gyre. The Alaska Current flows counterclockwise along the southeastern coast of Alaska and the Aleutian Peninsula. The convergence zone of these subarctic gyres and the central gyre, known as the Subarctic Boundary, crosses the western and central North Pacific at about 42°N and marks the steepest change in the abundance of cold-water vs warm-water species. To the south of the central gyre, the equatorial current system consists of the North Equatorial Countercurrent between the North and the South Equatorial Currents.

An important differentiating characteristic between the Pacific and other ocean basins is the strong effects of El Niño—Southern Oscillation (ENSO) events. Two distinct modes of Pacific circulation exist, depending on the variability of trade winds stress. When the trade winds weaken and are replaced by westerlies at low latitudes in the western Pacific (an ENSO event), the entire heat balance at low latitudes is perturbed, a situation that can last from a few months to 1 or 2 years. When this occurs, the major oceanographic features usually found in the eastern tropical Pacific can weaken or even disappear completely, resulting in atypical distributions for many marine mammal species.

II. Marine Mammals of Cold Water Marine Ecosystems

Most of the endemic species of marine mammals in the North Pacific Ocean inhabit its cold temperate, subarctic, or arctic waters (Table I). Among the pinnipeds, in the family Otariidae, we can find several of these endemic species. In fact, of the seven species of otariids present in the North Pacific, five are endemic to the North Pacific, whereas the other two, because they are present in the Galapagos archipelago, are also represented in the South Pacific. The Guadalupe fur seal (*Arctocephalus townsendi*) now breeds only on Guadalupe Island, off Baja California. The northern fur seal (*Callorhinus ursinus*) is a pelagic species that ranges from the Sea of Okhotsk and southern Bering Sea to the Sea of Japan and northern Baja California. The California sea lion (*Zalophus californianus*) includes two geographical divisions: one on the Pacific coast and one in the Gulf of California. Some animals have also been sighted on both sides of the Atlantic, but represent escapees from captive facilities. Along the western side of the Pacific, the Japanese sea lion (*Zalophus japonicus*) is, very probably, extinct. The last confirmed sighting took place 50 years ago. The Steller sea lion (*Eumetopias jubatus*) inhabits the coastal and immediate offshore waters of the cool temperate North Pacific.

Of the eight species of phocids (seals) present in the North Pacific Ocean, four are endemic: the spotted seal (*Phoca largha*), the ribbon seal (*Histriophoca fasciata*), the Hawaiian monk seal (*Monachus schauinslandi*), and the northern elephant seal (*Mirounga angustirostris*). The former two inhabit the pack ice zone of the arctic North Pacific, although the ribbon seal becomes pelagic during the summer. The Hawaiian monk seal, which probably represents the most primitive of the living phocids, inhabits the northwestern chain of the Hawaiian Islands,

[a]Endemic species are shown in bold.

whereas the northern elephant seal, whose population numbers once dwindled down to a few tens, ranges throughout the northeastern Pacific, from the Aleutian Islands to the Gulf of California. Other seals present in the North Pacific are the bearded seal (*Erignatus barbatus*) and the ringed seal (*Pusa hispida*), which are both arctic species, the harbor seal (*Phoca vitulina*), whose range extends from the Bering Sea to Baja California, and the hooded seal (*Cystophora cristata*), present only as a rare vagrant into the Beaufort Sea and Bering Sea and even to southern California. The only living species of the family Odobenidae, the walrus (*Odobenus rosmarus*), also inhabits the arctic North Pacific.

There are many cetacean species present in the higher latitudes of the North Pacific. Among the Mysticeti, three families are found. The balaenids are represented by both the bowhead whale (*Balaena mysticetus*), which inhabits the pack ice zone of the Arctic, and the migrant and endemic North Pacific right whale (*Eubalaena japonica*), whose range extends from the Bering Sea to California in the east and Taiwan in the west. The only living representative of the family Eschrichtiidae, the gray whale (*Eschrichtius robustus*), occurs only in the North Pacific, as the North Atlantic populations are extinct. At present, the western, or "Korean," gray whale population is in very low numbers, whereas the eastern, or "California," population is considered to have fully recovered from past exploitation and ranges from subarctic waters to Baja California. Five species of rorquals are found in the cold waters of the North Pacific. The humpback whale (*Megaptera novaeangliae*) inhabits all the oceans of the world, from high-latitude summer FEEDING grounds to tropical winter grounds. The sei whale (*Balaenoptera borealis*) is also present in all oceans, but in more temperate waters than other rorquals. The common minke whale (*Balaenoptera acutorostrata*) can be found from the Chukchi Sea almost to the equator. The blue whale (*Balaenoptera musculus*) lives almost everywhere in the world, from the tropics to the arctic pack ice. The fin whale (*Balaenoptera physalus*), also almost worldwide in distribution, can be sighted in the North Pacific from the Okhotsk Sea, Bering Sea, and Chukchi Sea to Taiwan, Hawaii, and Baja California (including the Gulf of California).

The cosmopolitan sperm whale is present from the equator to the edges of the pack ice. The ranges of the two species of

the family Kogiidae are somewhat smaller, but they are present in temperate and tropical waters around the world. The pygmy sperm whale (*Kogia breviceps*) inhabits oceanic waters, whereas the dwarf sperm whale (*Kogia sima*) lives over the continental shelf and slopes.

The family Ziphiidae is well represented in the North Pacific. Cuvier's beaked whale (*Ziphius cavirostris*) lives in all temperate and tropical waters around the world, whereas the North Pacific bottlenose whale (*Berardius bairdii*) is an endemic species, present only in the temperate and subarctic North Pacific. Also endemic are Hubbs' beaked whale (*Mesoplodon carlhubbsi*), in temperate waters, and the saber-toothed whale (*Mesoplodon stejnegeri*), which ranges from subarctic waters to the cold temperate North Pacific. The pygmy beaked whale (*Mesoplodon peruvianus*) is a recently discovered species, known only from the Gulf of California and Peru. Hector's beaked whale (*Mesoplodon hectori*), although considered to be circumglobal in the temperate waters of the Southern Hemisphere, can also be regarded as a North Pacific marine mammal because individuals have stranded and been sighted off southern California (although recent genetic analyses suggest that these may have been of a different, undescribed species).

Both members of the family Monodontidae are also present in the North Pacific Ocean. The beluga (*Delphinapterus leucas*) inhabits the Arctic Sea and spreads into its adjacent seas, mainly in shallow shelf waters. The narwhal (*Monodon monoceros*) is present as a vagrant in the Chukchi Sea and Bering Sea.

Several delphinids found in the cold North Pacific are widespread species that mainly inhabit warm waters and are discussed in the next section. In addition, the cosmopolitan killer whale is present from equatorial regions to the polar pack ice. The long-finned pilot whale (*Globicephala melas*) represents a special case. This species is bipolar in temperate waters and, although it is common in the North Atlantic, there are no historical records of living animals in the North Pacific. However, skulls were recovered at two archeological sites in Japan, in areas now occupied by the short-finned pilot whale (*G. macrorhynchus*). Two other species present in this area are endemic to the North Pacific: the northern right-whale dolphin (*Lissodelphis borealis*), in subarctic and temperate waters, and the Pacific white-sided dolphin (*Lagenorhynchus obliquidens*) (Fig. 2), also in cool temperate areas. Other species of *Lagenorhynchus* occupy this same niche in the North Atlantic and Southern Hemisphere. However, studies have indicated that the genus might be polyphyletic, and the Pacific white-sided dolphin might indeed represent a different genus. If this were indeed the case, the correct scientific name for the Pacific white-sided dolphin would be *Sagmatias obliquidens*.

Four species of porpoises are present in the North Pacific. Dall's porpoise (*Phocoenoides dalli*) is endemic to the cold temperate waters of North Pacific. The recently discovered and critically endangered vaquita (*Phocoena sinus*), with only a few hundred individuals left, is endemic to the northern Gulf of California. Its closest relative (Burmeister's porpoise, *Phocoena spinipinnis*), curiously, does not live in the North Pacific, but in southern latitudes, indicating that the vaquita evolved independently in the Gulf of California when it became trapped there after crossing the equator during the last cooling period. The other two species present are the harbor porpoise (*Phocoena phocoena*), restricted to shallow coastal temperate waters, and the finless porpoise (*Neophocaena phocaenoides*), which inhabits coastal waters along the mainland of southern and southeastern Asia and Japan, as well as living up the Yangtze River system, up to 1600 km inland.

A member of the order Sirenia, the only herbivorous marine mammals, used to be present in the cold waters of the

Figure 2 *The Pacific white-sided dolphin* (Lagenorhynchus obliquidens), *thought closely related to a North Atlantic congener, may be a separate lineage and deserve a different genus name. Evidence on either side of this question can be interpreted in different ways. This dolphin is pelagic, is found in large herds, and occurs in colder waters of the Northern Pacific. Photo courtesy of NMFS.*

North Pacific. The Steller's sea cow, endemic to shallow subarctic waters of this ocean, has been extinct since 1768. Hopes for the survival of the species went up briefly in 1962, but the alleged sighting has been discredited.

Two other marine mammals in the North Pacific do not belong to the "traditional" marine mammal groups. One is the sea otter, which is endemic to the North Pacific and inhabits the cold temperate and subarctic zones. This species dipped to near EXTINCTION at the end of the 19th century and beginning of the 20th century. The other is the polar bear, which inhabits the pack ice regions of the Arctic Ocean and contiguous seas and adjacent coastal areas.

III. Marine Mammals of Warm Water Marine Ecosystems

The marine mammals that inhabit these ecosystems tend to be also present south of the equator, or even in other oceans. Among the otariids, two Pacific species occur only in tropical waters. The Galapagos sea lion (*Zalophus wollebaeki*) was originally confined to this archipelago, but a small rookery now exists on La Plata Island (01°S), which is why the species cannot be considered endemic to the North Pacific. The Galapagos fur seal (*Arctocephalus galapagoensis*) is also endemic to this equatorial archipelago.

Many of the cetaceans present in warm waters are widespread species, with wide latitudinal ranges, and have already been referred to in the previous section (Table I). This is the case of most rorquals, except for Bryde's whale (*Balaenoptera brydei*), which prefers tropical and warm temperate waters, and the small-type or pygmy Bryde's whale (*Balaenoptera edeni*), which lives in coastal and shelf waters of the eastern Indian Ocean and the western Pacific. Among the ziphiids, some are found exclusively in warm water. Such is the case of the gingko-toothed whale (*Mesoplodon ginkgodens*), which lives in tropical and warm temperate areas of the Indian and Pacific Oceans, and Blainville's beaked whale (*Mesoplodon densirostris*), also with a tropical and warm temperate distribution, but around the world. Most beaked whales, especially the genus *Mesoplodon*, are rarely spotted at sea and, even when they are, their identification is extremely difficult. It is very probable that some species have not been described yet. One such undescribed species of *Mesoplodon* has been sighted in the eastern tropical Pacific (*Mesoplodon* sp. A), and it is possible that large unidentified "tropical bottlenose whales" seen in the tropical Indian and Pacific Oceans are indeed Longman's beaked whales (*Indopacetus pacificus*), although this will remain a mystery until specimens are collected.

In addition to the widespread delphinids mentioned in the Section II, several species typically found in warm waters can also range into temperate waters. Probably the most familiar is the common bottlenose dolphin (*Tursiops truncatus*), which is present in temperate and tropical zones of all oceans. The species usually inhabits coastal areas and shallow offshore banks, although there are pelagic populations that live far offshore. The type specimen of the Indian Ocean bottlenose dolphin (*Tursiops aduncus*) comes from the Red Sea, but some *aduncus*-like *Tursiops* have been recorded from the western Northern Pacific (Taiwan). The striped dolphin (*Stenella coeruleoalba*) is also found worldwide in temperate and tropical waters, as are Risso's dolphin (*Grampus griseus*) and the false killer whale (*Pseudorca crassidens*). Other species are characteristic of the tropical and warm temperate waters around the world and thus are also found in the North Pacific. Such is the case of the rough-toothed dolphin (*Steno bredanensis*), the pantropical spotted dolphin (*Stenella attenuata*), the spinner dolphin (*Stenella longirostris*), Fraser's dolphin (*Lagenodelphis hosei*), the melon-headed whale (*Peponocephala electra*), the pygmy killer whale (*Feresa attenuata*), and the short-finned pilot whale (*Globicephala macrorhynchus*). Both the short-beaked common dolphin (*Delphinus delphis*) and the long-beaked common dolphin (*Delphinus capensis*) (Fig. 3) inhabit tropical and warm temperate waters worldwide. However, while the former lives offshore, the latter is a coastal species. The Pacific hump-backed dolphin (*Sousa chinensis*) is distributed discontinuously in coastal waters of the western Pacific, as well as river basins. It is also present in the southern Pacific.

The dugong (*Dugong dugon*), the only sirenian found in warm North Pacific waters, has a widespread but discontinuous range along the continental coasts among the islands of the Indian and western Pacific oceans.

IV. Aquatic Mammals of River Ecosystems

The river basins, systems, and their mouths in southeastern Asia provide a unique habitat for several cetacean species (Table I). The most important hydrographic system for marine mammals is the Yangtze River, and several species can be found here. The baiji (*Lipotes vexillifer*) lives exclusively in fresh water and is endemic to this basin, from its estuary upstream for 1600 km. The Pacific hump-backed dolphin (*Sousa chinensis*) can ascend as far as 1200 km up this river system as well. The finless porpoise (*Neophocaena phocaenoides*) inhabits the coastal waters along the mainland of southern and southeast-

Figure 3 *The long-beaked common dolphin* (Delphinus capensis) *inhabits the North Pacific but is also found in disjunct populations in other warm waters around the world. The short-beaked common dolphin* (D. delphis) *is smaller. Common dolphins were not distinguished as separate species until the mid-1990s. Photo by R. S. Wells, Chicago Zoological Society.*

ern Asia and Japan and also ranges into the middle and lower reaches of the Yangtze River and its tributaries. Finally, the Irrawaddy dolphin (*Orcaella brevirostris*) is distributed discontinuously in shallow and murky waters at the mouth of rivers around the Asian mainland and Australia, as well as in river systems, such as the Mekong.

V. Conservation Issues

The problems faced by North Pacific marine mammals are common to marine mammals in other areas of the world: pollution, habitat degradation, fishery interactions, directed takes, and lack of sufficient resources for successful protection and MANAGEMENT. Although the hunting of marine mammals for oil, meat, or fur has been largely reduced by international agreements, some species are still targeted. The active harpoon fishery for the North Pacific endemic Dall's porpoise is still active and causes the largest fishery-related mortality for any cetacean species in the world. A large number of animals from several species are taken incidentally each year by net ENTANGLEMENTS, fishery bycatch, or boat strikes. Two North Pacific marine mammal species have been driven to extinction by humans in the recent past: the Japanese sea lion and the Steller's sea cow. Several other North Pacific species are dangerously close to following in their wake, as is the case for the vaquita, the baiji, the western population of the gray whale, and the North Pacific right whale. However, the recovery of other North Pacific species gives us reason for hope. The northern elephant seal, driven down to a few tens of individuals by hunting in the early 1900s, now numbers in the tens of thousands. The eastern gray whale, whose current population size is similar to its preexploitation stock size, was taken off the U.S. endangered species list in 1995. With continued protection, two species that once faced extinction are now showing positive signs of recovery: the sea otter and the Guadalupe fur seal. Because of their mobility and vast geographic ranges, the distributions of most marine mammal species extend across borders and international waters. For these reasons, effective management and conservation strategies depend greatly on international agreements that coordinate objectives and efforts.

Ocean Environment

PAUL C. FIEDLER
Southwest Fisheries Science Center, La Jolla, California

Marine mammals live, feed, and reproduce in a vast, three-dimensional fluid environment—the ocean. Air breathing necessitates frequent attendance to the sea surface for all marine mammals, while pinnipeds cannot reproduce in the water and have thus retained a close tie to land or ice. Despite these ties to the boundaries of the ocean environment, oceanography is an important part of the study of marine mammals. Habitat and distribution of marine mammals are affected by the physical and chemical properties of the water through which they swim and communicate, the topography of the ocean bottom where they feed, the physical state of the ocean surface where they breathe and haul out, and numerous factors influencing the distribution of food organisms.

I. Surface Temperature, Salinity

Temperature at the earth and ocean surface generally decreases from the equator to the poles (Fig. 1), but local processes complicate this simple pattern. Upwelling brings cold water to the surface along the equator and along eastern boundaries between oceans and continents. Ocean currents move cold water equatorward along these eastern boundaries and warm water poleward along western boundaries.

Salinity of the surface waters of the open ocean varies between 32 practical salinity units (psu) in the subarctic Pacific and 37 psu in subtropical gyres. This variation affects the density of seawater and thus the distribution of mass and the resulting thermohaline circulation. Salinity variations over this range have little or no physiological effect on marine mammals, but can influence the availability of food organisms through effects on stratification and circulation. At the coastal and polar limits of the ocean and in marginal seas, processes such as local precipitation and evaporation, river runoff, and ice formation can result in salinities less than 10 and greater than 40 psu. Marine mammals have adapted to tolerate even these extremes.

II. Surface Currents, Winds

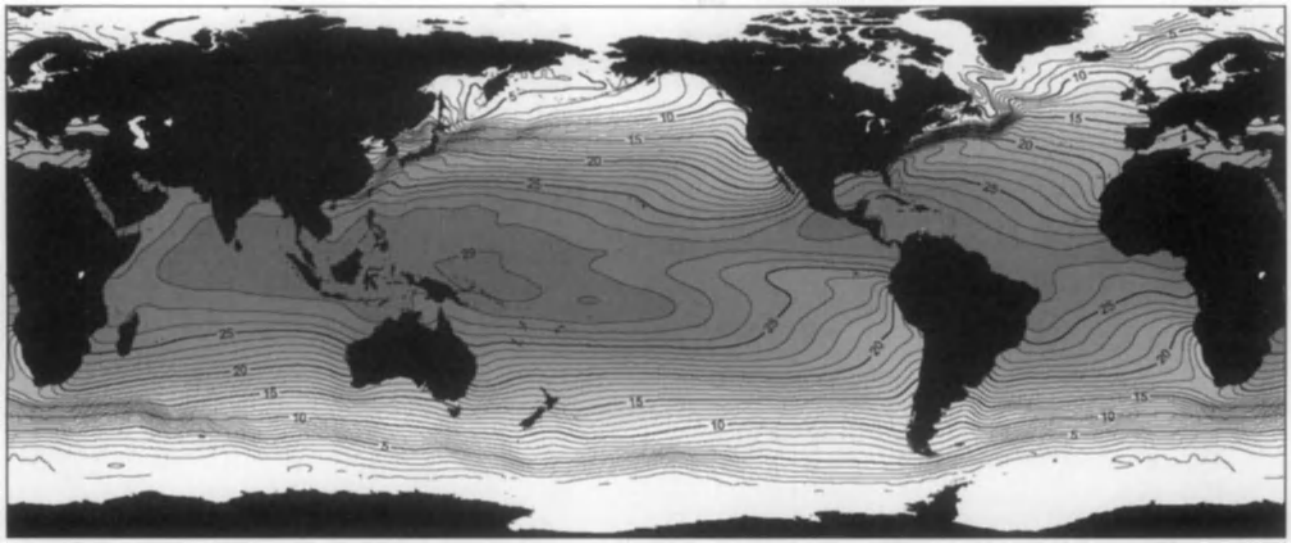
Surface waters of the ocean are constantly in motion due to waves, tides, and currents. Currents move water across ocean basins and thus alter the distribution of temperature, salinity, and, indirectly, food organisms. Ocean currents are driven by energy from the sun, both by changes in the distribution of mass due to heating and cooling and by wind forcing at the surface. The distribution of solar radiation and rotation of the earth set up a basic pattern of winds consisting of (1) easterly trade winds over low latitudes, (2) westerlies over midlatitudes, and (3) polar easterlies. Heating and cooling of land masses and the seasonal cycle of solar energy input alter this basic pattern.

The surface circulation of most of the area of the world's oceans consists of subtropical gyres, which move anticyclonically (Fig. 2). Equatorial currents move from east to west, western boundary currents (Gulf Stream, Kuroshio) move warm water from near the equator toward the poles, eastward currents (Antarctic Circumpolar, North Pacific) move water back across the oceans on the poleward side of the gyres, and eastern boundary currents (California, Peru, Canary, Benguela) move cold water toward the equator.

The strength of these currents varies seasonally. Eastern and western boundary currents spin off eddies, on the order of 100 km in diameter, which move both water and prey organisms and alter the distribution of favorable habitat for marine mammals. Eastern boundary currents are sites of seasonal coastal upwelling, when equatorward winds move surface water offshore and deep nutrient-rich water is brought to the surface. Westward equatorial currents are also sites of upwelling, due to divergence of surface water caused by the rotation of the earth.

III. Vertical Structure

Physical (and biological) variability in the ocean environment is generally much greater in the vertical than in the horizontal dimension. Water temperature may be nearly constant for a few meters or tens of meters below the surface in the mixed layer but then decreases rapidly with depth in the thermocline. Vertical changes in salinity may contribute to this



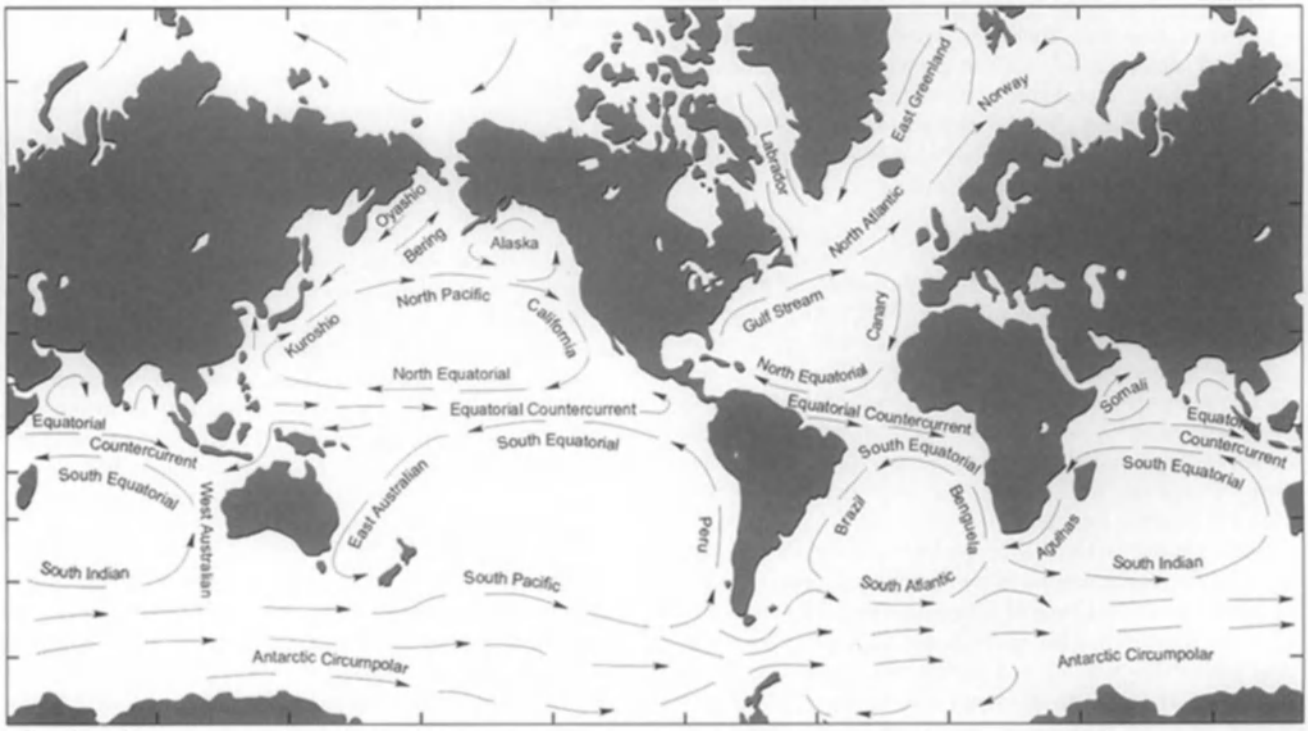


Figure 1 *Mean sea surface temperature (°C).*

stratification, especially in polar seas. Stratification influences productivity because deeper, colder water has higher nutrient concentrations than the warmer water near the surface. Stratification also influences the distribution of food organisms.

IV. Productivity

Biological productivity is the rate of production of living matter; oceanographers often speak of "production," which is the variable standing stock of living organisms and is closely linked to productivity. Primary productivity in the ocean is the rate of production of plants (phytoplankton) and is often limited by light and nutrient availability, both of which are controlled by physical oceanographic processes. Light intensity at the sea surface varies with latitude and time of year, as well as time of day. Thus, photosynthesis occurs in polar seas only during summer. Light intensity decreases rapidly with depth, so

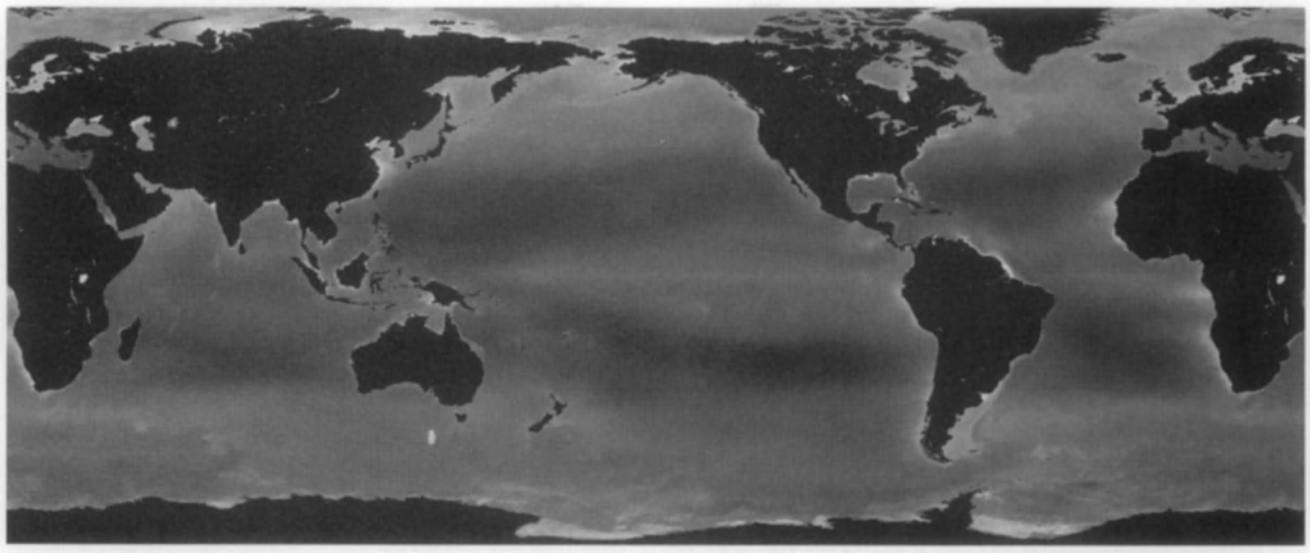

Figure 3 *Mean phytoplankton pigment concentration from SeaWiFS satellite data, 1998–1999, increasing from darker to lighter grays; uniform light gray near the poles indicates missing data.*

that photosynthesis is possible within only a few meters or tens of meters of the sea surface (Fig. 3).

Plant growth also requires nutrients (nitrate, phosphate, and, for some phytoplankton, silicate). The importance of micronutrients—notably iron—in some regions of the open ocean, such as the Southern Ocean around Antarctica where many baleen whales feed, has been recognized in recent years. Nutrient availability is affected by oceanographic processes including stratification, wind and tidal mixing, circulation, and upwelling.

Marine mammals consume zooplankton, fish, squid, and even other marine mammals. Therefore, distribution and foraging are not directly determined by primary production. Food chains involving marine mammals are as short as diatoms–krill–baleen whales. Sperm whales (*Physeter macrocephalus*), however, consume large deep-living squid and are at least four steps removed from primary production at the sea surface.

V. Ice

Ice is an important component of the habitat of migratory and endemic marine mammals in both the Arctic and the Southern Ocean. Ice cover varies seasonally with temperature and is also subject to the influence of winds and currents. There must be some open water in any ice-covered habitat utilized by marine mammals to allow access to both air and food. Ice on the sea surface is found in a variety of types (pack ice, icebergs, shore ice, fast ice, drift ice, new ice) and forms (small floes, brash ice, pancake ice, etc.).

Sea ice in the Arctic is tightly packed except at the ice edge. Much of the Arctic Ocean is permanently ice covered. The Antarctic has a broad zone of looser pack ice with many internal leads. Most of this ice melts during summer. Polynyas are areas within the pack ice that are almost always clear of ice. Providing both access to the water and locally enhanced productivity, they are relatively more important in the Arctic than in the Antarctic.

VI. Temporal Variability

The ocean environment varies seasonally, especially at higher latitudes where ice closes accessibility to most species during winter. Seasonal variability in wind-driven upwelling causes significant changes during the year even in the tropics. The ocean environment varies between years as well. The cycle in the ocean–atmosphere system known as the El Niño Southern Oscillation (ENSO) or simply "El Niño" causes major changes in the tropics every 3 to 5 years. Both seasonal and interannual variability occur in all marine mammal habitats. However, the relative magnitude of variability at each scale varies (Fig. 4).

Marine mammals have experienced climate change—variations in the ocean environment over periods of hundreds to thousands of years—throughout their evolutionary history. Concern is now focused on the possible effects of rapid global warming caused by mankind's input of excess carbon dioxide into the atmosphere. Scientists generally, although not universally, agree that by 2100 the global average temperature will increase by 1 to 3°C, the sea level will rise by several tens of centimeters, and sea ice coverage will be reduced. Changes in environmental variability on shorter time scales, such as the frequency or magnitude of El Niño events, the amplitude of seasonal cycles, or the frequency or intensity of storms, are possible. Regional changes in precipitation, circulation and upwelling, and UV-B (ultraviolet) radiation are expected.

VII. Effects on Life History and Function

Temperature can be a critical factor in the energy budget of warm-blooded mammals. However, marine mammals live and breed in the polar ice and even small, young harp seals (*Pagophilus groenlandicus*) are able to tolerate freezing temperatures. Some baleen whale species tend to be slightly larger in the cold Southern Ocean than in the warmer North Pacific. Adaptations, including an insulating BLUBBER layer and an ability to reduce

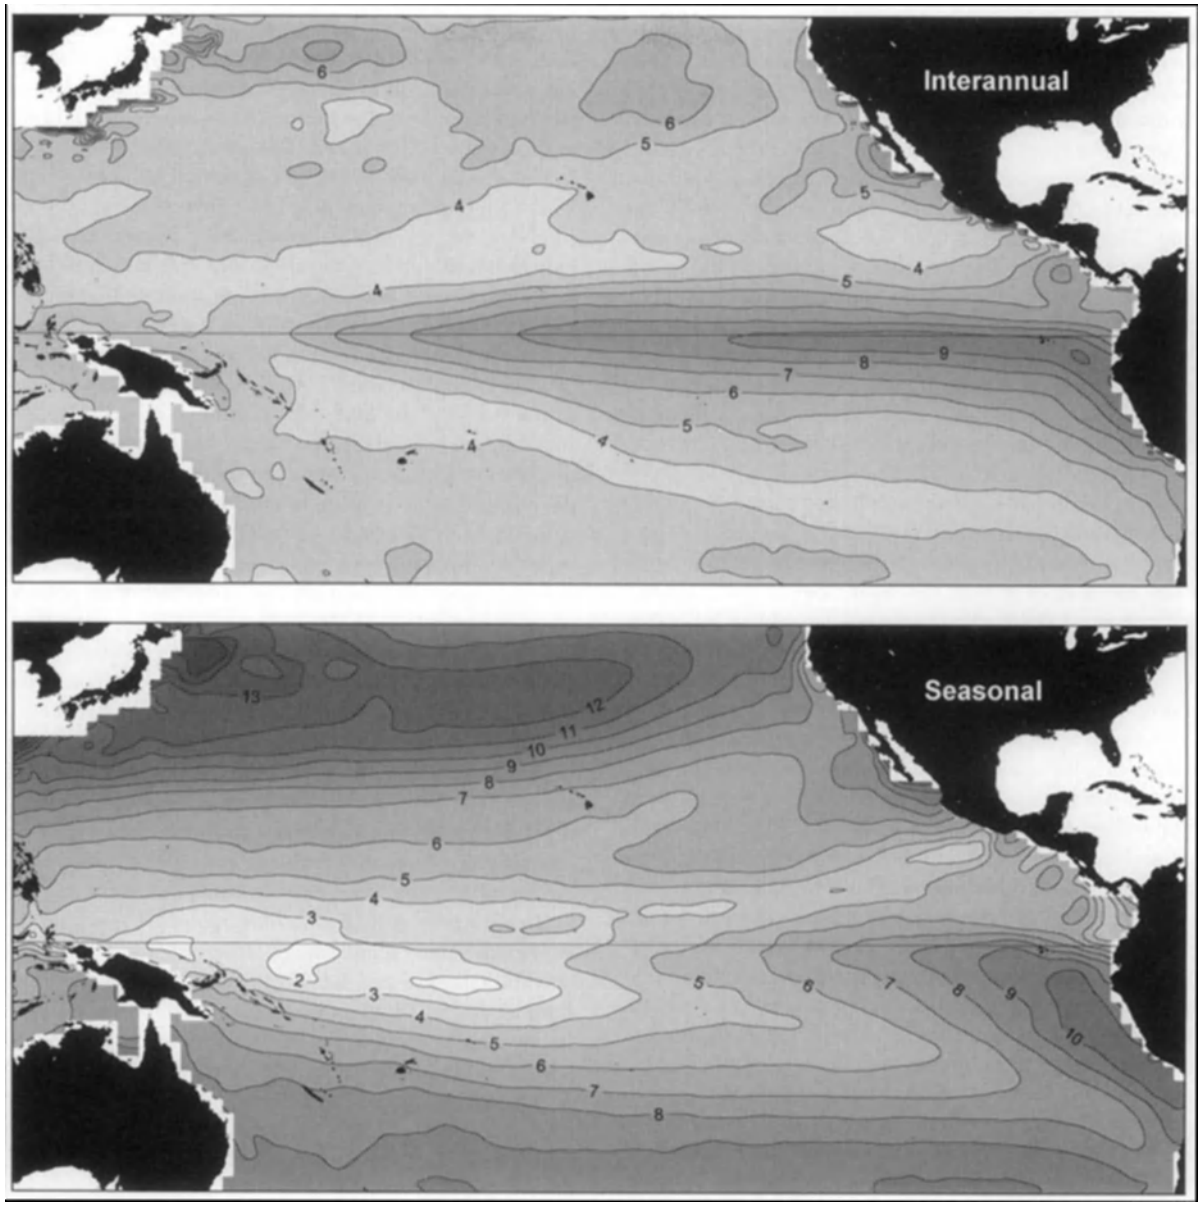

Figure 4 *Approximate interannual and seasonal ranges in sea surface temperature in the temperate and tropical Pacific in °C.*

blood circulation to peripheral parts of the body, have reduced the direct influence of temperature on distribution.

It has long been believed that large whales migrate from summer polar FEEDING grounds to warmer tropical breeding grounds because of adverse effects of low temperature on growth and survival of neonates. However, this hypothesis is no longer supported by considerations of energy intake, insulation by blubber, and heat loss. Even though the energy cost of migration may be very low for large whales, adult whales do not optimize their energy budget by migrating to warm tropical or temperate waters.

Cetaceans use underwater sound in several ways. Odontocetes use high-frequency sound to locate prey individuals and patches over short distances. Mysticetes use low-frequency signals for navigation and COMMUNICATION. While the effects of temperature, salinity, and pressure on the propagation of sound in water are well known, it is not known whether oceanographic variability can affect the use of sound by marine mammals. If blue and fin whales (*Balaenoptera musculus* and *B. physalus*) use the low-frequency sound channel of the deep ocean to acoustically "visualize" their environment, variations in water properties very likely distort or obscure the image they can obtain.

VIII. Effects on Feeding

Marine mammals are generally apex predators, or at the top of the food chain, although some of them are preyed on by killer whales (*Orcinus orca*) and leopard seals (*Hydrurga*

leptonyx). Because they are motile, social, and intelligent, they are able to take advantage of prey in locally dense patches. Like all aquatic and terrestrial predators, marine mammals cannot forage efficiently on average concentrations of prey. It has been shown that right whales (*Eubalaena* spp.) and humpback whales (*Megaptera novaeangliae*) require concentrations of prey that are more dense than the maximum densities observed by net sampling. This is an indication of the limitations of oceanographic sampling, as well as the paucity of prey in the ocean environment. Sampling by acoustic backscattering from echo sounders and by photography with tethered cameras has not revealed small patches of prey of the required densities.

Prey consumed by marine mammals include crustaceans (copepods, euphausiids or krill, amphipods, shrimp), cephalopods (squid), and schooling fish (herring, capelin, cod, mackerel, myctophids or lanternfish, and others). Availability of these prey in dense patches has been linked to oceanographic features, including bathymetry, fronts, eddies, and primary productivity. Except for bathymetry, these features or characteristics of the ocean environment vary over time.

Many baleen whales feed on dense patches of zooplankton or smaller fishes. The distribution of feeding North Atlantic right whales (*E. glacialis*) can be predicted by surface temperature and bathymetric variables, including depth and slope. These are the simplest oceanographic variables to measure, but they explain the distribution of whales only indirectly through effects on prey. Zooplankton patches are available in productive coastal waters, where upwelling and wind mixing results in high primary production, and in polar seas, where high primary productivity results from summer insolation and enhanced phytoplankton growth at the melting ice edge and even under the ice. The patches are often located at bathymetric features such as the shelf edge, islands, and seamounts, because bathymetry affects circulation and production and serves as a cue for aggregation of krill and fish. Blue whales feed on KRILL at the ice edge in the Antarctic, but also at the shelf edge off California (Fig. 5).

Along the northeast United States continental shelf, cetaceans tend to frequent distinct regions based on food preferences. Piscivores—humpback, fin, and minke (*B. acutorostrata*) whales and bottlenose (*Tursiops truncatus*), Atlantic white-sided (*Lagenorhynchus acutus*), and common dolphins (*Delphinus delphis*)—are most abundant over shallow banks in the western Gulf of Maine and midshelf east of Chesapeake Bay. Planktivores—right, blue, and sei (*B. borealis*) whales—are most abundant in the western Gulf of Maine and over the western and southern portions of Georges Bank. Teuthivores (squid eaters)—sperm and long-finned pilot (*Globicephala melas*) whales and Risso's dolphins (*Grampus griseus*)—are most abundant at the shelf edge. Most of these patterns can be related to the availability of specific prey. Right whales feed on dense patches of copepods in the vicinity of the Great South Channel. Humpbacks and fin whales feed on a small schooling fish, the American sand lance, which is very abundant on Stellwagen Bank and Jeffreys Ledge in the Gulf of Maine and is also abundant off Chesapeake Bay.

Cetaceans are distributed over distinct depth ranges along the continental slope in the northwestern Gulf of Mexico. Deep-diving teuthivores, such as Risso's dolphins, sperm whales, and beaked whales (*Ziphiidae*), are found near temperature fronts in deep water, where their squid prey may aggregate. Sperm whales are more abundant in regions of high zooplankton biomass and steep topography in the Pacific Ocean, where deep-diving squid are aggregated. Most of the 19th-century sperm whaling grounds in the Pacific were in regions of coastal or oceanic upwelling where primary production is high. However, the occurrence of some whaling grounds in unproductive waters, such as the region around Tahiti, and the absence of catches in productive waters, such as the California upwelling, indicate that other factors affect the availability of prey to whales and/or whales to whalers.

In the Antarctic, both Antarctic fur seals (*Arctocephalus gazella*) and minke whales (*Balaenoptera bonaerensis*) are found in the marginal ice zone, where primary productivity and, presumably, prey availability are enhanced. Winter pack ice extends out beyond the narrow Antarctic continental shelf and over the deep ocean. Minke whales, beaked whales, and several species of seals live in this ice and feed on krill (the euphausiid *Euphausia superba*), myctophid fish, and squid. As the pack ice retreats in summer, many of these winter residents and other predators, including large baleen whales, male sperm whales, and killer whales follow the ice edge to feed on abundant plankton and nekton. Right whales, feeding on smaller copepods not concentrated at the ice edge, remain in open waters north of the retreating ice.

Ice is an important habitat component for breeding and shelter of pinnipeds. Antarctic ice floes in the marginal ice zone are a refuge for fur seals (*Arctocephalus gazella*) from predation by killer whales. In contrast, crabeater seals (*Lobodon carcinophaga*), are found in the interior of the pack ice where larger, more stable floes provide BREEDING SITES.

In the Arctic, gray (*Eschrichtius robustus*), bowhead (*Balaena mysticetus*), and beluga whales (*Delphinapterus leucas*) migrate into the Chukchi and Beaufort Sea north of Alaska to feed in summer and fall. Bottom-feeding gray whales feed in shallow, ice-free waters; piscivorous belugas feed in deep water near the ice edge; and planktivorous bowhead whales feed closer to the coast where ice cover is less. These distribution differences are clearly related to prey availability. River plumes formed by summer runoff into the Arctic have been shown to limit the distribution of prey and thus determine the distribution of foraging whales.

IX. Effects on Distribution and Migration

The distribution of baleen whales on summer feeding grounds and movement on these feeding grounds are associated with oceanographic features, including fronts between water masses, eddies along these fronts, eddies caused by circulation around islands and capes, and oceanic and coastal upwelling. Prey availability is enhanced by nutrient input and enhanced primary production, or by convergence and aggregation of plankton. Japanese whalers have exploited concentrations of (1) sei whales off Japan where the warm Kuroshio current meets the cold Oyashio, (2) fin whales in a cold cyclonic eddy and in a mixing zone between cold coastal waters and warmer Bering Sea waters in the western subarctic Pacific, (3) fin whales at shelf edge fronts and upwelling zones off islands in the eastern Bering Sea, and (4) blue and fin whales at the polar front north of the Antarctic pack ice.

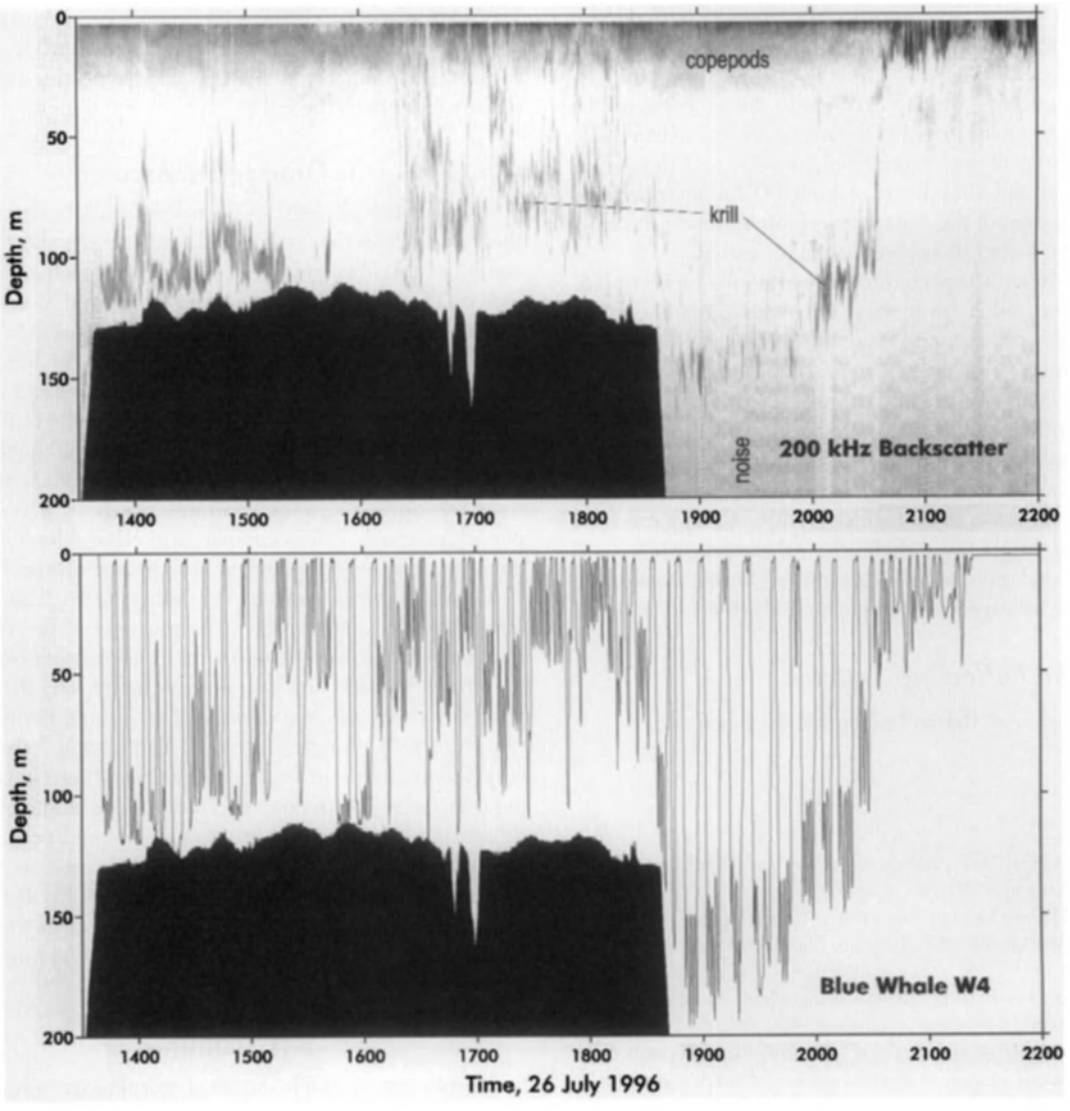

Figure 5 *Track of a blue whale (bottom) diving into and feeding on a layer of krill (top) at the shelf edge off Santa Rosa Island, California. Reprinted from* Deep-Sea Research II, *45, Fiedler, P. C.,* et al., *Blue whale habitat and prey in the California Channel Islands, pp. 1781–1801, Copyright 1998, with permission of Elsevier Science.*

Relatively little is known about the migration routes of most baleen whales between summer feeding grounds and winter breeding grounds. Gray whales migrating south along the California coast remain near the coast and apparently use bottom topography for navigation. Humpback whales have been tagged off Hawaii and observed to linger at seamounts in the middle of the North Pacific on the way to summer feeding grounds in the Gulf of Alaska. Seamounts are known to be sites of aggregation of fish. These whales may be feeding, regrouping, or simply navigating.

X. Effects of Climate Change

Direct effects of temperature increase are unlikely for most marine mammals because of their mobility and thermoregulatory ability. However, direct effects could occur for populations at the limits of their range or with physical limits to migration. For example, the vaquita (*Phocoena sinus*) is a rare species trapped at the warm northern end of the Gulf of California. Other species, such as the beluga whale, with low skin pigmentation and living in a polar region subject to atmospheric ozone depletion, may suffer direct effects of increased UV-B radiation.

Indirect effects on marine mammal populations will occur through alterations of habitat characteristics and distribution, and prey availability. Global warming is predicted to be greatest at high latitudes in the Northern Hemisphere. The resulting reduction of ice cover in the Arctic will affect ice-associated species through changes in the distribution of critical habitat such as polynyas and the ice edge. Seasonal and geographical shifts in prey availability in both the Arctic and the Antarctic may have

a variety of indirect effects: nutritional status and reproductive success, geographic range, and timing or patterns of migration. Bowhead whales and narwhals (*Monodon monoceros*), and especially beluga whales, which feed close to the ice edge, will be affected by reduced ice extent in the Arctic. Warming could also reduce the extent of pack ice in the Antarctic and thus affect the distribution and abundance of krill. Declining krill abundance in the region of the Antarctic Peninsula during the early 1990s has been linked to low winter sea ice extent.

Global warming is expected to be less intense at lower latitudes. However, reduction in wind-driven coastal and equatorial upwelling is possible and may reduce prey availability for marine mammals. A decline in zooplankton biomass off California since 1951 has been linked to warming of surface waters, increased stratification, and reduced mixing and upwelling of nutrients. Odontocetes that depend on squid, such as sperm whales, may be affected more adversely because cephalopod populations are known to be highly variable. A rising sea level will change the lagoons and shelf areas where gray whales and humpbacks breed, but past changes in these breeding sites are known to have occurred over longer periods of geologic time.

Odobenocetops

CHRISTIAN DE MUIZON
National Museum of Natural History, Paris, France

One of the most unexpected recent discoveries in marine mammal paleontology is that of a new family and genus of tusked cetacean—Odobenocetopsidae, *Odobenocetops*—from the early Pliocene beds of the Pisco Formation of Peru (Muizon, 1993; Muizon *et al.*, 1999). As its name indicates, the new marine mammal presents several similarities with the living walrus, *Odobenus rosmarus*. However, *Odobenocetops* is clearly a cetacean and presents a startling and unprecedented example of convergence with the walrus in its cranial morphology and inferred feeding habits (Muizon, 1993; Muizon *et al.*, 1999). *Odobenocetops* is known from two species: *O. peruvianus*, Muizon, 1993, and *O. leptodon*, Muizon, Domning, and Parrish, 1999, with the former being slightly older than the latter.

I. Descriptive Anatomy

Odobenocetops (Figs. 1–3) has lost the elongated rostrum of the other cetaceans. Instead, the rostrum is short, rounded, and blunt and formed by the premaxillae, which are greatly enlarged. They have large, asymmetrical ventral alveolar sheaths holding sexually dimorphic tusks. The right tusk of the male is large and can reach 1 m or more in length. The left tusk is approximately 25 cm long, of which a few centimeters only were erupted. Both tusks are straight. In the female, both tusks approach the size of the left tusk of the male, although the right tusk is slightly larger than the left. Premaxillary sheath and tusks are oriented posteroventrally. The bony nares have displaced anteriorly (when compared to other odontocetes). The palate is very deep and arched, and its anterior border is U to V shaped. *Odobenocetops* lacks maxillary teeth. The orbits face anterolaterally and dorsally. The portions of the frontal and maxillae, which cover the temporal fossae in other odontocetes, have been reduced and narrowed in such a way that the temporal fossae are opened dorsally. The glenoid cavity is an anteroposteriorly elongated groove. The occipital condyles are very salient and more convex than in any other Pliocene or living cetaceans. The periotic and tympanic have the characteristic morphology observed in other delphinoid cetaceans. The mandible is unknown. The postcranial skeleton is poorly known. The atlas is shortened anteroposteriorly as in other odontocetes, and the forelimb has the basic pattern of that of other odontocetes. The length of the body could have ranged from 3 to 4 m.

II. Affinities

Despite its extremely modified morphology, several characters of the skull clearly relate *Odobenocetops* to the delphinoid cetaceans. Cetacean characters of *Odobenocetops* include the presence of large air sinuses in the auditory region connected to well-developed pterygoid sinuses; the thickened and pachyostotic tympanic bulla; and the dorsal opening of the narial fossae. Odontocete affinities of *Odobenocetops* are attested by maxillae covering the supraorbital processes of the frontals, although they are partially withdrawn secondarily; the dorsoventral expansion of the pterygoid sinuses; the presence of large premaxillary foramina (in *O. peruvianus* only); and the asymmetry of premaxillae and maxillae in the facial region. The sigmoid morphology of the dorsomedial view of the involucrum and the presence of a medial maxilla–premaxilla suture at the anterolateral edge of each narial fossa are delphinoid characters (Muizon, 1988). Several characters of the pterygoid, alisphenoid, and temporal fossa indicate close affinities of *Odobenocetops* and the Monodontidae (Muizon, 1993; Muizon *et al.*, 2000). In view of the exceptional specializations of *Odobenocetops*, it was referred to as a new odontocete family, the Odobenocetopsidae, regarded as the sister group of the Monodontidae.

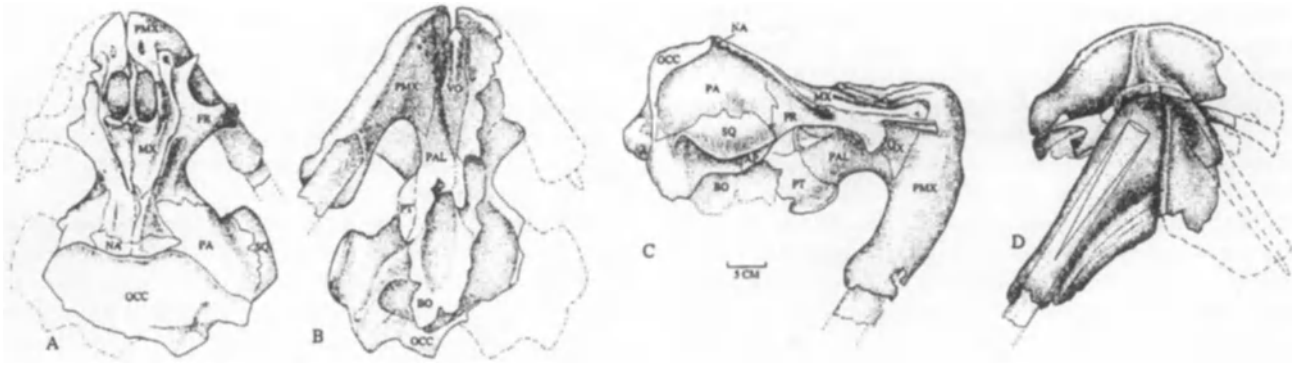

Figure 1 Odobenocetops peruvianus: *Skull of a male in dorsal (A), ventral (B), lateral (C), and anterior (D) views. Scale bar: 5 cm. AP, alisphenoid; BO, basioccipital; FR, frontal; MX, maxilla; NA, nasal; OCC, occipital; PA, parietal; PAL, palatine; PMX, premaxilla; PT, pterygoid; SQ, squamosal; VO, vomer. Modified from Muizon (1993), reprinted with permission from* Nature *(365: 745–748) copyright (1993) Macmillan Magazines Ltd.*

The occurrence of tusks in *Odobenocetops* is a convergence with *Monodon* as in the latter genus the large tusk of the male is implanted in the left maxilla, whereas in *Odobenocetops* it is implanted in the right premaxilla. Consequently, the tusks of *Monodon* and *Odobenocetops* are not homologous.

III. Functional Anatomy and Habits

A. Feeding Adaptations

Odobenocetops and the living walrus show several morphogical convergences: a large and deep palate; strong development of a wide, blunt snout, which is highly vascularized and innervated with strong muscular insertions, suggesting the presence of a powerful tactile upper lip; the presence of tusks; and a reduction of maxillary dentition (postcanine maxillary teeth are absent in the fossil walrus *Valenictus chulavistensis*). The living walrus feeds mainly on benthic invertebrates (e.g., *Mya, Clinocardium, Tellina, Spisula, Macoma*) (Fay, 1982), sucking out the siphon and foot of bivalves or gastropods shells, using

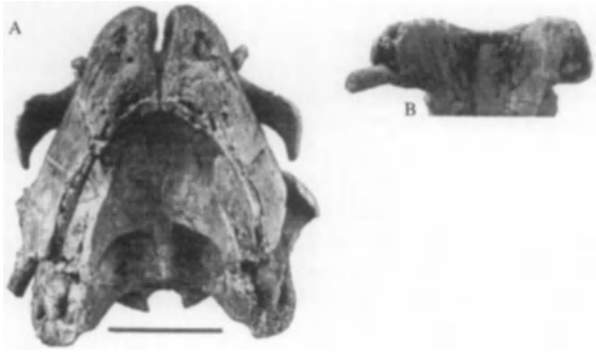

Figure 2 Odobenocetops peruvianus: *skull of a female in anteroventral view (A); ventral view of the anterior region of the palate of the same skull (B). Scale bar: 5 cm. From Muizon et al. (1999), reprinted with permission from the* Comptes Rendus de l'Académie des Sciences, Série IIA, *329: 449–455) copyright (1999) Elsevier.*

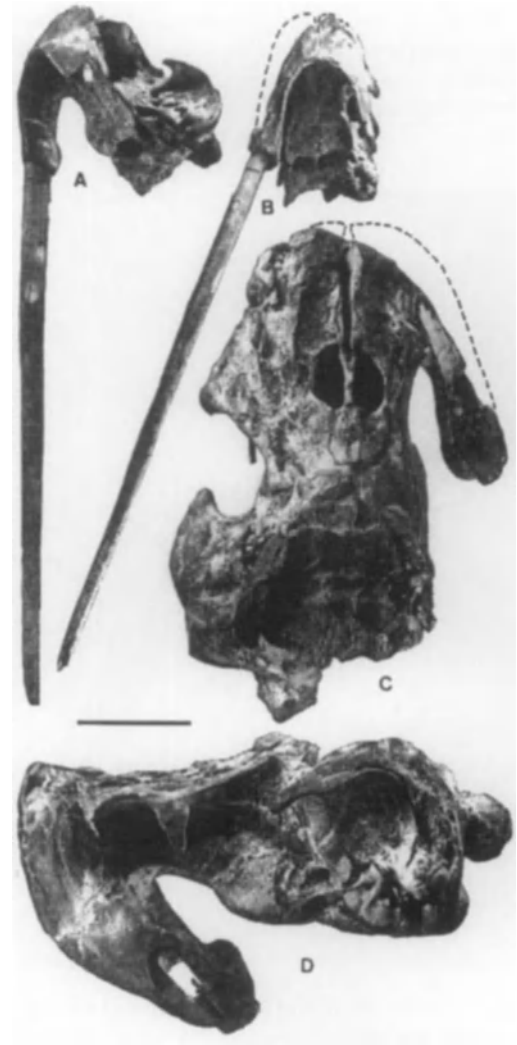

Figure 3 Odobenocetops leptodon: *skull of a male in left ventrolateral (A), anteroventral (B), dorsal (C), and left lateral (D) views. Scale bar: 20 cm (A, B); 10 cm (C, D). From Muizon* et al. *(1999), reprinted with permission.*

the tongue as a piston powered by the very large lingual retractors and depressors. Their mouth works like a powerful vacuum pump. Given the anatomy of its palate, it is likely that *Odobenocetops* presented a similar feeding adaptation. This adaptation was probably even more efficient in *O. leptodon* because its palate is longer than in *O. peruvianus*. *Odobenocetops* therefore probably fed on benthic invertebrates (bivalves and gastropod mollusks and/or crustaceans), which are abundant in the Pisco Formation at Sacaco. Because of the great vascularization of the inferred upper lip, it is possible that, as in the walrus, *Odobenocetops* had vibrissae, which would have had an important tactile role in the search for food. When feeding on the sea floor, the body of *Odobenocetops* was probably held in an oblique position as is observed in the living walrus (Fig. 4).

B. Vision vs Echolocation

VISION and HEARING were probably slightly different in the two species of *Odobenocetops*. Because of the shortening of the rostrum and the very short space between the premaxillary foramina and the nares, it is probable that the premaxillary air sacs in *O. peruvianus* were absent, unlike in other odontocetes. Furthermore, a melon was also probably absent or very reduced. In contrast, in *O. leptodon*, fossae for premaxillary sacs are clearly present on the premaxillae, just anterior to the nares as are observed in other odontocetes. Furthermore, the dorsal surface of the rostrum is longer and wider and there is enough space for a small melon anterior to the nares. The cetacean melon is related to echolocation and, consequently, *O. peruvianus* was probably devoid of echolocating ability, whereas some echolocating ability may have been present in *O. leptodon*.

The anterodorsal edge of the orbit (i.e., the anterior border of the supraorbital process of the frontal) in *O. peruvianus* is deeply notched, allowing good anterodorsal binocular vision. In contrast, this region of the frontal in *O. leptodon* is only slightly concave, which reduced binocular vision.

The probable lack of ECHOLOCATION ability in *O. peruvianus*, was probably compensated for by good anterodorsal binocular vision. As in the walrus, vision was especially useful when the animal was searching for food on the sea flood with the body in an oblique position. In *O. leptodon*, limited binocular vision was compensated for by echolocation ability as in other odontocetes.

Figure 4 *Reconstruction of* Odobenocetops leptodon *(males) in swimming and feeding position. The third individual in the background is in ventrolateral view from the left side in order to show the erupted small left tusk. From Muizon* et al. *(1999), reprinted with permission. Painting by Mary Parrish (Smithsonian Institution, Washington, DC).*

C. Tusk, Position and Function

The posteroventrally oriented tusks are certainly one of the most unusual characteristics of *Odobenocetops*. Because of its great length and slenderness, the right tusk of the male was probably very fragile and it was unlikely that the animal swam with the tusk held at a 45° angle with the axis of the body. Comparison of the occipital condyles to the anterior articular facets of the atlas indicates that, when swimming, the dorsal plane of the skull was oriented anterodorsally and that the tusk was approximately parallel to the axis of the body. When feeding, the large tusk was dragged on the sea floor, and because of the oblique position of the body, the tusk was held at an angle of 20° to 40° with the axis of the body (Fig. 4). In other respects, the convexity of the occipital condyles of *Odobenocetops* indicates that its neck was extremely mobile, allowing a degree of head movement approaching 90° or more.

The narwhal tusk is mainly used in social activities. The orientation and length of the large tusk of *Odobenocetops* suggest that this tooth was very fragile and was unlikely to have been used to exert forces (in digging or fighting). The probable SEXUAL DIMORPHISM in the size of the tusks of *O. peruvianus* points to a nonviolent social role (Muizon *et al.*, 2001). In addition, the tusks of walruses and the premaxillary tusks and sheaths of *Odobenocetops* may play a role in bottom feeding as orientation guides to keep the mouth and any vibrissae (if present) in constant position relative to the substrate.

Although suction feeding has been increasingly recognized among odontocetes (e.g., *Tursiops, Globicephala, Phocoenoides, Phocoena, Monodon, Delphinapterus, Physeter, Mesoplodon, Berardius*), the extreme modifications of *Odobenocetops* are unique among the Cetacea and suggest concomitant expansion of the adaptive breadth of the order. *Odobenocetops* occupied, in the Southern Hemisphere, an ecological niche otherwise unknown among odontocetes that was similar to that of the odobenine walruses, which were widespread in the Northern Hemisphere during the Pliocene.

Origins of Marine Mammals

MICHAEL A. TAYLOR
National Museums of Scotland, Edinburgh, United Kingdom

Whales, pinnipeds, and sirenians are examples of a major evolutionary phenomenon: the dramatic transformation of terrestrial amniotes (reptiles, birds, and mammals) to a more or less fully aquatic lifestyle. Indeed, marine mammals are far from unique, for this has happened several tens of times in evolutionary history. The whales are ecological replacements for the extinct ichthyosaurs, which were reptiles as fish-like as whales. The sea lions have a body form and swimming method broadly similar to those of the penguins, the extinct great auk (*Pinguinus impennis*) and plesiosaurs. Other examples include the plotopterid birds, mosasaurs (aquatic lizards), at least two lineages of marine crocodilians, and the mollusc-eating placodont reptiles that were analogous to the modern sea otter (*Enhydra lutris*). Yet, however many times it has happened, it is still a huge transition from a terrestrial animal, adapted to live, feed, and breed on land, to an animal such as a whale, which is so notoriously fish-like that its relationships puzzle nonbiologists. Indeed, how whales could have arisen from land mammals was a question routinely posed by opponents of Darwin's "Origin of Species," and he himself regarded it as a crucial issue.

The problem can be approached today by asking what phylogenetic route the transition took: what are the actual relationships? Then what can we say about the animals that were the actual intermediates? What did they look like and in what habitats did they live? What was, in fact, the ecological route of the transition? And, in parallel, does the evidence make functional sense that corroborates the hypothesis? This article focuses on general issues common to all lineages.

I. How the Transition Can Be Studied

It is a central tenet of Darwinian evolutionary theory that relatively gradual changes can lead to major transitions. Under natural selection, a species can gradually change if this is advantageous (more correctly, advantageous through increasing the frequency of the individual gene alleles under selection). The degree of adaptation need not be perfect. An animal only has to be sufficiently well adapted to gain some advantage; even quite a poor degree of adaptation can be enough. For a land animal, the occasional ability to swim, however poorly, can be critical in escaping predators or locating new food resources. Furthermore, adaptation is "fuzzy": animals have some flexibility in how they use their adaptations, allowing natural selection to start driving change in either direction. There is almost no such thing as a purely land mammal, for most mammals can at least swim in an emergency. This provides the potential basis for the evolution of a more aquatic lifestyle.

The transition from a land animal to, say, a whale will have taken place by a relatively gradual process with many intermediate forms. For this transition from land to sea to be possible, natural selection should be able to act along the whole range of the spectrum, and each intermediate form across the spectrum should be reasonably well adapted. In other words, there should be no insurmountable adaptive barrier in the way. (The available evidence on the origin of marine mammals is not sufficiently fine-grained for worthwhile discussion of the fine detail of this transition—for instance, whether morphological change was truly gradual or was concentrated in bursts during the formation of new species, as the hypothesis of punctuated equilibria predicts.)

The first line of evidence for demonstrating the viability of a transition is direct, from actual fossils of the transitional forms (or more probably close relatives). They may not (yet) be available, but are enormously valuable when they are. Early whales are an excellent example.

The second line of evidence for the viability of a transition is the existence of a spectrum of biological analogues, unrelated species that demonstrate a complete range of adaptations from fully terrestrial to fully marine. Their survival is evidence that their various lifestyles, and therefore the stages in the transition, are viable.

The third type of evidence is to some extent an independent test. It comprises theoretical biomechanical analyses that confirm that particular hypotheses of evolutionary transitions are functionally possible. Conversely, a hypothesis that required a functionally implausible intermediate form would thereby be considerably weakened.

II. Environment of the Transition

What resources drove natural selection during the land–sea transition? The most likely one is food. Less obvious but also very important are shelter from predators and shelter from extremes of temperature. Different resources occur in different environments; e.g., seaweed occurs on the shore and in seawater, but basking in the sun may only be practical on land. It is likely that the transition was driven by the move between environments in order to exploit resources.

The fact that the transition is driven by nondirectional natural selection has the major implication that selection and therefore evolution can in principle simply halt, or reverse direction, for greater or lesser periods, within any one lineage. This has undoubtedly happened. Indeed, certain forms are truly amphibious, relying on a highly specific combination of land and water resources to enable a lifestyle that is otherwise impossible. For instance, the HIPPOPOTAMUS feeds on land at night, but rests in the water during the day, whereas the river otter (*Lutra lutra*) forages in water but comes out to warm up, rest, and breed. To speak of these as being stuck at an intermediate stage of the evolution of aquatic forms risks missing the truth, which is that such amphibious forms are highly adapted in their own right. Crocodilians likewise evolved a highly efficient amphibious freshwater and estuarine lifestyle, which remains the main crocodilian way of life. However, some crocodilian lineages became fully marine and others reverted to a fully terrestrial lifestyle. Suggestions that some modern terrestrial groups are secondarily terrestrial, derived from amphibious or aquatic forms, are therefore entirely reasonable in principle and can only be assessed on actual evidence. Such suggestions have been made for snakes, proboscideans, and human beings, for instance.

What was the environment of the transition from land to sea? There are various possible environments where land, fresh water, and sea variously meet:

1. Freshwater river
2. Lake or other body of standing fresh water
3. Estuary with at least some saltwater influence
4. Sandy open seashore
5. Rocky open seashore
6. Unusual habitats, especially highly productive ecosystems rich in food; modern examples include mangrove swamps, the Florida Everglades, and the regularly flooded lowland riverine forests of the Amazon Basin. It must not be forgotten that, quite apart from the effects of human activity today, ecosystems in the past may have been very different, even without allowing for the "wild card" of unpredictably unusual habitats without any modern analogue.

These different environments pose varying advantages and problems to animals that exploit them. Freshwater rivers and lake shores, however, offer good opportunities for amphibious forms such as hippopotamuses, which rest in the water but feed on land at night. However, because of the risk of stranding during occasional droughts, only the largest rivers are suitable for fully aquatic animals such as odontocetes. Conversely, rocky shores offer plenty of fish and cephalopods to animals such as river otters, and molluscs and sea urchins to animals such as sea otters. However, life in salt water poses problems of salt excretion and THERMOREGULATION. River otters lack blubber and use air-filled fur for insulation. They risk death if their coats are not washed in fresh water, as the salt water mats their coats when it dries. They are therefore dependent on the availability of standing pools of fresh water on shore.

An example of a hypothesis of simple transition from land to sea through a single habitat, rocky seashores, can be formulated using modern analogues:

1. Primarily terrestrial carnivore/carrion feeder, not normally a swimmer, but foraging on the shore above water, e.g., stoat (*Mustela erminea*).
2. Feeding facultatively on rocky shores above water and in rock pools, and possibly diving for food. Some swimming ability, but not much more than most terrestrial mammals, e.g., American mink (*Mustela vison*).
3. Shallow-water swimmer, foraging routinely in inshore water, for example, benthic invertebrates, remaining on land otherwise (e.g., for resting, thermoregulation, and breeding). Swimming by forceful kicks of webbed hind feet linked to flexion and extension of back, supplemented by dorsoventral undulation of a flattened tail, e.g., river otter (pursuit predator) or the archaic whale *Ambulocetus* (probably an ambush predator).
4. Shallow-water swimmer and diver, remaining in the water for much of the time and specializing in aquatic food. Swimming somewhat more specialized for aquatic movement, notably the development of bone ballast in buoyancy control, which slows the animal, e.g., the sea otter.
5. Fully specialized swimmer, feeding in open water but perhaps resting and breeding on beaches inaccessible to land predators, with increased development of a caudal fin to provide most or all of the thrust, e.g., archaic protocetid whales such as *Rodhocetus* and the living gray seal (*Halichoerus grypus*) (in which the hind feet are modified to the functional equivalents of caudal fins).
6. Fully aquatic, not coming to land at all, e.g., short-beaked common dolphin (*Delphinus delphis*).

This testable hypothesis is given as an illustrative example based solely on carnivorous mammals on rocky temperate coastlines, and alternatives can be developed for other groups and other environments. Nevertheless, note that this hypothesis contains two critical elements:

- Ecological plausibility—these are stages in a gradual spectrum, exploiting resources as they become newly accessible
- Functional plausibility—again, these are stages in a gradual spectrum, with a clear explanation for how the development of caudal fin propulsion might occur, which can be reinforced by biomechanical analyses

Second, there may be no one single environment for the transition. Because the transition may take place in stages, natural selection can operate in successively different ways depending on the environment of the time. This has major implications, as discussed later.

It is also possible, and even likely, that the transition from land to water moved through a series of habitats, not just one. This may be important in easing the direct transition from land to sea. For instance, the rocky shore model given earlier does not offer any obvious answers to the problem of the origin of sirenians, which are marine herbivores. Individual red deer (*Cervus elaphus*) facultatively eat intertidal marine algae or "seaweed," and interestingly the North Ronaldsay breed of domestic sheep, which has long been confined to the shore of North Ronaldsay in the Orkney Islands, is now so adapted to a

diet containing at least some algae that it cannot survive on grass alone. However, there are no living specialized mammalian grazers on algae comparable to (say) the Galápagos marine iguana (*Amblyrhynchus cristatus*). This might be explained on two grounds: (1) that the transition did go through a rocky shore phase, and it just happens that no analogues are alive today, in which case the extinct Pliocene aquatic sloth *Thalassocnus* may be one such analogue; or (2) that the transition took place somewhere else, presumably in fresh water or estuaries because sandy beaches are devoid of edible plants. This leads to another possible spectrum, again with some modern analogues, but this time moving through geographical as well as niche space:

1. Riverine animal, walking (but not normally swimming) in water and feeding on land, e.g., hippopotamus, or land animal wading in fresh water to feed on aquatic plants.
2. More aquatic, swimming, feeding on freshwater plants in lakes and rivers.
3. Aquatic, swimming form, feeding in estuaries.
4. Fully aquatic, feeding in estuaries and nearshore, e.g., manatees (*Trichechus* spp.).
5. Fully aquatic, feeding largely or wholly on marine plants, e.g., dugong (*Dugong dugon*) and Steller's sea cow (*Hydrodamalis gigas*).

Note that this offers one explanation of how land animals can survive in the salt-rich "desert" of the sea, by way of intermediate forms able to cope with increasingly brackish water (although alternatively a marine mammal might be derived from desert-living land mammals, which are already adapted to retaining body water, e.g., by excreting urine much saltier than the blood).

The environment, or environments, of transition also bias the fossil record. Even if an animal dies, escapes scavenging, and is fossilized, it is not necessarily buried where it lived in life. For instance, water currents might have moved the carcass. To summarize a complex situation, corpses in estuaries and rivers are apt to be swept out to sea. Carcasses of animals that lived on rocky coasts, which are being eroded, tend not to be preserved *in situ* as there is no sediment to bury them in. Carcasses on sandy coasts also tend not to be preserved because these coasts are relatively high-energy environments that disrupt the corpse. If the carcasses are buried, this may be because they have drifted offshore and sunk to the sea floor, or possibly because open sea animals have been stranded on the shore and preserved there. Only animals in rivers and lagoons have much chance of being preserved where they lived, and even then riverine animals are quite likely to be washed away downriver. These biases are borne in mind by competent paleontologists and can be partly mitigated by functional analysis (which would reveal anomalies such as an amphibious animal in an open-sea deposit).

III. Functional Issues

The functional problems involved in the transition from land to water, such as swimming, FEEDING, and sensory physiology, are mostly discussed elsewhere in other entries. Here is a case study, focusing on buoyancy control, and showing how this one function interacts with several others, such as swimming and feeding.

Land mammals breathe air and may also rely on air-filled fur for heat insulation, especially in temperate and polar regions. This air makes swimming and diving difficult if the buoyancy provided by air in the lungs (and any fur) is not precisely compensated by the denser parts of the body such as bone. This wastes at least part of the swimming effort, which goes to staying up or down in the water rather than thrusting the animal forward. Animals well adapted to aquatic life have proper adaptations to buoyancy control separate from swimming, which can thus be optimized for forward movement. However, locomotion interacts with respiration here. Air in large lungs is useful as an oxygen store, but only for animals that do not swim fast (because the added bulk slows them down) or dive deeply (because larger lungs compress more with depth, making buoyancy changes even greater, and because of the risk of the "bends" if high-pressure air in the lungs is allowed to remain in respiratory exchange with the bloodstream). To compensate for the air in their lungs, marine mammals may have stones (gastroliths) in the stomach or massively enlarged bony skeletons for ballast. Alternatively, they may reduce the size of their lungs and replace air-filled fur with naked skin underlain by an insulating layer of subcutaneous fat or BLUBBER. In practice, of course, all functions and organs are interdependent. For instance, sirenians can only tolerate their large lungs and correspondingly massive skeletons because they feed on plants that do not swim away, whereas odontocetes have to be much faster swimmers to catch their prey, and their smaller lungs are coordinated with the evolution of much lighter skeletons. These changes appear to occur in predictable patterns in the evolution of marine mammals and their reptilian and avian analogues:

1. Land animal, relatively buoyant in water, e.g., stoat.
2. Amphibious animal with little or no bone ballast, because it slows it too much on land, but remaining too buoyant in water for efficient locomotion, e.g., American mink, river otter, polar bear (*Ursus maritimus*), desmostylians, *Thalassocnus* (sloth), *Ambulocetus* (primitive whale), and Galápagos marine iguana. Tied to living on land (or ice) for most of the time.
3. Primarily aquatic form with bone ballast in the form of larger, or denser, bony skeletons. Swimming can be decoupled from buoyancy control and made more efficient, e.g., sea otter and some primitive whales. Typical of animals living close inshore. Nile crocodile (*Crocodylus niloticus*) uses gastroliths but is not quite so fully aquatic.
4. Further evolution into more specialized fully aquatic forms, three different groupings being identifiable depending on locomotor and feeding adaptations, which drive selection in different ways, even reversing it:
 a. Slow-swimming predators (or herbivores) on sessile food such as plants or benthic invertebrates: full development of bone ballast and large lungs that act as air stores and give rapid loss of buoyancy during a dive as the increasing water pressure compresses the lungs, enabling the animals to become negatively buoyant and walk on the bottom, e.g., placodonts (extinct reptiles feeding on hard-shelled benthic invertebrates) and sirenians. This is an

essentially shallow water adaptation, linked to inshore and coastal waters.

b. Predators on mobile food—an apparently intermediate body plan of underwater fliers with hydrofoil-shaped swimming limbs, using gastroliths and/or bone ballast for buoyancy control: plesiosaurs, penguins, and sea lions. Also permitting open sea lifestyles, but (in penguins and sea lions) allowing them to retain hindlimbs relatively unmodified for use when breeding on land (it is not clear what plesiosaurs did, as their two pairs of hydrofoil "wings" are essentially identical). Also permits open sea lifestyles, although these animals are for some reason more coastal in lifestyle and distribution than the cetaceans.

c. Predators on mobile food—fast swimming with caudal fins: selection for improved speed and acceleration leads to reversal of selection to give extensively lightened skeletons and smaller lungs (which mean less change of net buoyancy with depth, making deep diving more efficient); e.g., ichthyosaurs and cetaceans. Permits open sea lifestyles.

IV. The Problem of the Intermediate

The problems of functional change are not a simple matter of moving from terrestrial to aquatic adaptations. "Amphibious" forms have to tolerate an intermediate level of adaptation, develop a doubly functional anatomy (which may itself involve a level of compromise), or remain poorly adapted in one of the two environments. This is not in itself a problem if the benefits compensate for the disadvantages, as it is better to be an inefficient swimmer (in terms of energy cost of locomotion) with access to abundant aquatic food than to starve on land.

However, a net increase in energy intake is not sufficient. Animal species do not normally exist in isolation, but have to compete with one another for resources. It is not clear how intermediate forms can survive at all under these circumstances. At any one time and place an intermediate form will always risk being outcompeted by a land specialist or by a sea specialist, if not both. For instance, an intermediate form will be a slower and less energy-efficient swimmer than a specialist marine form, and a slower and less efficient runner than a specialist land form. River otters are not quite as nimble as comparable land mustelids, and sea otters are more aquatic but still clumsier on land. The dilemma can only be resolved if, as seems likely, intermediate forms rely on "refuges" free of competition. These refuges might be real physical ones, in space and time, or virtual ones, in ecological "niche space." Possible refuges and examples of animals exploiting them include:

1. Ecological isolation in an area inaccessible to land or water predators and competitors: possibly sea otters in rocky shallow water.
2. Specialization in a dietary resource not exploited by similar animals: sea otters feeding on hard-shelled shallow water invertebrates.
3. Time averaging of predator avoidance, e.g., getting into the water when a land carnivore is around, but getting out when a shark arrives. The risk that both will be around at the same time so that escape becomes impossible is a multiple of the two separate probabilities that each will be around, and is therefore smaller than either.
4. Time averaging of food or other resource, e.g., hippopotamuses feeding on land at night, but retreating to water during the day.
5. Combining complementary resources not available to pure land or pure water specialists, e.g., using land to bask in the sun to gather heat, but wading and diving in cold water to feed on algae, as adult Galápagos marine iguanas do (perhaps only relevant to those mammals that are small enough and live in cold enough sea water to have problems with thermoregulation, notably river otters on northern temperate seacoasts).
6. Geographical isolation to escape land predators, perhaps on oceanic islands, e.g., Galápagos marine iguana.
7. Isolation in evolutionary time. Modern marine mammals evolved as replacements for the Mesozoic marine reptiles, the last of which went extinct in the mass extinction at the end of the Cretaceous. The mammals were thus sheltered from competition by these direct analogues in a way that would not be the case today (at least before human interference). However, this is only a partial explanation, as early Tertiary marine mammals had to contend with predatory fishes and crocodiles in fresh water and in the sea, together with land predators.

It is entirely possible that more than one type of refuge was exploited during the evolution of any one marine mammal lineage, perhaps even at the same time.

V. The Limits of Adaptation

So far the discussion has been based on what is evolutionarily, ecologically, and functionally plausible—roughly, what is permitted by the ecological context, the laws of physics, and the need for gradual transformation through a series of equally viable ancestors. However, the adaptation of marine mammals is also limited by phylogenetic constraint: the concept that an evolutionary lineage's change is limited in direction or in scope by inherited features. Indeed the need to evolve along a continuous spectrum of viable forms is in itself such a constraint, as suggested by the repeated patterns in the evolution of buoyancy control outlined earlier. But does the inherited body plan itself pose constraints? A good example seems to be marsupial "whales," or rather their nonexistence, which at first sight seems surprising. Convergent evolution with placental mammals has generated, for instance, marsupial "mice," "cats," and "wolves," so why not "seals" and "whales"? This is probably because marsupial young are born at a very immature stage compared to placental mammal young and develop within the mother's pouch or hanging from the teat so that they would drown the moment their mother went swimming. Marsupials cannot therefore easily evolve aquatic forms. The only well-attested semiaquatic marsupial is the yapok or water opossum (*Chironectes minimus*), which forages for prey such as fish and crustaceans in fresh water. In the female, the waterproof pouch can be closed off with a sphincter to keep water out, and the young can tolerate the ensuing low oxygen levels for many min-

utes. However, this is an impractical solution for a lifestyle involving swimming for more than brief periods. The marsupial mode of reproduction therefore appears to be a phylogenetic constraint impeding the development of fully aquatic lifestyles beyond the semiaquatic stage. Because placental mammals carry their young for much longer periods, they have been able to bypass this constraint.

Indeed, it can be argued that many marine mammals (and marine amniotes more generally) are, or were, not fully aquatic. The pinnipeds, the penguins, marine turtles, and most seabirds (for instance), remain critically dependent on breeding on land or on floating ice, which has major impacts on their biology. They have to retain at least some ability to move on land, compromising full adaptation to life in water. Even so, they are extremely vulnerable to land predators when they go ashore to breed. They therefore have to swim or fly, sometimes over global distances, to suitable rookery areas in sometimes inhospitable environments. The spectacular concentrations sometimes resulting at these ROOKERIES provide dense populations of potential mates and competitors, which may drive intense competition between males, selecting for massive sexual dimorphism, as in elephant seals (*Mirounga* spp.). Plainly something about their various modes of reproduction prevents young being born live, or if it is born live, from surviving in water. These animals therefore still occupy an evolutionary refuge of the kind outlined earlier in the form of predator-free, land breeding areas.

Whales and sirenians do give birth to live young in water and have therefore—or concurrently—lost the ability to move on land, freeing them to become entirely adapted to life in water, just as the ichthyosaurs did more than a hundred million years before. Whales and sirenians, then, seem to be the only truly marine mammals with no remaining link to the land that their ancestors left millions of years before. Nevertheless, the contrast between ichthyosaurs and dolphins reveals evidence of phylogenetic constraint in what are superficially functionally optimal animals. They are superficially very similar, under the same selective pressures of a fully aquatic lifestyle, with fishlike bodies with dorsal and caudal fins and long narrow snouts for snapping at fish and cephalopods underwater. They even give, or gave, birth to live young underwater (fossils of gravid female ichthyosaurs have been found). Still, they differ in ways that reflect their differing ancestries. Ichthyosaurs were (presumably) derived from lizard-like land reptiles that ran by using lateral undulations of their bodies to increase the forces and movements of their legs, and hunted by sight rather than smell. Ichthyosaurs accordingly had tails that beat from side to side with vertically oriented caudal fins. They also had huge eyes for seeing in deep or silt-laden water. In contrast, dolphins were ultimately derived from small nocturnal insectivorous mammals rather shrew-like in habits, with high-frequency hearing and rudimentary sonar (as in rats and blind people) and whose running was enhanced by dorsoventral flexion and extension of the body. Accordingly, dolphins swim with up and down beats of their tails, which bear horizontally oriented caudal fins. Instead of the huge eyeballs of ichthyosaurs, the domed foreheads of dolphins contain the sonic lenses and huge brains needed to send sonar pulses and process the resulting data. Thus even the most adapted of the marine mammals show the signs of their origins.

Osmoregulation

DANIEL P. COSTA
University of California, Santa Cruz

An organism can be thought of as a large volume of fluid surrounded by a body wall. Mammals must maintain both the concentration and the volume of this internal fluid within a very narrow range and can only tolerate minor deviations. Even though most marine mammals live in an aquatic medium, the animals' internal fluid composition differs from the ambient environment and therefore requires active processes to maintain it. Osmoregulation describes the way in which the internal water and electrolyte concentration of this internal environment is maintained. When animals feed they take in both water and electrolytes that must be excreted. While they gain water from metabolizing food, they lose water through evaporation when they breathe to obtain the oxygen necessary for metabolism. Maintenance of a constant internal environment requires that whatever comes into the animal must equal what goes out. The easiest way to understand osmoregulation is to account for the ways water and electrolytes enter and leave the organism (Fig. 1). For example, if a dolphin consumes a

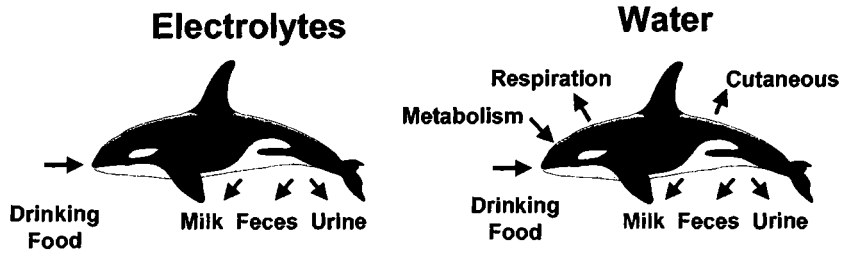

Figure 1 *Schematic of ways by which water and electrolytes enter and leave a marine mammal. Excretion of electrolyte and water as milk occurs only when females are lactating.*

large volume of water and electrolytes, it must have the capability to excrete an equivalently large volume in the feces and urine, through BREATHING, and in milk during lactation. Conversely, if a seal on the beach does not have access to food or water, it must be able to survive on the water produced from metabolism and have mechanisms in place to reduce water loss. Following the relative rates of water and electrolyte input and output helps us understand the mechanisms that marine mammals use for osmoregulation.

I. Water and Electrolyte Ingestion

Water and electrolytes enter the animal through the ingestion of food and water. Water that is consumed as water, i.e., water contained in the food or actively drunk, is called preformed water. Compared to terrestrial mammals, marine mammals consume a water-rich diet of fish and marine invertebrates, which are composed of between 70 and 80% water. Prey are also composed of electrolytes and nitrogen that require water for excretion by the kidney. Marine mammals face different osmoregulatory problems depending on the type of prey that they consume. For example, the ratio of water to electrolytes is quite different between vertebrate and invertebrate prey. The internal fluid of vertebrates is one-third the electrolyte concentration of seawater, whereas the internal fluid of invertebrates is essentially the same as seawater. Thus, a dolphin eating squid will get almost three times as much electrolytes than if it consumed fish. Furthermore, an animal such as a manatee with access to fresh water can drink fresh water to flush electrolytes, whereas an oceanic dolphin can only drink seawater. Water is also produced as a by-product of metabolism; this is called metabolic water production (MWP). Because the amount of metabolic water produced varies with the fuel oxidized, different diets produce varying amounts of metabolic water. For example, 1.07 g of water is generated for every gram of fat oxidized, 0.56 g of water per gram of carbohydrate, and only 0.39 g of water per gram of protein.

II. Water and Electrolyte Output

Both water and electrolytes are excreted in the urine and feces, whereas only water is lost through evaporation. Water is lost via evaporation both across the skin (cutaneous water loss) and through the lungs (respiratory evaporative water loss). Because marine mammals lack sweat glands there is no loss of electrolytes (salts) across the skin. Unlike sea birds and marine reptiles, marine mammals lack specialized glands to excrete salts. All salt excretion is through the kidney, and marine mammals have developed a specialized kidney to handle the large volume of electrolytes and water they process.

III. Do Marine Mammals Drink Seawater?

In most cases, marine mammals can derive sufficient water from their diet so that they do not need to ingest seawater. Measurements of the water, electrolyte, and nitrogen intake, coupled with measurements of evaporative, urinary, and fecal water loss, suggest that a feeding seal can get all of the water it needs from its prey (through both preformed and metabolic water). This is due to the high water content of the prey coupled with the low evaporative water loss of an animal living in a marine environment.

Do animals drink seawater when they become osmotically stressed in environments where the evaporate water loss is high? To determine whether a marine mammal can gain fresh water by drinking seawater we need to know whether the animal can excrete urine that is more concentrated than seawater. The more concentrated the urine, the greater the amount of "fresh water" that can be derived from the ingestion of seawater. A simple calculation can show how much water is gained or lost relative to the concentrating ability of the kidney (Table I). For example, if a humpback whale, *Megaptera novaeangliae*, consumed 1000 ml of seawater and its kidney had the ability to excrete urine with a chloride concentration of 820 mmol $\times$ liter^{-1}, it could gain 350 ml of fresh water. Whereas humans, who cannot produce urine as concentrated as seawater, would lose 350 ml of fresh water for every liter of seawater they consumed. The maximum urine concentrating ability of marine mammals and a few terrestrial mammals is presented in Table II.

So, do marine mammals drink seawater? Many species of marine mammals have the capacity to drink seawater, but they do not always do so. Fur seals and sea lions have been observed drinking seawater while fasting on the rookery. However, visual observations are not quantitative and do not allow an assessment of the relative importance of seawater ingestion to water balance. Isotopically labeled water and/or electrolytes have been used to quantify seawater drinking in a variety of marine

TABLE I
Differences in Urine Concentrating Ability of Humpback Whale, *M. novaeangliae*, and Human Given to Show a Gain or Loss of Body Water after Ingestion of 1 Liter of Seawater

	Seawater consumed (volume ml)	*Cl− concentration (mmol liter^{-1})*	*Max urine concentration (mmol liter^{-1})*	*Urine volume produced (ml)*	*Water balance gain or loss (ml)*
Whale	1000	535	820	650	+350
Human	1000	535	400	1350	−350

mammals (Table III). In these studies, the amount of water and/or electrolytes consumed in the food was added to that produced by metabolism and compared to the total amount of water and/or electrolytes that passed through the animal is measured by isotopic tracers. Using these methods, investigators found that sea otters, *Enhydra lutris*, and bottlenose dolphins, *Tursiops truncatus*, that were feeding and Galapagos fur seals, *Arctocephalus galapagoensis*, short-beaked common dolphins, *Delphinus delphis*, and short-finned pilot whales, *Globicephala melas*, that were fasting all consumed substantial amounts of seawater. In contrast, feeding and fasting harbor seals, *Phoca vitulina*, feeding northern fur seals, *Callorhinus ursinus*, and fasting Antarctic fur seals, *A. gazella* all had negligible amounts of seawater ingestion. Fasting northern elephant seal pups, *Mirounga angustirostris*, fast for up to 3 months without any measurable ingestion of seawater. The need to drink seawater varies with climate and habitat. For example, Galapagos fur seal females drank during the perinatal fast, whereas female Antarctic fur seals did not. The need to drink seawater in the Galapagos is most likely due to the increased evaporative water loss associated with a warm tropical environment.

TABLE II
Maximum Urine Chloride Concentration and Maximum Osmolarity Measured for Marine Mammals Compared to Values of Representative Terrestrial Mammal

	Cl concentration (mEq liter^{-1})	*Osmolarity (mOsm liter^{-1})*

Seawater	535	1000

IV. Relative Reductions in Water Loss

As described earlier, marine mammals do not need to drink seawater because they have reduced their evaporative water loss. Amazingly, northern elephant seals can fast for months without access to food or water. The only water available to fasting seals is MWP from the oxidation of fat and protein in their tissue. Remember that a positive water balance requires that water input equals water output. This requires that water lost in the urine, feces, and from evaporation be equal to or less than water produced from metabolism (MWP). How then do elephant seals, and probably other seals and sea lions, reduce their water loss?

A. Cutaneous Water Loss

Given their aquatic lifestyle, marine mammals have very low evaporative cutaneous water loss. In water there would be no evaporative water loss, and on land, because pinnipeds lack sweat glands, their evaporative loss is quite low. However, common dolphins and harbor porpoises, *Phocoena phocoena*, appear to lose a substantial amount of water across their skin surface. Common dolphins lose as much as 4 liter H_2O day^{-1} or 70% of their total water intake. It may be that seawater ingestion is necessary to make up for the water lost across the skin.

B. Respiratory Evaporative Water Loss

Endotherms lose water through respiration by the simple physics of warming and saturating the air they breathe. Ambient air is inhaled, warmed, and humidified to core body temperature. For example, air fully saturated (100% relative humidity) with water at 10°C contains 10 mg H_2O per liter of air, whereas fully saturated air in the lungs at 37°C contains 40 mg H_2O per liter of air. Unless there is a mechanism to recover water, a seal would lose 30 mg of H_2O for every liter of 10°C air it inhaled.

Marine mammals employ a few tricks to reduce the water lost through respiration. The first is to breathe periodically, i.e., to inhale, hold their breath, and then exhale. This is called apneustic breathing. Apneustic breathing increases the amount of oxygen extracted per liter of air inhaled. Whereas terrestrial animals typically extract 4% oxygen per breath, marine mammals can extract as much as 8% per breath. This allows marine mammals to breathe less frequently and thereby lose less water because they make

TABLE III
Rate of Seawater Ingestion Measured Using Isotopic Tracer Techniques in Marine Mammals

		Rate of seawater consumption		
	Body mass (kg)	*ml kg^{-1} day^{-1}*	*ml day^{-1}*	*Proportion of total water influx (%)*

fewer respirations to obtain an equivalent amount of oxygen. Pinnipeds, sea otters, and polar bears, *Ursus maritimus*, reduce their respiratory evaporative water loss further by employing a nasal countercurrent heat exchanger. It has been suggested that dolphins, which lack nasal turbinates, recover respiratory water through the adiabatic cooling associated with explosive respirations.

Nasal Countercurrent Heat Exchanger Marine mammals, rodents, and desert ungulates have small passageways in their nasal passages that allow them to recover water vapor and heat that was added to the air at inhalation. Nasal turbinates are composed of very small passageways that allow intimate contact between the inhalant air and the nasal membranes (Fig. 2). As the cold air passes across the small nasal passage, it is warmed and water evaporates. Heat and moisture are transferred from the nasal passage to the air so that by the time it leaves the nasal turbinate it is warmed and humidified to body temperature. In the process of warming the inhaled air, the membranes lining the nasal passages have cooled. On the following exhalation the warm moisture-laden air is cooled as it passes over the cool membranes. As the air temperature declines water vapor condenses and is recovered in the nasal passage (Fig. 3).

C. Fecal Water Loss

Although there are no direct measurements, fecal water loss of feeding cetaceans is probably quite high. Fecal water loss in

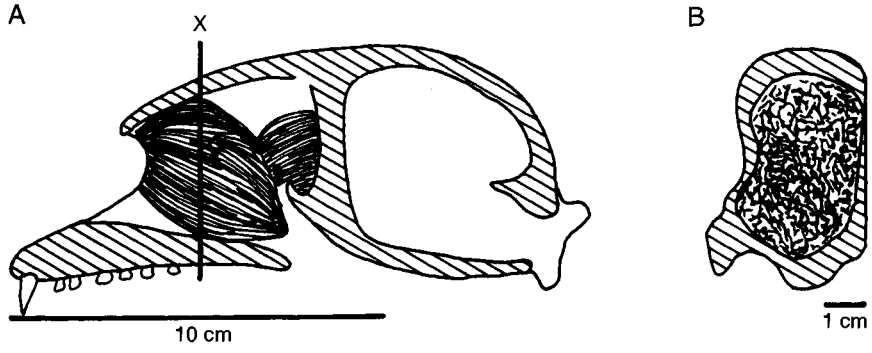

Figure 2 *(A) Sagittal section of a weanling elephant seal skull showing the nasal turbinates. (B) Cross section through one-half of the skull at line "X" in A. From Huntley* et al. *(1984). Reproduced with permission of the Company of Biologists, Ltd.*

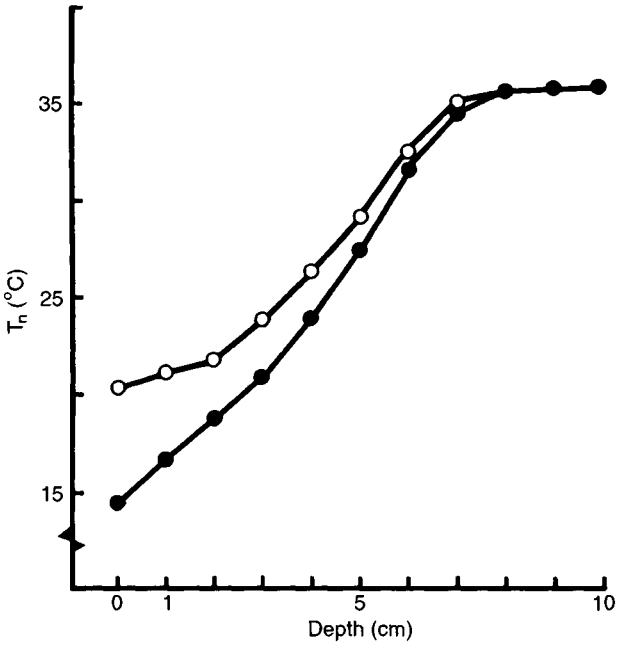

Figure 3 *Temperature at 1-cm intervals within the nasal passage of a weanling elephant seals where the ambient air temperature was 15°C (○) and 5°C (●). From Huntley* et al. *(1984). Reproduced with permission of the Company of Biologists, Ltd.*

pinnipeds feeding on fish is comparable to that of terrestrial carnivores. However, it is not clear how marine mammals that ingest seawater avoid the laxative effect of $MgSO_4$. Fasting animals have negligible fecal water loss, as their fecal production is quite small.

Water, Lipid, and Protein Content of Marine Mammal Milk Compared to Human and Cow

	% water	*% lipid*	*% protein*
Balaenoptera musculus	45.4	41.5	11.9
B. acutorostrata	60.4	24.4	13.6
Physeter macrocephalus	64.5	24.4	9.1
Tursiops truncatus	69.6	15.3	11.5
Arctocephalus galapagoensis	58.5	29.4	12.1
Callorhinus ursinus	44.3	41.5	14.2
Neophoca cinerea	64.7	25.8	9.5
Mirounga angustirostris	36.6	54.4	9.0
Cystophora cristata	33.7	61.4	4.9
Halichoerus grypus	36.6	52.2	11.2
Human	87.6	3.8	1.2
Cow	87.3	3.7	3.3

D. Urinary Water Loss

The rate and amount of water lost in the urine are directly related to both the urine concentrating ability of the kidney and the hydration state of the animal. The kidney ultimately regulates the water and electrolyte state of the animal. When there is a surplus of water, the kidney produces diluted urine, whereas during periods of water stress, the kidney excretes concentrated urine. The kidney must be able to excrete metabolic end products in the form of urea and all excess electrolytes with the water that remains after cutaneous, respiratory, fecal, and in some cases, lactational water loss. While at sea, marine mammals either get all of their water from their prey or they drink seawater. This requires the processing of large urine volumes at moderate to high urine concentrations, and most marine mammals (cetaceans, pinnipeds, sea otters) have a specialized lobulate or reniculate kidney that enables them to do this.

Pinnipeds, such as the northern elephant seal, undergo prolonged fasts on land without access to water. These animals are able to stay in water balance by a combination of low rates of evaporative water loss coupled with low rates of urine production. Elephant seals utilize fat almost entirely (96–98%) for their metabolism while fasting. Fat oxidation produces only CO_2 and H_2O, whereas the oxidation of protein results in CO_2, H_2O, and urea. Urea is the end product deamination of amino acids and requires water to be excreted by the kidney. Therefore, fat is not only an efficient way to store energy, it is also economical with respect to water balance.

V. Water Balance during Reproduction

Many female pinnipeds do not have access to water while they suckle their young and thus could become dehydrated during lactation. However, marine mammal milk is high in lipids and low in water compared to terrestrial mammals (Table IV). This has the advantage of providing the young with the maximum amount of energy with minimal loss of water from the mother. This is likely an advantageous by-product of the energetics of marine mammal lactation and not a derived adaptation for water balance. It is important to note that pups also do not have access to water and therefore must be capable of maintaining their water balance entirely from water contained in the milk and that derived from its oxidation.

Otters

JAMES A. ESTES AND JAMES L. BODKIN
U.S. Geological Survey, Santa Cruz, California

The otters (Mustelidae; Lutrinae) provide a unique look into the evolution of marine living by mammals. This is because most extant marine mammals have been so highly modified by long periods of selection for life in the sea that they bare little resemblance to their terrestrial ancestors. Marine otters, in contrast, are recent expatriates from terrestrial and freshwater habitats, and some species still live in both environments. Contrasts within this group, and among the otters, terrestrial mammals, and the more highly adapted pinnipeds and cetaceans potentially offer deep insight into mammalian adaptations to life in the sea. Among the marine mammals, sea otters also provide the clearest understanding of predation and ocean ecosystem function. This is due in part to serendipitous opportunities provided by history and in part by the relative ease with which shallow coastal systems where sea otters live can be observed and studied. These two qualities of the otters are what make them interesting to marine mammalogy. Thus, our contribution to this volume on the marine mammals is built around these themes.

I. Evolution and Phylogeny

Mustelids radiated from primitive arctoid carnivores at the Eocene/Oligocene border. Early lutrine phylogenies were based on the morphology of fossil and extant species, from which the otters were viewed as a monophyletic group that diversified into three clades: the fish eaters (*Lutra, Lontra,* and *Pteronura*), crab eaters (*Aonyx*), and the sea otter (*Enhydra*). However, the otters probably have been under strong selection for parallel or CONVERGENT EVOLUTION, thereby confounding efforts to understand phylogenetic relationships based on morphology. Distinctive features of the three purported clades might thus have resulted from differences among their common ancestors or selective divergence resulting from different prey (fishes vs invertebrates) or habitats (the ocean vs fresh water). Patterns of brain form and function exemplify this problem in the otters. Architectural and functional differences among otter brains correlate with their principal foraging modes: invertebrate vs fish feeding. Sensory and motor function in the brains of all mammals map mediolaterally along the prefrontal gyrus. The fish-eating otters, which require precise sensory/motor function of the mouth and facial area, have well-developed proximal regions of the prefrontal gyrus. In contrast, the invertebrate feeding otters (*Enhydra* and *Aonyx*), which require precise sensory/motor function of their forelimbs for prey capture, have more highly developed lateral regions of the prefrontal gyrus. But are these features primitive or derived? If primitive, then they might accurately reflect phylogeny; otherwise, they surely do not.

Nucleotide sequence analysis of the mitochondrial cytochrome *b* gene was used to disassociate the confounding effects of adaptation in constructing a lutrine phylogeny for 9 of the 13 extant species (Fig. 1). These data demonstrate that earlier phylogenies based solely on morphology were grossly inaccurate. The molecular analysis indicates three primary clades, including: (1) the North American river otter (*Lontra canadensis*), neotropical otter (*L. longicaudus*), and marine otter (*L. felina*); (2) the sea otter (*Enhydra lutris*), Eurasian otter (*Lutra lutra*), spotted-necked otter (*Lutra maculicollis*), cape clawless otter (*Aonyx capensis*), and small-clawed otter (*A. cinerea*); and (3) the giant otter (*Pteronura brasiliensis*). Fundamental life history differences (e.g., seasonal vs aseasonal reproduction; direct vs delayed implantation) between Eurasian and North American river otters, species once thought to have formed only after the late-Pleistocene isolation of Asia and North America, make much more sense under the molecular phylogeny. The pattern of long terminal branches and short internal branches in the phylogenetic tree further suggests rapid evolutionary radiation of the otters. Estimates of divergence time indicate that the clades containing *Pteronura* and *Lontra* had separated by the late Miocene. This phylogeny also suggests that sea otters, the only fully marine otter and the most distinctive of all otter species in terms of their morphology, physiology, and behavior, diverged recently but have taken on these different characters because of strong selection imposed by life in the sea. Lutrines appear most closely related to the extant *Mustela* (mink, weasels, and polecats), although whether the otters originated from one or multiple radiations of this group remains uncertain.

II. Marine Otters

At least 6 of the 13 extant otter species are fully or partially marine living (Fig. 2). All of the marine living species or populations occur at high latitudes. Sea otters (North Pacific Ocean) and the chungungo (*Lontra felina;* southeast Pacific Ocean) are the only lutrines that feed exclusively in the sea. Sea otters range from the northern Japanese archipelago, across the rim of the Pacific to about central Baja California, Mexico. Chungungos range along the west coast of South America from Peru to southern Chile. Sea otters typically rest and give birth at sea where chungungos only enter the sea briefly to hunt. Chungungos often go ashore to eat their prey, rest, give birth, and rear their young in dens formed in rocky areas just above high

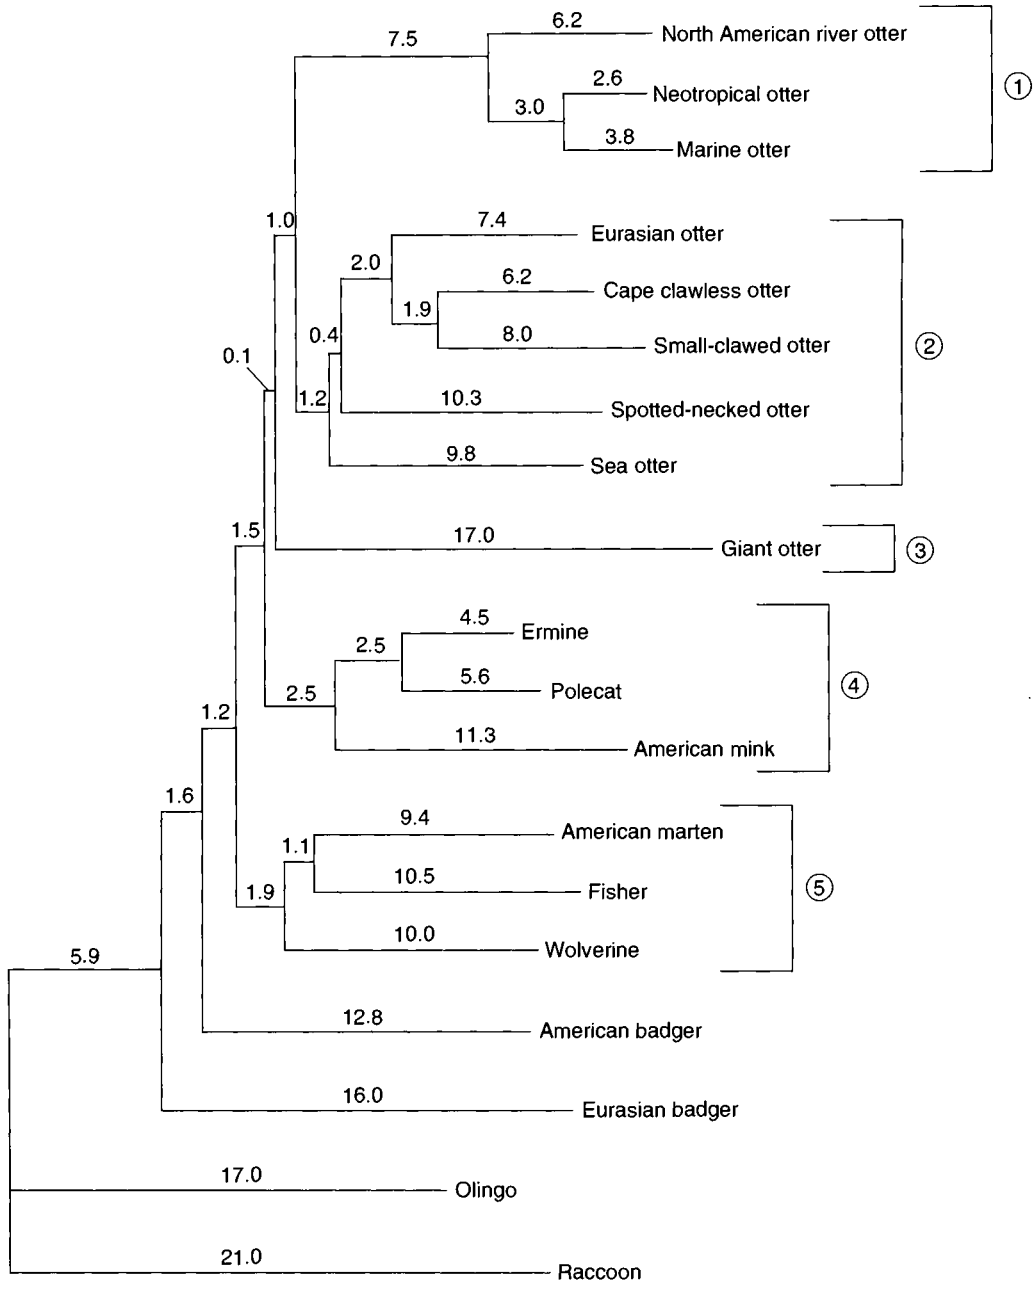

Figure 1 *Phylogeny of the otters. Marine otter is* Lontra felina; *Olingo is* Bassaricyon. *For numbers, see text. From Koepfli and Wayne (1998).*

water. Sea otters occupy a broad range of habitats, from protected bays to exposed outer shores, whereas chungungos occur only along exposed shorelines. Marine living populations of *Lontra provicax* occur in the protected inner waters of coastal Chile and southern Argentina. Marine living populations of North American otters occur northward from about San Francisco in the Pacific and Martha's Vineyard in the Atlantic. Marine living populations of Eurasian otters have a roughly similar latitudinal distribution (from about Portugal northward to northern Scotland and Scandinavia in the North Atlantic; from Japan into Russia in the North Pacific). Marine living populations of cape clawless otters occur in the southernmost regions of South Africa. Tropical lutrines, in contrast, rarely enter the sea.

While marine living species or populations of otters occur only at high latitudes, freshwater living otters occur over a much broader latitudinal range: from the most poleward ice-free environments to the tropics in the northern and southern hemispheres of both the Old and the New worlds. These distributional differences between marine- and freshwater-living otters probably relate to latitudinal differences in production between

Figure 2 *Geographical distributions of marine-living otters.*

freshwater and coastal marine habitats, and the fact that otters have secondarily entered the sea from their primitive freshwater environments. At low latitudes, freshwater production exceeds that of the ocean, whereas at high latitudes this pattern is reversed. This production gradient may have drawn the primitively freshwater living otters into the sea at high latitudes. The most compelling evidence for the proposal is provided by Hans Kruuk's comparative study of freshwater and marine living populations of Eurasian otters in northern Scotland. Kruuk found that marine living populations are able to meet their energy requirements by 2–3 hr of fishing per day, whereas those living in freshwater must double to triple the time investment in foraging to meet their energy requirements. Remarkably different population densities of marine and freshwater living otters further indicate that production and food availability are superior in coastal marine habitats. Reported densities for Eurasian and North American river otters in rivers and streams at high latitudes range between about 1 and 5 individuals per 10 km. Marine living populations of these same species are about fivefold greater, and sea otter densities range from 60 individuals per 10 km shoreline in California to >300 individuals per 10 km shoreline in the Aleutian Islands. These data indicate that otters at high latitudes maintain higher population densities in the sea than they do in freshwater and that freshwater habitats are only marginally capable of producing enough food to meet their energy requirements.

Different population densities of otters in freshwater and marine environments appear to have influenced the evolution of social behavior. Low-density freshwater environments afford little or no opportunity for males to compete for females; consequently, all of the freshwater living otters appear to have monogamous or promiscuous mating systems. In contrast, the elevated production and resulting high female densities may have driven sea otters to their strongly polygynous mating system.

III. Status and Trends

Except for the sea otter, there is little current information on the status and trends of marine living otter populations. The chungungo, listed in IUCN's "Red Data Book," is believed by some authorities to be threatened with EXTINCTION. Illegal harvesting for fur, habitat destruction in the form of deforestation, mining, and pollution, and competition with fisheries are thought to be the species' main threats. Chungungos are rare from Peru southward through central Chile, but there are conflicting reports on their abundance from Chiloe Island southward to Cape Horn.

North American river otters are common to abundant along much of the west coast of North America. Their abundance along the Atlantic coast of North America is uncertain, and information on population trends is lacking for both areas. Eurasian otters are common in marine habitats of Europe and Russia, especially from Norway to Scotland in the eastern North Atlantic. However, as for marine living river otters in North America, information on the status and trends of these populations is lacking. Coastal populations in Asia are practically unknown. The status and trends of marine living populations of southern river otters and cape clawless otters are unknown or unreported.

IV. The Sea Otter

A. History

Species resembling modern sea otters (based on body size and dentition) had arisen by the Miocene. There are two recognized lineages, one of which led to the extinct *Enhydriodon* and the other of which led to *Enhydritherium* and presumably to modern sea otters, *Enhydra* spp. Members of both lineages possessed large flattened molars for crushing the exoskeletons of their invertebrate prey. Fossil remains of these early sea otters are known from North America, Eurasia, and Africa. The distribution of modern sea otters, which apparently arose during the late Pliocene or early Pleistocene, was restricted to the north Pacific Ocean (Fig. 3). One extinct species, *E. macrodonta*, is described from the late Pleistocene of California.

Aboriginal maritime hunters apparently depleted sea otter populations, as evidenced by the character of faunal remains in Aleut kitchen middens. However, judging from the large numbers of otters encountered by European fur hunters at the time

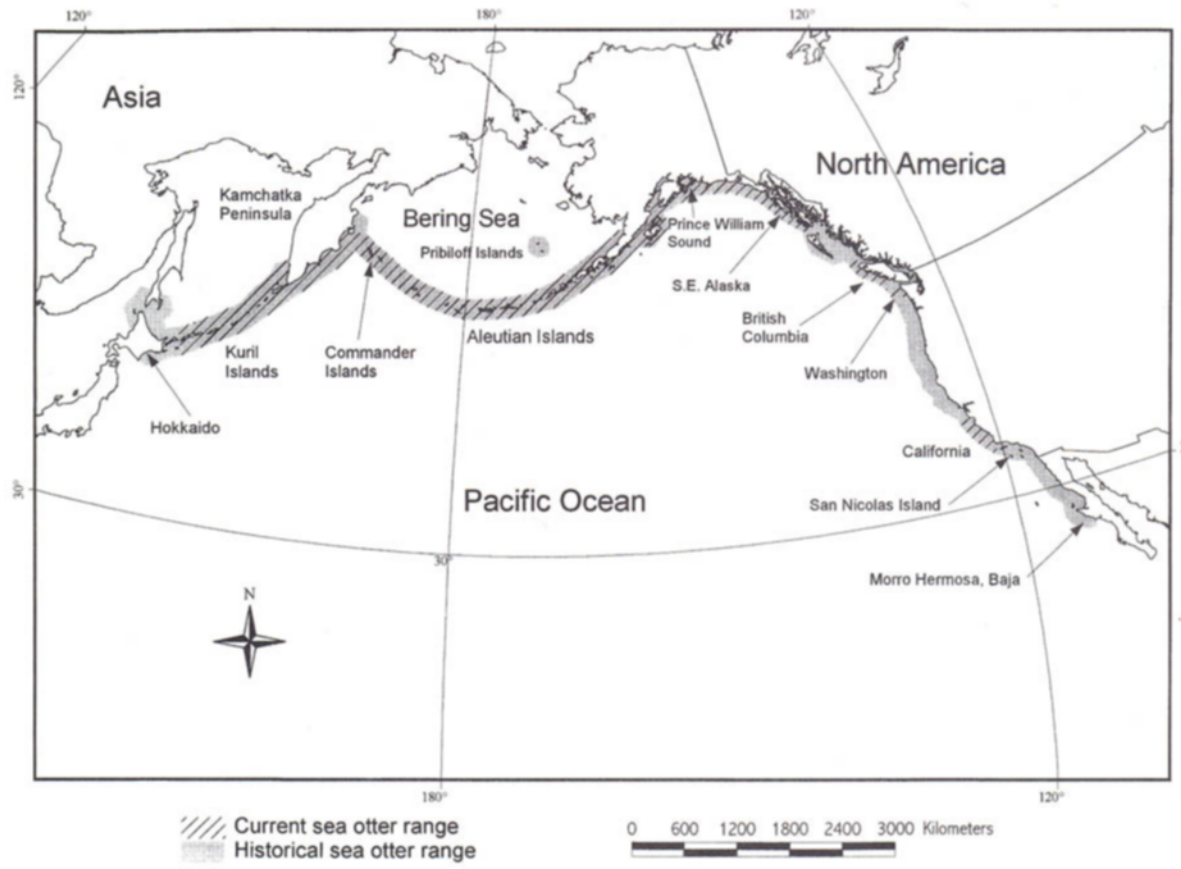

Figure 3 *Historical and current distribution of sea otters in the North Pacific Ocean. Modified from Kenyon (1969).*

of their first contact with aboriginal peoples, these reductions probably were limited to village sites. Sea otter populations subsequently were hunted to near extinction between 1750 and 1900 in the Pacific maritime fur trade. About a dozen remnant colonies in total containing no more than a thousand or so individuals survived into the early 20th century. Following protection in 1911, these colonies increased and several had again reached historical levels by the late 1930s or early 1940s. Reintroductions were undertaken in the 1960s and 1970s to reestablish sea otters in Southeast Alaska, British Columbia, Washington, and Oregon, and sea otters were relocated to San Nicolas Island (southern California) in 1987. Most of the translocated populations increased at rates of 17–20% per year, about the theoretical maximum (R_{max}) for sea otters. The California sea otter population has increased at a much lower rate: about 5% per year. Although precise reasons for the slow population growth in California sea otters are uncertain, the general cause is elevated mortality rather than reduced fertility. All or most of the sea otter's range in Asia is now reoccupied. Several populations in the Kuril and Commander islands had recovered to historical levels by the 1970s or 1980s.

While sea otter populations generally have increased in number and range during the 20th century, there are exceptions. In apparent response to increased killer whale predation, sea otter populations across the western and central Aleutian archipelago declined by roughly 90% during the 1990s. The geographical extent of this decline is uncertain. Several thousand sea otters were killed by the *Exxon Valdez* oil spill in 1989, and while the overall impact of this event on the population is unclear, chronic detrimental effects appear to have persisted through the 1990s. The California sea otter population, which increased slowly throughout most of the 20th century, has since declined by about 12%. The reintroduced population at San Nicolas Island, after declining sharply because of emigration, has remained roughly stable at 15–25 individuals since the early 1990s. Reintroduced sea otter populations in Southeast Alaska, British Columbia, and Washington all continue to increase in numbers and range.

B. Morphology and Physiology

Little is known about vision and hearing in sea otters. However, they are difficult to approach from upwind, thus suggesting sensitive olfaction. Sea otters appear to sense estrous females and territorial males by moving to a downwind position from other animals. Adult male sea otters may locate estrous females by following water-borne scents. Upon entering a group of conspecifics, sea otters often perform a ritualized greeting that appears to involve scent recognition. They have a complex vocal repertoire and at least one vocal modality, the scream, is recognizably distinct among individuals.

The high thermal conductivity of water presents severe challenges to aquatic mammals. This is especially so for small species (because of high surface/volume ratios) at high latitudes or in areas of intense upwelling (because of the cold water). The high capacity for heat loss probably explains why so few marine mammal species are small. As the smallest fully aquatic mammal, sea otters face an especially severe thermal challenge because they spend all or most of their lives immersed in cold water. This challenge has somehow been met by increasing heat production or reducing heat loss. Like other mustelids, the basal metabolic rate of sea otters is well above that predicted from the Kleiber curve, and sea otters gain additional heat by the specific dynamic activity (SDA) of digestion. Sea otters lack the BLUBBER layer that insulates cetaceans and pinnipeds, instead depending on their dense fur. Although fur in air is a superior insulator to blubber, it has three disadvantages in water: high maintenance costs, the inability to regulate heat flow, and compressibility at depth.

In order to maintain the fur's insulation, sea otters must groom almost continuously, an activity that consumes up to 10% of their time. Because fur (in contrast to blubber) is an inflexible insulator, sea otters require some means of facilitating heat loss during exercise. This apparently is accomplished mainly through the enlarged rear flippers, which are sparsely furred and high vascularized. The sea otter's flippers also may absorb heat from solar radiation. The compressibility of fur causes it to lose volume, and hence insulative value, with increased depth. The rate of heat loss is doubled at a depth of about 10 m (the equivalent of two atmospheres) and is essentially unrestricted during deep dives. Water conservation also presents a challenge to sea otters because they feed primarily on marine invertebrates, which are isotonic to seawater. They meet this challenge with a large and efficient kidney.

Like all marine mammals, sea otters must dive to feed. This poses three problems: oxygen debts are incurred, with associated changes in CO_2 concentration and pH; lactate buildups occur during prolonged, anaerobic dives; and rapid and extreme pressure forces nitrogen from the lungs into blood and other tissues, resulting in nitrogen toxicity and "the bends." Although sea otters do not dive to such extreme depths as many other marine mammals, they are considerably better divers than other otter species, being able to attain depths in excess of 100 m. The respiratory system is appropriately modified for deep diving. For instance, the tracheal length–width ratio is less in sea otters than in river otters, thus permitting more rapid and complete air exchange before and after a dive. Like the pinnipeds, sea otters have cartilaginous airways that empty directly into their alveoli, thus ensuring patency until alveolar compression collapse during deep dives. Sea otters also have comparatively large lungs that provide both oxygen storage and increased buoyancy. Although the sea otter's blood hemoglobin concentration is similar to that of most terrestrial mammals and less than that of most phocid seals, oxygen–hemoglobin affinity in the sea otter is relatively high, thus increasing their blood–oxygen storage capacity.

C. Locomotion

Locomotor efficiency of the semiaquatic otters is reduced on both land and in the water compared with fully terrestrial or fully aquatic mammals (Fig. 4). Among the lutrines, sea otters possess the most extreme modifications for aquatic propulsion. These include enlarged, flipper-like hindlimbs, a loosely articulated skeleton that permits increased flexibility, reduced forelimb length, and an increased tendency toward body movement and away from paddling in swimming.

The sea otter has retained a limited degree of terrestrial mobility while exhibiting morphological adaptations for improved aquatic locomotion. They rarely leave the water in some areas, whereas in others they haul out regularly. In rare instances, when sea ice prevents foraging north of the Alaska Peninsula, sea otters travel many kilometers inland in an apparent attempt to reach the Pacific Ocean.

Two types of terrestrial LOCOMOTION—walking and bounding—follow the pattern typical of terrestrial carnivores. In walking, the general motion is one of forward movement of alternate limbs in a rolling gait parallel to the long axis of the body. The head and neck are held close to the ground and the back may be horizontal, with the abdominal region contacting the ground, or the back may be arched. In some instances, sea otters pull themselves along the substrate with their fore paws. Running, described in *Lontra* spp. as a rapid forward movement in the same pattern as walking, has apparently been lost in the sea otter. Rapid movement of the sea otter on land is accomplished through bounding, where both forelimbs are moved forward simultaneously followed by simultaneous forward movement of the hindlimbs. During the bounding motion the back is usually highly arched. A maximum velocity on land of about 5 m/sec can be achieved in short bursts.

There are three forms of aquatic locomotion. Two of these are used predominantly while on the sea surface. One is accomplished by a sweeping motion of the tail and is used for

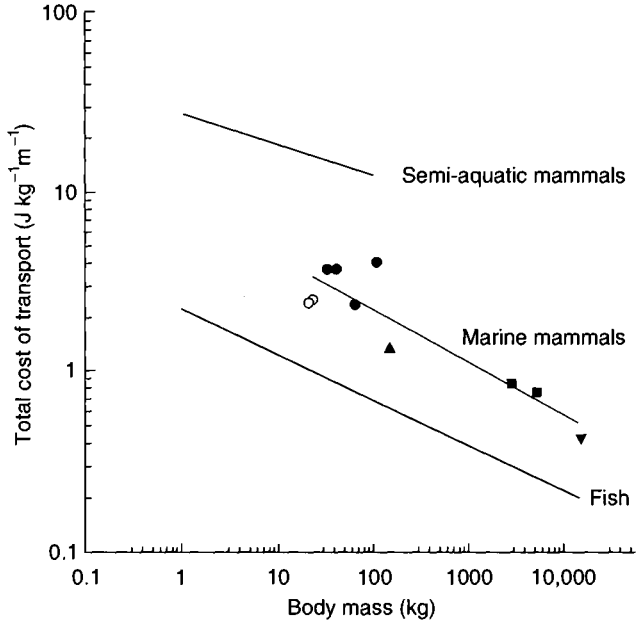

Figure 4 *The cost of transport for terrestrial, semiaquatic, and full aquatic mammals. From Williams (1999).*

slow movement while feeding, grooming, and maintaining its position while resting. The other, a paddling motion, consists of vertical thrusts and recovery of the hindlimbs while in either a supine or a pronate position. This type of movement is typically used during long-distance travel and may be interspersed with submerged travel, grooming, or foraging behavior. Paddling velocities range from about 0.5 to 1.0 m/sec.

A third means of aquatic locomotion in sea otters is accomplished by craniocaudal thrusts of the pelvic limbs, often including bending of the lumbar, sacral, and caudal regions for increased speed. This movement is used in diving. While swimming, the posterior margins of the hind flippers approximate the lunate pattern and undulating movement of the caudal fin of cetaceans. The sea otter loses swimming efficiency in the resistance and turbulence during the recovery stroke and through spaces between the flippers and tail.

Travel velocities over short distances (<3 km) range from about 0.5 to 0.7 m/sec, with a maximum of about 2.5 m/sec. Estimated average rates of travel over long distances (10–75 km) range from 0.16 to 1.5 m/sec. Submerged swimming speeds average about 1.0 m/sec.

D. Diving

Diving occurs during grooming, traveling, and foraging activities. Grooming dives usually occur before feeding or resting periods and are of short duration and shallow depth. Because locomotion is more efficient underwater than on the surface, otters frequently make relatively long (30–60 sec), shallow dives while traveling between resting and FEEDING areas.

The characteristics of foraging dives have been described at numerous locations within the sea otter's range. Two general types of data have been obtained: direct visual observations and remotely acquired information through radiotelemetry. Dive attributes from visual observations include dive duration, surface intervals between dives, and approximate water depths at the estimated dive locations. These data are inherently biased against animals foraging further from shore. Thus, estimates of average and maximum dive duration from animals instrumented with radio transmitters are substantially longer than those obtained visually.

Mean SWIMMING speeds during descent and ascent in foraging dives average about 1 m/sec. In California, average dive times vary with age and sex, with maximum values estimated from juvenile males and minimum values from adult females with dependent pups. The differences likely reflect differential habitat utilization, with juvenile males foraging in deeper water offshore and females with pups foraging in shallower water nearshore. Maximum reported dive durations are 246 sec in California and 260 sec in Alaska. Dive times and their interceding surface intervals correlate with water depth, although the deepest dives are not necessarily associated with maximum dive times. Surface intervals are highly correlated with prey size and type, with the longest intervals allied with the largest prey, thus reflecting associated increases in handling and consumption times. Sea otters commonly dive to depths exceeding 40 m in the Aleutian Islands, and there is one record of a sea otter drowned in a crab pot set in 91 m of water.

Information obtained using time–depth recorders (TDRs) from Southeast Alaska further indicates individual- and gender-related differences in mean and maximum foraging dive depth distributions. Generally, adult females dive to shallower depths than adult males, although some females regularly dive to depths exceeding 60 m. Most adult males foraged at depths between 40 and 60 m, although several repeatedly dove to depths exceeding 60 m. Maximum respective dive depths were 76 and 100 m for females and males, respectively.

E. Feeding Ecology

With a few notable exceptions, sea otters forage on sessile or slow-moving invertebrates from soft sediments, rocky reefs, and kelp canopy habitats (Table I). Prey are captured mainly with the forepaws rather than in the mouth. VISION probably is used to capture highly motile prey, such as fish. However, the fact that sea otters forage at night, in highly turbid water, and at great depths suggests that vision is not a requisite sensory modality for successful feeding.

Sea otters use their enlarged molariform teeth to crush the exoskeletons of their invertebrate prey. Tool use has developed in both the sea otter and Cape clawless otter as a further aid to foraging. This is accomplished by using rocks or other hard objects to break open the exoskeletons of their invertebrate prey. Tool use is unknown in all other mammals, except primates. Tool use renders any marine invertebrate, regardless of size or shell thickness, vulnerable to sea otter predation.

Foraging for infauna requires excavation of sediments, accomplished by digging with the forepaws while offsetting the effects of neutral buoyancy with the hind flippers. Excavations for burrowing clams may be up to 1 m in depth and require displacement of large amounts of sediments. Sea otters also obtain prey by pirating it from conspecifics. Territorial males most commonly employ this method by stealing food from females that forage within their territories.

While more than 150 prey species are known to be consumed by sea otters, only a few of these predominate in the diet, depending on location, habitat type, season, and length of occupation. In California, otters foraging over rocky substrates and in kelp forests mainly consume decapod crustaceans, gastropod and bivalve molluscs, and echinoderms. In protected bays with soft sediments, otters mainly consume infaunal bivalves (*Saxidomus nuttalii* and *Tresus nuttalltii*), whereas along exposed coasts of soft sediments, *Tivela stultorum* is a common prey. Important prey in Washington include crabs (species of *Cancer* and *Pugettia*), octopus (*Octopus* sp.), the intertidal clam (*Prototheca* sp.), sea cucumbers (*Cucumaria miniata*), and the red sea urchin (*S. franciscanus*). Less frequently recovered prey include the gumboot chiton (*Cryptochiton stelleri*) and the purple sea urchin (*S. pupuratus*). The predominantly soft sediment habitats of southeast Alaska, Prince William Sound, and Kodiak Island support populations of clams that in turn are the primary prey of sea otters. Throughout most of southeast Alaska, burrowing bivalve clams (species of *Saxidomus, Prototheca, Macoma,* and *Mya*) predominate in the sea otters diet, accounting for 50% of the identified prey. In Prince William Sound and Kodiak, clams account for 34–100% of the otter's prey. Mussels (*Mytilus trossulus*) apparently become more important as the length of occupation by sea otters increases, ranging from 0% at newly occupied sites at Kodiak

to 22% in long occupied areas. Crabs (*C. magister*) were once important sea otter prey in eastern Prince William Sound, but apparently these have been depleted by otter foraging and thus are no longer eaten in large numbers. Sea urchins are minor components of the sea otter's diet in Prince William Sound and the Kodiak archipelago. In contrast, the sea otter's diet in the Aleutian, Commander, and Kuril Islands is dominated by sea urchins and a variety of fin fish (including hexagrammids, gaddids, cottids, perciformes, cyclopterids, and scorpaenids). Sea urchins tend to dominate the diet of low-density sea otter populations whereas fishes are consumed in populations near equilibrium density. For unknown reasons, fish are rarely consumed by sea otters in regions east of the Aleutian Islands.

Sea otters also take advantage of episodically abundant prey. Examples include squid (*Loligo* sp.) and pelagic red crabs (*Pleuroncodes planipes*) in California and smooth lumpsuckers (*Aptocyclus ventricosus*) in the Aleutian Islands. Pelagic red crabs appear in coastal waters of southern and central California during strong El Niño events, and vast numbers of lumpsuckers appear episodically in coastal waters of the western and central Aleutian Islands to spawn. Sea otters, on occasion, attack and consume sea birds, including teal, scoters, loons, gulls, grebes, and cormorants.

Dietary diversity increased through time as otter populations recolonized new habitats and grew toward resource limitation. Similar patterns of increased dietary diversity have been chronicled in the Aleutian Islands, Prince William Sound, and California. These changes are probably the consequence of otters reducing the abundance of their preferred prey.

Studies of marked sea otters in California have shown extreme individual variation in diet and foraging behavior. Most otters specialize on one to three prey types. This individual variation does not appear to be directly influenced by prey availability as different individuals often consume different prey at the same time and place. Dietary patterns, which appear to be inherited matrilineally, persist for years and may be lifelong characters of individuals. The causes and consequences of individual foraging patterns remain uncertain.

F. Community Ecology

1. Food Web Effects In 1960, Hairston, Smith, and Slobodkin proposed that "the world is green" because predators regulate herbivore populations, in turn releasing plants from regulation by herbivory. Sea otters and kelp forests provided early empirical support for this hypothesis. The sea otter's role in structuring kelp forest communities was discovered by contrasting islands in the Aleutian archipelago at which the species was present in large numbers or absent, a serendipitous consequence of the Pacific maritime fur trade. Shallow reef habitats at islands with abundant sea otters had few sea urchins and well-developed kelp forests, whereas abundant sea urchins had destroyed the kelp forests at islands lacking sea otters (Fig. 5). The explanations for this pattern is a straightforward consequence of what has since come to be known as a "trophic cascade." That is, sea urchin populations are regulated by sea otter PREDATION, in turn allowing the kelp forest to flourish in the absence of significant herbivory. When otters were removed,

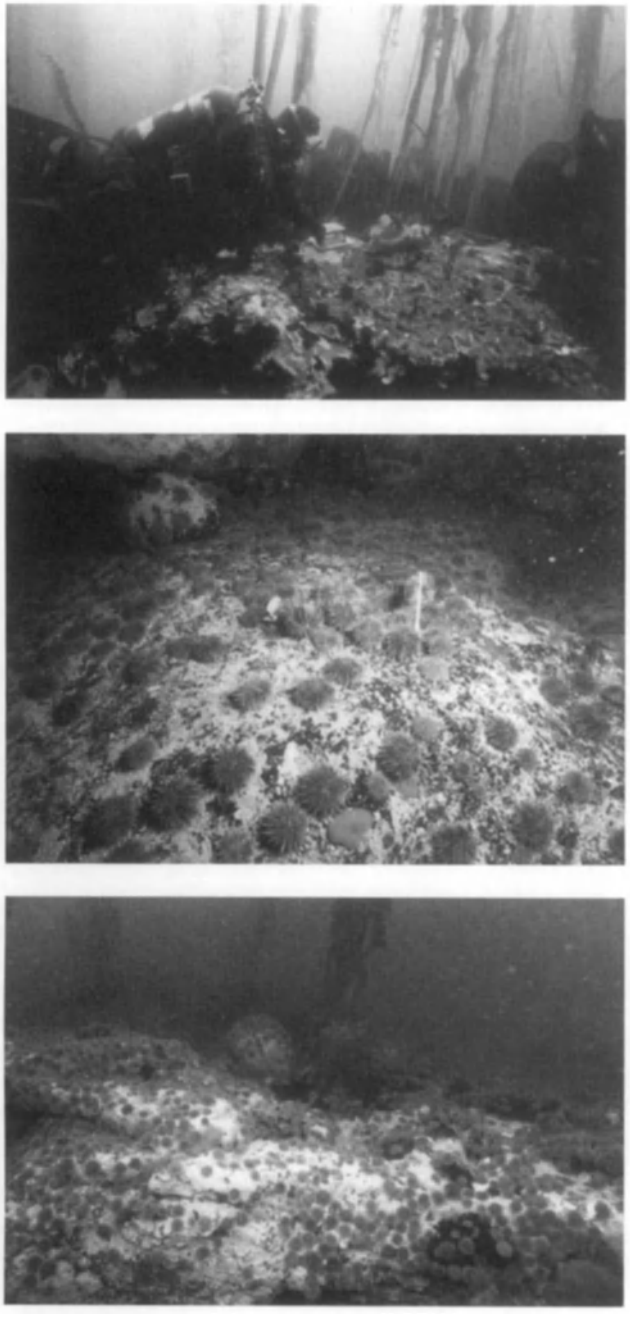

Figure 5 *Alternate community states in areas with (kelp forests) and without (sea urchin barrens) sea otters. Photographs were taken of reef habitats at about 10-m depths in the western Aleutian Islands.*

sea urchins increased to such levels that deforestation occurred. Similar patterns between areas with and without sea otters have since been documented in Southeast Alaska, British Columbia, Washington, and California. Time series studies of areas in which sea otters have become reestablished or declined provide further evidence that the presence or absence of sea otters maintains these alternative states of community organization. Similar trophic cascades resulting from the effects of apex predators are now known for many systems.

Numerous indirect effects of the sea otter–urchin–kelp trophic cascade are known or suspected (Fig. 6). Most of these relate to the role of kelp as habitat and a source of production for other species of consumers in coastal food webs. The kelps (order Laminariales) and other species of macroalgae are extremely productive, in large measure because none of the essential ingredients for photosynthesis (light, water, CO_2, and nutrients) are limiting in shallow coastal waters at high latitudes. Thus, systems with and without sea otters (and thus with and without well-developed kelp forests) vary substantially in total productivity. This fact was confirmed using the naturally occurring stable carbon isotopes to measure the relative photosynthetic contributions of macro- vs microalgae across islands of the Aleutian archipelago with and without sea otters. Total production was estimated to be three to four times greater where sea otters were present. Further tests of the otter-productivity hypothesis were done by outplanting recently settled barnacles and mussels from a common source to intertidal and subtidal habitats at islands with and without sea otters. Growth rates were two to five times greater in otter/kelp-dominated systems.

The limiting effects of otters on sea urchins and other herbivorous invertebrates reduce the disturbance from herbivory, thus enhancing the strength of competitive interactions among kelp species. This effect has been demonstrated in the Aleutian Islands, Southeast Alaska, British Columbia, and central California. Further indirect effects on higher trophic level consumers result from increased production, altered habitat, or competition with otters for common food resources. The production effects are so strong that they almost certainly influence numerous co-occurring species. Bald eagle (*Haliaetus leucocephalus*) and harbor seal (*Phoca vitulina*) densities are substantially greater on islands of the Aleutian archipelago that also support abundant sea otter populations. Radically different DIETS and patterns of foraging behavior occur in glaucous winged gulls (*Larus glaucescens*) between sites with and without sea otters. Sea otters also appear to influence the population densities of benthic feeding sea ducks. Common eiders (*Somateria mollissima*), which feed mainly on sea urchins, mollusks, and other benthic invertebrates, occur at higher densities where otters are rare or absent than where they are abundant. Otters also influence predator–prey interactions between sea stars and mussels in the Aleutian archipelago. The biomass of sea stars at Attu Island declined by roughly two orders of magnitude following the spread of sea otters into Massacre Bay along the island's southeastern shore, in turn substantially increasing the survival rates of mussels and barnacles. This example is of particular interest because the influence of sea star predation on mussel beds (enhanced species diversity by the predation-induced reduction in competitive exclusion by the dominant mussels) is one of the most well-known and influential paradigms in ecology. The influence of sea otters on kelp beds even appears to elevate the environmental carrying capacity for otters themselves. Although sea otters limit the abundance of their benthic invertebrate prey, coastal fish populations are enhanced by increased production and the habitat

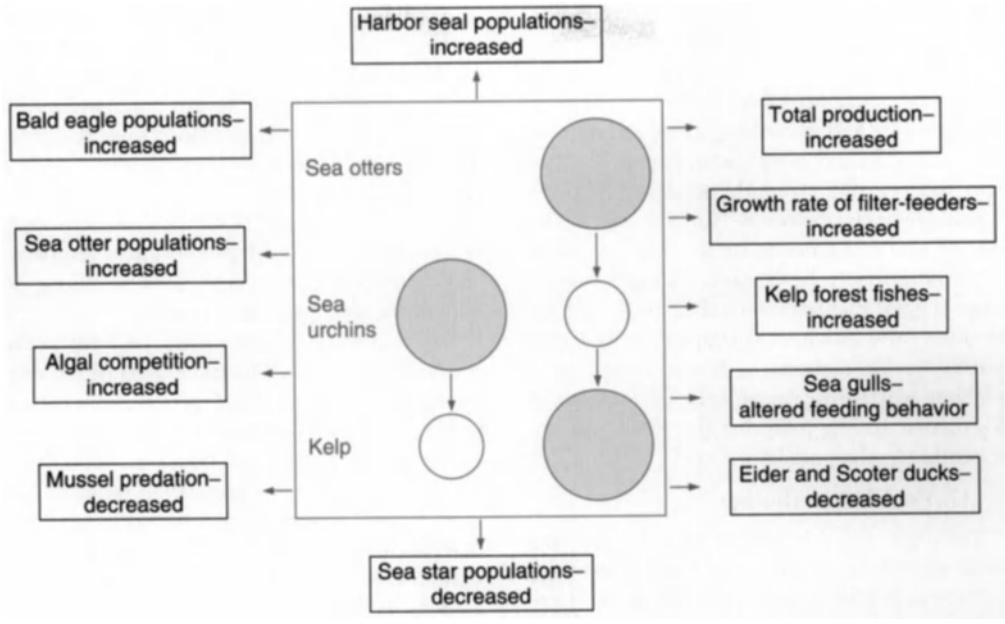

Figure 6 *A schematic of trophic cascades in kelp forest systems with and without sea otters (central box). Known or suspected indirect effects of these interactions are represented at the perhipheries.*

provided by kelp forests. Besides elevating the equilibrium density, this interaction may stabilize sea otter populations because the fishes are less vulnerable than benthic invertebrates to population regulation by sea otter predation.

The top-down influences of apex predators through trophic cascades have been incorporated into a conceptual model relating the strength of plant–herbivore interactions to trophic complexity (Fig. 7). The model predicts that plant–herbivore interactions should be strong in food chains with an even number of trophic levels (e.g., two, four, and so on) and relatively weak for odd-numbered food chains (e.g., one, three, five, and so on). The accumulated evidence from three decades of research on sea otters and kelp forests is highly consistent with that view.

2. Evolutionary Forces Strong species interactions maintained over sufficiently large scales of space and time should inevitably lead to selective responses in the interacting species. This expectation, coupled with predicted differences in the strength of plant–herbivore interactions between odd- vs even-numbered food webs, has led to a view that kelp forests in the North Pacific Ocean evolved in the absence of intense herbivory. While the kelps have no FOSSIL RECORD, a variety of evidence indicates that they radiated in the North Pacific Ocean during the late Cenozoic in concert with sea otters, their recent ancestors, and other groups of benthic feeding marine mammals. The hypothesis that predators decoupled the coevolution of kelps and their herbivores was evaluated by contrasting various features of marine plants, invertebrate herbivores, and plant–herbivore interactions between North Pacific and Australasian kelp forests. Australasian kelp forests were chosen for this contrast because they lack predators of comparable effect to sea otters. Because kelp forest systems in the North Pacific and Australasia, respectively, evolved as odd-numbered (three) vs even-numbered (two) systems, the coevolution of plant defenses and herbivore resistance to those defenses were hypothesized to be strong in Australasia and weak in the North Pacific.

Marine algae were known to use secondary metabolites as their chief defense against herbivory. Therefore, the initial test of this evolutionary hypothesis was to compare the diversity and concentration of secondary metabolites between North Pacific and Australasian seaweeds. This comparison demonstrated that phlorotannins (the principal secondary metabolites in brown algae) were roughly an order of magnitude more concentrated in southern hemisphere kelps, in some cases approaching 20% dry

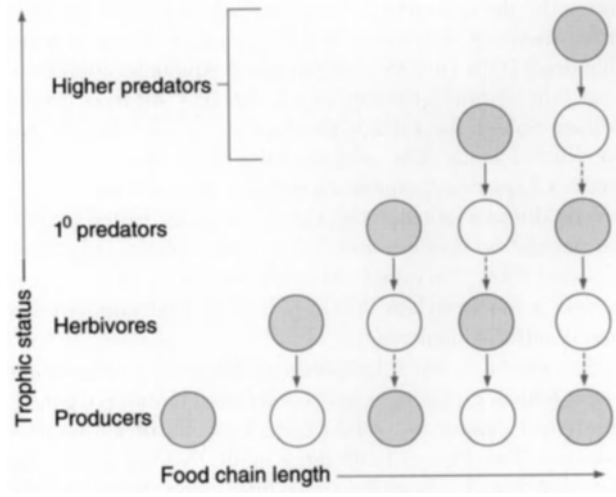

Figure 7 *Fretwell's (1987) model of alternating plant–herbivore interaction strength with increasing food chain length.*

weight. A second prediction of the hypothesis was that herbivore resistance to algal secondary metabolites is stronger in Australasian than in North Pacific species. This prediction was tested by extracting the metabolites from both North Pacific and Australasian seaweeds and measuring their strength of feeding deterrence to Pacific and Australasian herbivores. Regardless of their source, the strength of deterrence by phlorotannins was dramatically greater on North Pacific herbivores, thus suggesting that resistance to these compounds had evolved in southern hemisphere herbivores. This perspective and supporting data suggest that sea otters, their recent ancestors, and perhaps other predators have decoupled the coevolution of plant–herbivore interactions in North Pacific kelp forests, thus explaining why North Pacific kelp forests were so vulnerable to destructive grazing following the demise of sea otters and other benthic feeding predators.

G. Population Biology

1. Genetics Sea otters provide unique opportunities for the study of marine mammal population and conservation genetics. The sea otter's dependency on benthic/demersal habitats and limited diving capacity restrict its distribution to shallow coastal environments. Its small home ranges (generally <20 km of coast) probably restrict gene flow. Extensive human harvests reduced and fragmented sea otters into a small number of isolated colonies, from which all current populations are derived. Additionally, translocations from either one or two remnant populations have resulted in viable reestablished populations in Washington, British Columbia, and Southeast Alaska. Pleistocene glacial advances and retreats likely influenced genetic exchange. Isolation and extinctions caused by ice sheets extending over large coastal areas probably resulted during glacial maxima, whereas high levels of gene flow must have occurred as these areas were recolonized during periods of glacial retreat. Both morphological and genetic examinations of sea otters indicate some level of population structuring prior to 18th and 19th century fur harvests.

Sea otter skull size declines from Russia, across Alaska, and into California, and variation in skull morphology forms the basis for the three currently designated subspecies: Russia, *E. l. lutris;* Alaska, *E. l. kenyoni;* and California, *E. l. nereis.* Mitochondrial DNA (mtDNA) haplotype frequencies identify at least four distinct grouping of sea otters: California, Prince William Sound, the Kodiak/Aleutian/Commander Islands, and the Kuril Islands. The magnitude of difference in current mtDNA haplotype frequencies suggests at least some level of genetic differentiation among these groupings existed prior to the population declines and isolation that occurred between 1750 and 1900. The extant California population probably represents a monophyletic mtDNA lineage that contains two unique mtDNA haplotypes.

The extent to which long-term evolutionary processes and recent human exploitation have contributed to modern genetic differences among and within the subspecies of sea otters is unknown. The degree of difference in mtDNA haplotypes suggests that there has been little gene flow across the range of the species from California to the Kuril Islands of Russia. However, low levels of mtDNA sequence divergence in sea otters across their range also suggest that major phylogenetic breaks or long-term barriers to gene flow do not exist.

There is concern over the potential for loss of genetic diversity stemming from severe population bottlenecks experienced by sea otter populations over the past two centuries. However, theoretical analyses suggest that as little as 23% of the original genetic variation was lost from the California population because of this bottleneck effect. Subsequent empirical studies show that a high proportion of diversity was maintained during the period of recent isolation among populations, thus supporting this theoretical result.

Reintroduced and remnant sea otter populations provide the opportunity to study the effects of the duration and magnitude of bottlenecks on genetic diversity and population growth rates. In sea otters, mtDNA haplotype diversity is significantly correlated with both minimum population size and the number of years a population remained at that minimum size. No relationship was detected between genetic diversity and population growth rates, although translocated populations demonstrated significantly higher annual growth rates (λ = 1.18–1.24) than remnant populations (λ = 1.06–1.09). Genetic diversity is greater in translocated populations that were derived from two source populations compared with those derived from a single source population. Haplotype frequencies in populations with estimated founding sizes of 4 and 28 animals (Washington and British Columbia) differed from the source populations, probably signaling the effect of genetic drift. This interpretation is supported by the fact that haplotype frequencies from sea otters in Southeast Alaska, a translocated population with an estimated founding size of 150 individuals, did not differ from the source populations.

As sea otters continue to reoccupy former habitat, and currently isolated populations become contiguous, we may be afforded the opportunity to view the process of genetic exchange across the species' range. Genetic differences currently observed among geographically isolated populations may diminish, reducing current levels of genetic population structure.

2. Demography As in all sexually reproducing species, sea otter populations are regulated by age- and sex-specific rates of reproduction and survival. These life history patterns in sea otters are more similar to those of the pinnipeds (with whom they share the ocean as a common environment) than they are to the other lutrines (with whom they share a more recent common ancestor). Perhaps the most remarkable life history feature of sea otters is that they almost invariably conceive and give birth to a single young, a character shared with other marine mammals but not other lutrines (Fig. 8).

Female sea otters typically become sexually mature at 3 years, occasionally earlier. The reproductive cycle is normally 1 year, with roughly 6 months from conception to birth and another 6 months from birth to weaning. Substantial learning occurs during this latter period. Primiparous females usually fail to successfully wean their pups, probably because they have not yet learned to be good mothers. Adult females apparently enter estrus within several hours to a few days after mother/pup separation (either from weaning or death). The majority of preweaning deaths occur shortly after birth. Thus, in many areas there

Figure 8 *A female sea otter with her pup.*

is a biannual peak in births, with the primary peak occurring in spring or early summer and the secondary peak (by females who failed in their previous cycle) in fall or early winter. Females continue to reproduce throughout life, with little or no evidence for either reproductive senescence or adjustments of fertility rate to environmental variation.

Population regulation in sea otters occurs largely or exclusively through variation in age- and sex-specific mortality rates. The high rates of population growth that have been observed in parts of Alaska, Canada, and Washington (17–20% per year, near the theoretical R_{max}) could only be realized if the probability of mortality from birth to senescence were very low. As growing populations become limited by resource availability, the mortality rate in young otters increases greatly. Data from the Aleutian Islands and central California indicate that about half of the pups born fail to reach weaning age. The probability of mortality during the next 6 months, while as yet unmeasured, also seems to be relatively high. Mortality rates from about 1 year of age to physiological senescence (10–15 years) are low, even in food-limited populations. Thus, the principal mechanism of population regulation in sea otters appears to be starvation-induced mortality early in life.

Although the sex ratio at birth is about 50:50, the postweaning mortality rate is greater in males than in females, thus resulting in a female-biased adult sex ratio. The elevated male mortality probably is caused by aggressive interactions with adult males, thus forcing juvenile males to disperse into lower-quality habitats. These mortality patterns are reflected in the age and sex composition of beach-cast carcasses at locations where populations are at or near equilibrium density. In California, the age composition of beach-cast sea otter carcasses more closely resembles the age structure of living populations, thus indicating an elevated mortality rate of prime-age animals. Because of the generally similar age-specific birth rates across all sea otter populations, this elevated mortality in prime-age animals is responsible for a depressed growth rate in the California sea otter population.

H. Behavior

The behavioral ecology of sea otters strongly reflects life in the sea. Vigorous grooming is the species' behavioral hallmark. Sea otters probably spend more time and energy grooming their fur than any other mammal. This is accomplished by rubbing, rolling, blowing, and splashing. Grooming is necessary for cleaning and replenishing air to the under fur.

Sea otters are unusual among both carnivores and marine mammals in the generally small size of their home ranges, which typically includes no more than several miles of shoreline. Both males and females occasionally move longer distances for uncertain reasons. Extralimital sightings in central Baja California and near Wrangel Island in the Chuchi Sea demonstrate that, on occasion, individual sea otters move hundreds of miles.

Adult male sea otters maintain territories that in California average about 40 hectares. Adult females apparently move freely among these territories, but the territory holder aggressively excludes juvenile males. The precise function of male territoriality in sea otters is unclear, although ultimately territories serve to increase reproductive success. Adult males frequently harass females with large pups in an apparent effort to force separation, thus inducing the female to enter estrus and bear his offspring. Copulation occurs repeatedly during brief consorts, after which the males and females separate. A male grasps the female's nose in his mouth and rolls vigorously on the surface of the ocean to achieve intromission. Distinctive nose scars in adult females often result from this behavior. In severe cases, trauma to the nose and facial region may result in death to the female. Some males seem especially prone to such brutality. Upon killing their mate, these males usually continue to copulate with the corpse, sometimes for days following her death. Adult male sea otters have been observed attempting to copulate with young harbor seals, in two such instances killing the seals during the process.

This sea otter's polygynous mating system (and the resulting high male libido) likely evolved in response to their unusually high population density, thus promoting male competition for females as the limiting resource in sexual reproduction. Polygynous mating systems are typical of all otariids and some phocids in temperate latitude systems but apparently are rare or absent in other species of otters. As is true for other polygynous species, male sea otters provide no parental care.

I. Conservation and Management

1. Asia The status of sea otter populations throughout most of Asia is uncertain. Sea otters currently occupy all of their historic range in Russia and have been reported from northern Japan. However, present-day abundance is believed to be less than during the preharvest period, as areas of low density occur along the Kamchatka Peninsula and northern Japan. Sea otters recolonized Bering Island, in the Commander Islands, in about 1983. This population continued to increase until 1990, at which time it declined by about 40%. The population has remained stable since that time at about 3500 individuals. Systematic surveys of sea otter populations have not been done throughout most of Asia as recent governmental change has resulted in dramatic reductions in support of CONSERVATION and research programs.

2. Alaska Remnant and reintroduced sea otter populations experienced rapid and widespread recovery during most of the

20th century, probably due in large measure to the superabundant prey resources that developed in their absence. In some areas these growing populations eventually attained levels where food or other resources became limiting. These patterns of recovery and growth have been heralded as one of conservation's great success stories. However, there are new concerns over the sea otter's long-term welfare.

A. OIL SPILLS AND OTHER FORMS OF MARINE POLLUTION. The *Exxon Valdez* oil spill killed large numbers of sea otters—the minimum mortality estimate was 750 individuals. Moreover, in the 10 years since the *Exxon Valdez* spill, sea otter populations in oil-impacted areas have recovered at an annual rate of 3.3% per year, far below the growth rate observed in this same population prior to the spill. This had led some to conclude that chronic effects from the *Exxon Valdez* spill continue in Prince William Sound.

In the early 1990s, high levels of PCBs were discovered in sea otters from the Aleutian archipelago. These now appear to be associated with past military activities in the area. Although concentrations measured in sea otter tissues exceed those known to be harmful in mink, presently there is no other evidence that they are having detrimental effects on sea otters.

B. HUMAN HARVESTS. Alaska natives are permitted to harvest sea otters for traditional purposes. Presently, most harvested animals are taken from Southeast Alaska and the Kodiak archipelago. There are no restrictions on take and large numbers are currently being removed from some populations. Sustainable harvest levels and take quotas need to be developed from life table data and the spatial ecology of individual otters. Quotas also should take into account the status and genetic structure of populations, and the availability of food and space.

C. DECLINE IN CENTRAL ALEUTIANS. During the 1990s the abundance of sea otters in the west-central Aleutian Islands has declined by about 80–90%. Available evidence indicates that these declines were caused by increased predation by killer whales. Killer whales may have switched from consuming pinnipeds to sea otters following the collapse of Steller sea lion and harbor seal populations in western Alaska during the late 1970s and 1980s. While the geographic extent of the sea otter declines appears to be large, additional surveys are needed to determine the range and magnitude of decline. As the result of these declines, sea urchin populations have increased, followed by a dramatic increase in the rate of herbivory and subsequent deforestation of the nearshore community (Fig. 9).

3. British Columbia The sea otter population in British Columbia continues to grow and expand its range. Conflicts with various shellfisheries are the primary concern of resource managers, whereas others believe that the population is still precariously small. Sea otter harvests have been proposed but at present are not permitted under either national or provincial law.

4. Washington/Oregon Like British Columbia, the Washington sea otter population continues to expand in numbers and range. From the relocation site near La Push on the outer coast, otters have spread around Cape Flattery eastward through the Straits of Juan de Fuca. These animals now occupy tribal waters of the Makah Indians and are rapidly depleting red urchin populations, which until recently supported a tribal fishery. Sea otters are presently absent from the coast of Oregon.

5. California California sea otters have long been the objects of debate and controversy. Fishery interests have maligned sea otters because they compete with humans for various commercial and recreational resources. Conservationists, however, have been concerned with the small size and slow growth rate of the California sea otter population. Increased trafficking of oil tankers and outer continental shelf oil development along the California coast have heightened concern that a spill might reduce or even extinguish the California sea otter population. For these reasons, the California sea otter population was listed as "Threatened" in 1977 under the U.S. Endangered Species Act. The U.S. Fish and Wildlife Service adopted a recovery plan for the California Sea Otter in 1981. Congress subsequently established Public Law 625 in an effort to both enhance the California sea otter population and protect shellfisheries. In 1987, under provisions of this law, sea otters were reintroduced to San Nicolas Island in southern California. The otter population at San Nicolas Island dwindled to about 15 individuals over the next several years, after which it remained relatively stable through the 1990s, despite the birth of at least 50 pups. Reasons for the growth failure of the population at San Nicolas Island are uncertain.

For most of the 20th century, the California sea otter maintained a slow but steady increase in numbers and range. There was a period of decline from the mid-1970s to the early 1980s, apparently resulting from increased losses in a coastal set net fishery. The population resumed growth almost immediately following the implementation of protective measures. The California sea otter population again began a gradual decline in the mid-1990s. Reasons for the current decline are uncertain. Reasonable possibilities include increased pollution and disease, incidental losses in fishing gear, and food resource limitation.

During this most recent period of numerical decline, the California sea otter's range expanded southward, thus resulting in large numbers of otters moving south of Pt. Conception into the "no-otter zone" established by PL 625. Shellfishery interests are presently demanding that these otters be removed, whereas conservation groups are demanding that something be done to curtail the ongoing population decline. The U.S. Fish and Wildlife has yet to decide how they will respond to this unfortunate dilemma.

6. Mexico Except for occasional wanders from central and southern California, sea otters are currently absent from the waters of Baja California.

V. Concluding Remarks

After having been hunted to the brink of extinction, sea otters have recovered dramatically. While the status of other marine living otters is less certain, these animals appear better off than their freshwater-living counterparts, many of which are in a very bad way because of human exploitation and various kinds of habitat destruction. The relative well-being of marine otters is thought to result from habitat destruction being less problematic

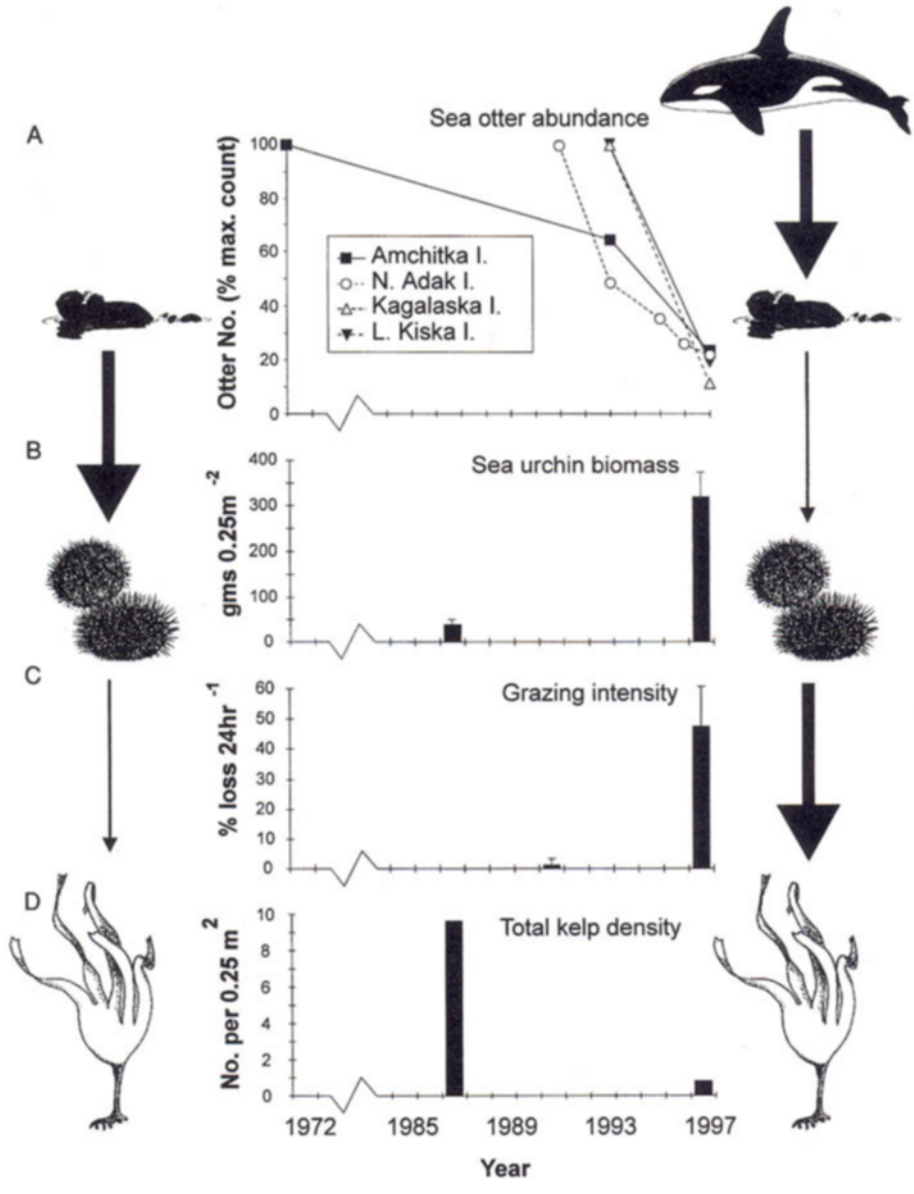

Figure 9 *Changes in sea otter abundance over time at several islands in the Aleutian archipelago, and concurrent changes in sea urchin biomass, grazing intensity, and kelp density measured from kelp forests at Adak Island. Error bars indicate 1 SE. The proposed mechanisms of change are portrayed in the margins: the one on the left shows how the kelp forest ecosystem was organized before the sea otter's decline and the one on the right shows how this ecosystem changed with the addition of killer whales, an apex predator. Heavy arrows represent strong trophic interactions; light arrows represent weak interactions. Reprinted with permission from Science 282, Estes* et al., *Killer whale predation on sea otters linking coastal with oceanic ecosystems, pp. 473–476. Copyright 1998 American Association for the Advancement of Science.*

in the sea than it is on land. While that may be true, coastal marine environments increasingly are the recipients of terrestrial pollution and are being overexploited by numerous fisheries. Furthermore, scientists are beginning to understand that the coastal zone is linked in important and complex ways with both the open sea on its one side and land on the other. The fact that people live in disproportionately high densities along the land–sea margin is a direct threat to coastal marine ecosystems and many of the species that depend on these systems. All of this does not bode well for the future of marine living otters. Overall, sea otters are far more abundant today than they were 50 years ago. However, the recent and ongoing declines of otter populations in Alaska and California may be among the first signs from these animals that coastal oceans are in peril.

In the process of recovery, expanding otter populations have come into conflict with fishery interests that developed during their absence. Similar conflicts surround other carnivores, but in few cases is the effect so apparent as it is with sea otters and shellfisheries. These conflicts strongly testify to the role apex predators often play in regulating their prey populations. Numerous other species and ecosystem-level processes are also influenced by the indirect effects of sea otter predation. Again, these examples have helped lead to the growing realization that apex predators often play complex but important roles in the maintenance of biodiversity, and thus that any affective strategy for biodiversity conservation must be sufficient to include viable populations of apex predators.

Pacific White-Sided Dolphin and Dusky Dolphin

Lagenorhynchus obliquidens and *L. obscurus*

KOEN VAN WAEREBEEK
Peruvian Centre for Cetacean Research, Lima

BERND WÜRSIG
Texas A&M University, Galveston

Because of their morphological similarities, the stocky dusky dolphin *Lagenorhynchus obscurus* from the Southern Hemisphere and the Pacific white-sided dolphin *Lagenorhynchus obliquidens* from the northern Pacific Ocean have long been recognized as phylogenetically closely related species despite the absence of a FOSSIL RECORD. Several researchers have gone so far as to suggest that the latter could almost equally well be regarded as a subspecies of the dusky dolphin. A close scrutiny of morphological and life history parameters, however, does not support this premise. Recent cytochrome *b* sequence analysis is consistent with the "sister-species" hypothesis, and the divergence date is estimated at 1.9–3.0 million years ago (Cipriano, 1997).

I. Pacific White-Sided Dolphin

Described in 1865 by Theodore Gill from three skulls collected in California, the boldly colored Pacific white-sided dolphin is black or dark gray on the back and posterior sides, as well as on the short snout, the leading edge of the tall dorsal fin, and the pointed flippers. The light gray thoracic patch is sharply delineated from the white belly by a thin dark line, in contrast with the dusky dolphin, which lacks this line and a sharp demarcation. Gray, linear dorsal flank blazes, often called "suspender stripes," project forward from the grayish flank patches along the back and disappear above the eyes (Fig. 1). The average adult size is 2.1–2.2 m with a body weight of 75–90 kg. Exceptionally, a length of 250 cm (males) and 236 cm (females) can be reached (Walker *et al.*, 1986) and a maximum weight of 181 kg, which is at least 50% heavier than the dusky dolphin.

A. Distribution

The mostly pelagic Pacific white-sided dolphin has a primarily temperate distribution across the North Pacific, from Taiwan to the Kurile and Commander Islands on the west and from 20–21°N to 61°N on the east, as well as more or less continuously across the North Pacific. Some seasonal shifts occur; while more common in coastal waters during fall and winter, these dolphins move offshore during spring and summer, in rough synchrony with movements of anchovy and other prey (Leatherwood *et al.*, 1984; Walker *et al.*, 1986).

No subspecies are recognized but either two or three populations are distinguished from the northeast Pacific and another two forms seem to exist in Japanese waters. *L. ognevi* named by Sleptsov in 1955 is a synonym of *L. obliquidens*.

Figure 1 *The Pacific white-sided dolphin* (Lagenorhynchus obliquidens) *is usually found in pelagic waters of the North Pacific. Photo by Robert L. Pitman.*

B. Behavior

These acrobatic dolphins often form large herds, averaging some 90 individuals, but groups of more than 3000 dolphins have been reported. Some segregation occurs based on sex and age. They readily associate with many other cetacean species and avidly BOW RIDE. Generalist feeders, off California and Japan, *L. obliquidens* mostly prey on lantern fishes (Myctophidae), anchovies, hake, and squid (Fitch and Brownell, 1968); off British Columbia they feed on herring, salmon, cod, shrimp, and capelin (Heise, 1997a). Males and females become sexually mature at 170–180 and 175–186 cm, respectively. The calving season peaks during the summer, the gestation period is 1 year, and females reach sexual maturity at an estimated 7.5 years old (Heise, 1997b).

C. Abundance and Exploitation

Pacific white-sided dolphins are still fairly numerous; however, like for most delphinids, no total abundance estimates are available. On the continental shelf off northern and central California in the mid-1980s, a population of 85,000 dolphins was proposed, but a 1991–1993 estimate for the same general area amounted to only 11,200 (Barlow and Gerrodette, 1996).

While it is not taken in drive fisheries, Japanese fishermen for decades have harpooned at times large numbers. A single company, for example, landed 697 animals in May and June 1949. Nonetheless, precise catch statistics were not compiled until fairly recently, and the long-term effect of the exploitation on the western population has not been evaluated. At least tens of Pacific white-sided dolphins are taken each year incidentally to a variety of coastal fisheries off western North America. The now outlawed multinational pelagic driftnet fisheries in the North Pacific may have caused significant mortality, but reliable figures have not been published. Pacific white-sided dolphins have been maintained in captivity in the United States, Japan, and Canada, but survival rates have been low.

II. Dusky Dolphin

The dusky dolphin was described by John W. Gray in 1828 from a stuffed skin and a single skull shipped to the British Museum from the Cape of Good Hope. This smallish dolphin can be recognized by its short beak and the bluish black to dark gray of the dorsal field contrasting with the white belly, as well as the light gray of the thoracic patch and two-pronged flank patch (Fig. 2). The dark lips and eyepatch also stand out. The falcate dorsal fin is two-toned with a dark leading edge. Unlike in *L. obliquidens*, the linear dorsal flank blaze does not extend farther anteriorly than about midbody. Heavily pigmented specimens are found off Peru and Argentina. The holotype of *Delphinus fitzroyi* (Waterhouse, 1838) caught off Argentina from Darwin's ship *Beagle* was such a melanized form. Both males and females off Peru reach sexual maturity at about 175 cm, while the largest two known individuals out of many hundreds measured 211 and 205 cm, respectively. They rarely exceed 100 kg in weight. No significant dimorphism is present except that adult males, much as in Pacific white-sided dolphins, have a significantly bigger and more strongly curved dorsal fin, presumably a secondary sexual characteristic.

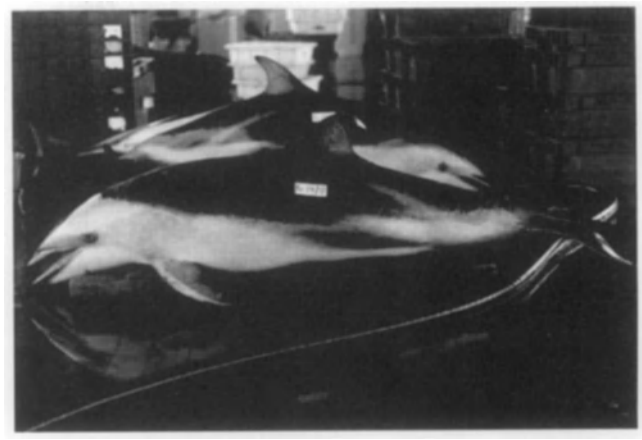

Figure 2 *The dusky dolphin* (L. obscurus), *which may be closely related to its northern congener, the Pacific white-sided dolphin, occurs in Southern Hemisphere waters in both the Atlantic and the Pacific. Photo by K. Van Waerebeek.*

Gestation lasts for some 13 months. In Peru and New Zealand, most births occur in winter but a few neonates appear during other seasons. In Argentina, summer is the prime birth season. In Peru, sexual maturity for females is estimated at 4.3–5 years and for males at 3.8–4.7 years. The lower values, which are the most recent, possibly indicate a density-dependent response to heavy exploitation (Chávez-Lisambarth, 1998). Female Patagonian dusky dolphins mature at 6.3 years of age (Dans *et al.*, 1997).

A. Distribution

Dusky dolphins are distributed around South America, from northern Peru south to Cape Horn and from southern Patagonia north to about 36°S, including the Falkland Islands; off southwestern Africa from False Bay to Lobito Bay, Angola; and in New Zealand waters, including off Chatham and Campbell Islands. Populations of unknown size inhabit waters surrounding oceanic islands of the Tristan da Cunha archipelago in the mid-Atlantic, the Prince Edward Islands, and Amsterdam Island in the southern Indian Ocean (Van Waerebeek *et al.*, 1995). Dusky dolphins have been confirmed from southern Australia but seem to be rare there. Their coastal habits explain the discontinuous DISTRIBUTION across the temperate southern ocean, reproductive isolation, and cranial differences at a subspecific level (Brownell and Cipriano, 1999). Dusky dolphins from southwest Africa and New Zealand are some 8–10 cm shorter than the ca. 185 cm average adult body size of Peruvian specimens of both sexes (Van Waerebeek, 1993).

B. Behavior

Although dusky dolphins can move over great distances—a range of 780 km is confirmed—no well-defined seasonal MIGRATION patterns are apparent. However, the Argentina and New Zealand populations exhibit inshore–offshore movements both on a diurnal and on a seasonal scale. Dusky dolphins over the extensive continental shelf of Patagonia forage cooperatively on small schooling fishes during the day. On the east coast of New Zealand, where deep oceanic waters reach close to shore, animals typically feed at night on prey associated with the deep

scattering layer (Würsig *et al.*, 1997). Some of these same dolphins, identified by natural marks on their bodies, have been found to feed cooperatively during daytime in the Marlborough Sounds on the northern edge of the South Island of New Zealand, reinforcing a generally held belief that these animals adapt behaviorally relative to habitat and prey availability patterns. Prey items include a variety of smaller fish; however, the diet everywhere tends to be dominated by anchovies, hakes, and several squid species. Surface feeding activity typically happens in large groups accompanied with extensive aerial display. It is believed that such aerial activity helps synchronize cooperative foraging and after-feeding social (including sexual) activities (Würsig *et al.*, 1989). Anomalous dentine deposition during El Niño years off Peru may reflect low foraging success. Killer whales (*Orcinus orca*) and some sharks are the only confirmed predators; dusky dolphins will enter very shallow water to avoid killer whales.

C. Abundance and Exploitation

In the absence of reliable ABUNDANCE ESTIMATES, the species' status is indeterminate. Unknown numbers are caught in gill nets in New Zealand waters, although current catches have dropped from those of the 1970s and 1980s. Off Argentina, from 1982–1994, a variable number of Patagonian dusky dolphins, typically a few hundred each year, died in midwater trawls. Arguably of biggest concern are fishery-related mortality levels in Peruvian coastal waters, where both directed and accidental entanglements in artisanal drift nets, as well as harpooning, have killed thousands each year since 1985. In the 1991–1993 period, an estimated 7000 animals per annum were captured, an exploitation thought to be unsustainable. It is believed but not confirmed that this level of human-caused mortality has dropped off in recent years, partly due to conservation legislation and partly because of the depletion of the population. Only a few individuals have been exhibited in aquaria in New Zealand, South Africa, and Australia, largely because dusky dolphins adapt rather poorly and have failed to reproduce successfully in captivity.

Paenungulates

PASCAL TASSY
National Museum of Natural History, Paris, France

The name Paenungulata, i.e., "near-ungulates," was coined in 1945 by the American paleontologist George Gaylord Simpson to group seven orders of placental mammals in a major taxon ranked as a superorder. This grouping included three orders—Sirenia (sirenians or sea cows), Proboscidea (elephants), and Hyracoidea (hyraxes, also called "dassies")—and four extinct orders—Pantodonta (pantodonts), Dinocerata (uintatheres), Pyrotheria (pyrotheres), and Embrithopoda (arsinoitheres). It must be emphasized that Simpson included an extinct group in the Sirenia, the desmostylians, as suborder Desmostyliformes (in modern times usually considered an order, DESMOSTYLIA).

I. The Extant of Paenungulates

The contents and validity of the Paenungulata are controversial. Simpson himself acknowledged the fact that the superorder

was "possibly polyphyletic." Probably amphibious, they were not as specialized to aquatic life as sirenians. Proboscideans are terrestrial but may have had an aquatic origin and hyracoids are terrestrial and arboreal (Fig. 1). The extinct orders were terrestrial and nearly all were unfamiliar herbivorous animals already diverse in the early Tertiary. Pantodonts were largely distributed in America and Eurasia, the largest forms being no larger than a cow. Uintatheres were frequent in North America and Asia and reached the size of living rhinoceroses and superficially resemble them with strange paired horns on both the front and the back of the skull. Pyrotheres were restricted to the early Tertiary of South America and developed features paralleling the elephants: the incisors were in the shape of short tusks and the nasal openings were retracted, indicating the presence of a trunk. Arsinoitheres (Fig. 2), first described in Africa (in the early Oligocene of Egypt), were also present in Eurasia, although rare. They reached the size of living rhinos. They possessed a gigantic pair of horns on the nasal bones and a much smaller one on the frontal bones.

According to Simpson, the "nucleus" of the Paenungulata was the association of proboscideans, sirenians, hyracoids, and the extinct arsinoitheres. Today it can be said that the nucleus of the nucleus is the grouping of the proboscideans and sirenians, now called the Tethytheria. The relationship of the tethytheres to other mammalian orders is much debated and, as a consequence, the content of Paenungulata remains an enigma.

However, most modern authors agree that pantodonts, uintatheres, and pyrotheres are not related to elephants and sirenians and are therefore not paenungulates. This leaves the question: Are Proboscidea, Sirenia, Hyracoidea, and Embrithopoda monophyletic and should they be called collectively Paenungulata? When only extant species are considered, this question can be phrased as: Are hyracoids closely related to elephants and sirenians?

II. Hyracoids

The order Hyracoidea includes eight species (the exact number is still debated), classified into three genera: *Procavia* or rock hyrax (Fig. 3), *Dendrohyrax* or tree hyrax, and *Heterohyrax* or bush hyrax. They live in tropical and subtropical habitats of Africa. *Heterohyrax* is known in east Africa, and *Dendrohyrax* is distributed in central and western Africa. *Procavia* is largely distributed in Africa, but ranges north into Lebanon. Today hyracoids are small animals the size of a rabbit. Some fossil hyracoids were very large, such as tapir-sized *Megalohyrax eocaenus* found in the late Eocene and Oligocene of the Fayum area in Egypt or *Pliohyrax graecus* from the Miocene of Eurasia. The earliest fossil hyracoids are known from middle or lower Eocene sites from Algeria and associated large (*Titanohyrax*) and small (*Microhyrax*) forms.

Extant hyracoids have feet with three toes. The third is the largest, and the first and fifth toe are absent. The hands have four fingers; the third is the largest, the fifth is reduced, and the first is lacking. The pattern of hands and feet is "serial," meaning that the bones of the carpus and tarsus are stacked into separate columns. This is a derived condition compared to the generalized mammalian condition, which is alternate, where the bones of carpus and tarsus are stacked in overlapping rows, like bricks in a wall. Hyracoids also display a structure considered primitive for ungulates: the presence of a central bone located between the trapezoid and magnum. Aspects of the hyracoid ankle are unique. A strong medial process (malleolus medialis) of the tibia articulates into a deep fossa situated on the astragalus medial to the main tibial articular facet. The astragalus has a flat distal articular surface for the navicular bone.

The gait is plantigrade. The sole of the foot has a soft elastic pad that allows cohesion on irregular substratum, such as trunks and branches. Sudorific glands keep the pad moist. The molars are lophodont. The first incisors are enlarged. The canines show an unusual shape: they are premolariform and nearly identical to the premolars so that canines were long understood as first premolars.

The cranium shows unique specializations, such as the postorbital bar (processus zygomaticus) made by both parietal and frontal bones. Also the hyoid apparatus is unique in the fact that the lingual process is formed by the hypohyal and not, as found elsewhere (i.e., perissodactyls and bovids), the basihyal.

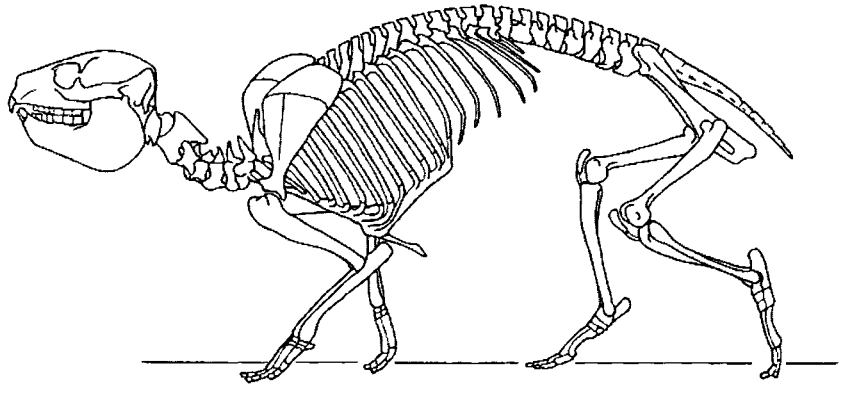

Figure 1 *Skeleton of the hyracoid* Procavia capensis. *Courtesy of M. S. Fischer. Length: 50 cm.*

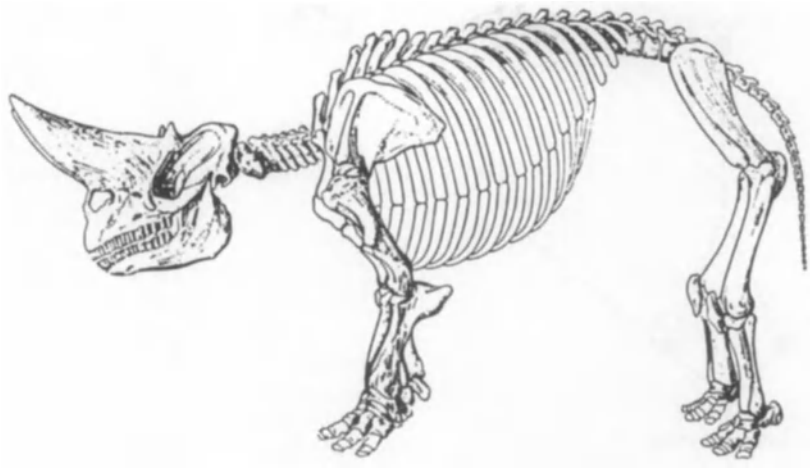

Figure 2 *Skeleton of the embrithopod* Arsinoitherium, *Fayûm, Egypt. Length: 3.50 m. From Andrews.*

Studies have shown that alleged primitive features, such as the plantigrady, were in fact derived secondarily. Ontogenetic development of the limbs shows that hyraxes are basic unguligrads.

III. Pantomesaxonian Interrelationships

Several authors classify extant perissodactyls, hyracoids, sirenians, and proboscideans in a clade called Pantomesaxonia (also named Altungulata). On the other hand, paenungulate characters that support a sister group relationship between hyracoids and tethytheres come from placentation and fetal membrane development and from the locomotor apparatus. The peculiar structure of hyracoid fetal membranes is also known in tubulidentates (the aardvark) and could be associated to a more inclusive group. The serial arrangement of carpals and tarsals is a classical character uniting paenungulates. However, this condition is also known in nonpaenungulate ungulates, such as *Phenacodus*, a genus known from the late Paleocene up to the late Eocene, and usually considered related to Perissodactyla (living tapirs, rhinoceroses, and horses). Among tethytheres, desmostylians do not show a taxeopod condition; hence a reversal is to be assumed for desmostylians. Other characters are clearly homoplastic, such as the amastoidy (lack of mastoid exposure on the cranium), which is also present in various taxa, such as rhinocerotids and pigs. The primitive condition is a reduced exposure (a possible pantomesaxonian character), which occurs in tapirs and in an extinct genus from the late Paleocene of China, *Radinskya*. The short face shared by living hyracoids and tethytheres is a homoplastic feature, as more primitive extinct hyracoids possessed a long face. On the other hand, different characters support sister group relationships between Hyracoidea and Perissodactyla. These include a flat distal articular surface on the astragalus for the navicular; the hoof with mesial side with horned fused lamellae; the course of the sternoscapularis muscle. The presence of an eustachian sac—a pharyngeal dilatation of the eustachian tube—has also been cited as a synapomorphy for hyracoids and perissodactyls. It is known in hyracoids, tapirs, and horses, but the black rhino *Diceros bicornis* lacks it. The eustachian sac changes the course of the internal carotid artery by pushing it away from the tympanic area of the osseous bulla. Because the course of the internal carotid is extrabullar in *Diceros*, this position is perhaps a reversal, an indication of a former possession of the eustachian sac in rhinocerotids. These characters support monophyly of hyracoids and perissodactyls and refute the monophyly of paenungulates. However, no molecular data support a sister group relationship between hyracoids and perissodactyls. On the contrary, various molecular analyses bring hyracoids closer to tethytheres with different exact topologies: sister group of tethytheres, or closer to sirenians, or closer to proboscideans.

Figure 3 *The rock hyrax* Procavia capensis *in its type area (Table Mountain, Cape Town, South Africa). Photo by P. Tassy.*

In conclusion, although many morphological classifications and phylogenies suggest monophyly of pantomesaxonians, the question of monophyly or paraphyly of paenungulates is still

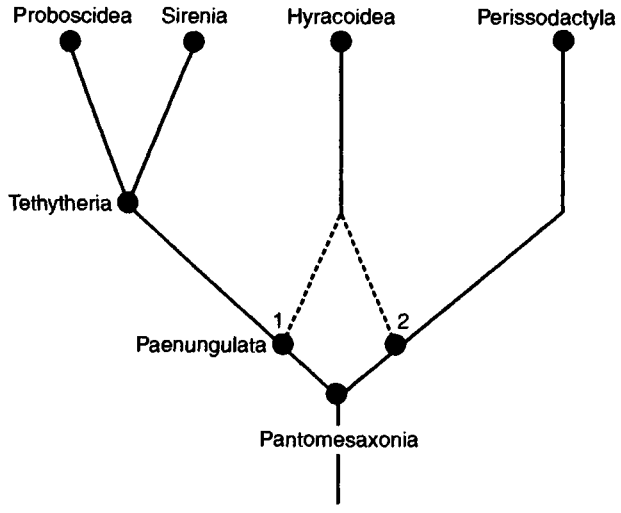

Figure 4 *Interrelationships of pantomesaxonians. If Hyracoidea is related to Perissodactyla (hypothesis 2) and not to Tethytheria (hypothesis 1), the Paenungulata (Proboscidea, Sirenia, and Hyracoidea) becomes paraphyletic.*

not satisfactorily resolved (Fig. 4). As a matter of fact, the recent classification of Mammalia by McKenna and Bell (1997) proposes a new name for extant elephants, sirenians, and hyracoids, i.e., for the nucleus of paenungulates sensu Simpson; the Uranotheria, introduced as an order made of three suborders: Hyracoidea, Tethytheria, and extinct Embrithopoda.

Paleontology

J. G. M. Thewissen
Northeastern Ohio Universities College of Medicine, Rootstown

Paleontology is the study of ancient life and, as such, it is rooted in observations of fossils. Fossils are traces of living beings that are older than 10,000 years. In the case of marine mammals, the remains most commonly preserved as most fossils are teeth and bones. However, there are many other kinds of fossils: tracks and burrows of an animal in petrified soil, mummified pieces of skin, or fossilized excrements called coprolites.

I. Fossilization

Fossilization is the process that makes a fossil out of a living organism. In marine mammals, the first step in fossilization usually starts with the death and burial of its body. This step is studied by a branch of paleontology called taphonomy. In order for fossilization to continue, this initial stage needs to be short, avoiding destruction of the remains by scavengers, waves, or other biological and physical elements. After burial, the remains are subject to diagenesis: a series of processes that act on the cadaver after burial and before exposure on the earth's surface. There are many diagenetic processes, common ones include chemical alteration of the bones by minerals dissolving in circulating water, deformation of the fossil by high pressures deep in the Earth's crust, and precipitation of minerals in cavities in the fossil bones. Diagenesis may last millions of years; it ends when the fossil is brought to the surface by forces that move blocks of sediments around and expose them to erosion.

In general, fossilization is a rare event, and even though an ancient ocean may have abounded with marine mammal life, very few of these organisms are usually preserved as fossils. However, there are taphonomic processes that concentrate marine mammal remains. Waves in a shallow sea, for instance, may wash dead marine mammals onto the beach, making them abundant in the fossilized beach deposit.

II. Collecting and Curation

Collecting marine mammal fossils can be easy when established sites, known to be rich in fossils, are visited. More commonly, however, it takes a thorough understanding of the local geology to discover localities that produce marine mammals. Geological maps are studied to determine the location of areas with sedimentary rocks that record a marine environment. Aerial photos or an actual survey of these areas is necessary to find out whether these sedimentary rocks are actually exposed and accessible. These areas are then subjected to a thorough inspection by eye while walking or crawling over the locality, a process called prospecting. Individual, dis-

persed fossils can then be gathered; this is called surface collecting. When rich concentrations of fossil bones occur, buried fossils can be exposed by digging or chiseling. This method of fossil collecting is called quarrying and may involved specialized manual skills and tools, power tools, and glues to harden fossils that disintegrate easily. Delicate fossils sometimes need to be fortified by encasing them in plaster or synthetic casts called jackets to ensure that they are not damaged during transportation. A third collecting method is called screen washing and is usually used only to collect small fossil fragments that are in relatively unconsolidated sediment. Large amounts of sediment are sieved, either on dry screens or by washing them through sieves with water. Sediment falls through the sieves, whereas fossils stay on them and can be gathered. Taking copious notes is an essential part of collecting fossils for scientific purposes. The topographic location where the fossil is found needs to be written down and marked on maps, and geological data about the sediments in which the fossil was found have to be noted. Without such notes, fossils lose much of their scientific value. After collection, fossils are returned to a fossil preparation laboratory, where sediment is removed and fossils are hardened with special glues. These procedures require considerable technical skills and insight into the physical and chemical properties of fossils and sediments. The last step in collecting fossils is curation, where fossils are assigned a unique museum number that can be used as an identifier in publications and as a guide to find the field records concerning the specimen.

Although preliminary identifications and study start in the field when a fossil is collected, a thorough investigation into the biology of a fossil marine mammal cannot be undertaken until the specimen is curated. Several natural history museums have large collections of fossil marine mammals, and these collections are studied by scientists who can use them for comparison with newly collected specimens. Common ways to study a fossil include making observations on its shape and taking measurements and attempting to identify the species that it pertained to. There is no limit to the number of means of study, and paleontologists have made many advances by applying methods and techniques originally developed in other sciences. Some of these new methods to study fossils include CT scan, stable isotope analysis, and the analysis of DNA sequences of fossils.

The last step of any scientific investigation, including paleontology, is the publication of the specimen in a scientific journal. This makes the existence of the new specimen known to the scientific community.

Pantropical Spotted Dolphin

Stenella attenuata

WILLIAM F. PERRIN
Southwest Fisheries Science Center, La Jolla, California

The pantropical spotted dolphin (*Stenella attenuata*) is a common resident of all tropical seas and has become familiar to many as the main species involved in the "tuna/dolphin problem" that has taken the lives of millions of dolphins over the last four decades.

I. Characters and Taxonomic Relationships

This dolphin can be identified externally by its long beak sharply demarcated from the melon, slender body, strongly falcate dorsal fin, and (in adults) spots (Fig. 1). The newborn calf is unspotted. Dark spots begin to appear ventrally in large juveniles. Near-adult animals and some young adults have large discrete or overlapping spots both above (light) and below (dark). In adults, the ventral spots fuse and fade to a medium gray, and the dorsal light spots intensify, sometimes to the point of making the animal appear nearly white above. The light spots sweep up behind the dorsal fin. The underlying pattern (observable in calves and juveniles) consists of a dark cape sweeping over the eye to maximum depth below the dorsal fin, a very light to dark gray lateral/ventral field, a narrow well-defined eye stripe to the apex of the melon, a dark band of varying definition extending from the lower corner of the mouth to the flipper, and dorsoventral division of the peduncle into darker upper and lower lighter halves. The last can also be seen in adults. The tip of the beak is white in adults. Details of coloration vary regionally. The large coastal spotted dolphin of the eastern tropical Pacific, *S. g. graffmani*, is extremely heavily spotted, whereas animals around Hawaii tend to be lightly spotted (Perrin and Hohn, 1994).

Sexually mature adults examined range from 166 to 257 cm ($n > 1650$) and weigh up to 119 kg (a 257-cm male from Panama Bay), with a wide GEOGRAPHIC VARIATION. Males are on the average slightly larger than females in body size and most skull characters.

This species may be confused in the tropical Atlantic with the endemic Atlantic spotted dolphin, *S. frontalis*, which is of similar size and may be seen in the same area. A distinguishing characteristic of *S. frontalis* is a light spinal blaze that sweeps up through the cape toward the dorsal fin, but this may be almost absent in some individuals. The dorsoventral division of the peduncle present in *S. attenuata* is absent in *S. frontalis*. The ground pattern is three-part, with a distinct cape, lateral field, and ventral field, as opposed to the two-part pattern in *S. attenuata*. Adults may have dark ventral spots on a very light

Figure 1 *Adult pantropical spotted dolphin in the eastern tropical Pacific. Photo by Robert L. Pitman, from Perrin and Hohn (1994).*

ground; this is not seen in adults of *S. attenuata* (ventral spots are medium gray and obscured by fusion).

The skull (35.6–46.0 cm long in 183 adults) overlaps with that of *S. frontalis* in tooth counts and all measurements; some specimens can be identified to species only through multivariate analysis (Perrin and Hohn, 1994). The skull in both species has a long narrow rostrum with no palatal grooves, about 35–50 teeth in each row, medium-sized rounded temporal fossae, convergent premaxillae, and arcuate mandibles. However, vertebral counts determined to date have been nonoverlapping: 74–84 (n = 75) vs 67–72 (n = 52) in *S. frontalis*.

The pantropical dolphin is a member of the delphinid subfamily Delphininae *senus stricto* (LeDuc *et al.*, 1999). In a cladistic phylogenetic analysis based on cytochrome *b* mtDNA, it shares a strongly supported polytomic clade with *S. clymene* and *S. coeruleoalba* (sister species), *S. frontalis*, *Delphinus* spp., and *Tursiops aduncus* (to the exclusion of *T. truncatus*). In skull characters it is similar to *S. frontalis*, *T. truncatus*, and *T. aduncus* vs another coherent series of species composed of *S. longirostris*, *S. clymene*, and *S. coeruleoalba*. However, these latter groupings are not supported by results of the molecular studies to date. Some of the similarities may be plesiomorphies, similarities due to the retention of primitive character states.

II. Distribution and Ecology

Distribution is worldwide in tropical and some subtropical waters, from roughly 30–40°N to 20–40°S (Jefferson *et al.*, 1993). It ranks first in abundance among cetaceans (second only to bottlenose dolphins, *Tursiops truncatus*) in the deeper waters of the Gulf of Mexico (Würsig *et al.*, 2000), second in the eastern tropical Pacific and the Sulu Sea, but only sixth in the tropical Indian Ocean (Balance and Pitman, 1998; Dolar, 1999). In the eastern Pacific, the offshore form, *S. a. attenuata*, inhabits the tropical, equatorial, and southern subtropical water masses, being most abundant in waters underlain by a sharp thermocline at depths of 50 m or less, a surface temperature over 25°C, and salinities less than 34 parts per thousand. In these areas, pantropical spotted dolphins commonly occur in large multispecies aggregations, including spinner dolphins (*S. longirostris*) and yellowfin tuna (*Thunnus albacares*). A large coastal subspecies, *S. a. graffmani*, occurs in the eastern tropical Pacific from Mexico to northern Peru; this form is replaced ecologically in the Atlantic by a large coastal form (unnamed) of the endemic Atlantic spotted dolphin, *S. frontalis* (Perrin and Hohn, 1994).

Prey of the offshore form include mainly small epipelagic fishes, squids, and crustaceans (Robertson and Chivers, 1997). Flying fish are a major diet item in some regions. The diet in the eastern Pacific overlaps greatly with that of the yellowfin tuna, *T. albacares*. Diet of the large coastal form is unknown but may include larger and tougher benthic fishes. Predators include the killer whale (*Orcinus orca*) and sharks, probably the pygmy killer whale (*Feresa attenuata*), and possibly the false killer whale (*Pseudorca crassidens*) and the short-finned pilot whale (*Globicephala macrorhynchus*). Parasites may cause direct or indirect mortality.

III. Behavior and Life History

Why spotted dolphins associate closely with tuna in the eastern Pacific is unknown, although it is suspected to be related to foraging efficiency at some level (Perrin and Hohn, 1994). Other suggested reasons for the association involve physiological efficiency or protection from predators. Immature and subadult males and females tend to form smaller schools or join larger spinner dolphin schools not associated with tuna. The breeding system is unknown but may be promiscuous as in the spinner dolphin. Spotted dolphins exhibit a wide variety of aerial behavior (but not spinning); juveniles (identifiable as such by their lack of spots) make especially high vertical leaps. In areas where they are not harpooned or pursued by purse seiners, they readily come to vessels to ride the bow wave and sometimes can be observed closely for long periods. Burst

swimming speed exceeds 12 knt (about 22 km/hr), and dives of up to 3.4 min have been observed.

Gestation is 11.2–11.5 months (Perrin and Hohn, 1994). Length at birth is 80–85 cm. Females reach sexual maturity at 9–11 years and males at 12–15 years. The calving interval is about 2–3 years but varies with population status. The length of nursing also varies greatly with population status, ranging from 1 to 2 years. Breeding is diffusely seasonal, with multiple peaks in some regions.

IV. Interactions with Humans

The species has not been kept successfully in captivity. Direct and incidental catches have been substantial. Japanese drive and harpoon fisheries take spotted dolphins for human consumption; the catch in 1 year (1982) was 3799 (Perrin and Hohn, 1994), and annual catches in 1994–1997 ranged from 23 to 449 (International Whaling Commission, 1999). Tuna fishermen seek out aggregations of spotted dolphins and tuna in the eastern tropical Pacific and set their nets on them to capture the tuna. Abundance of the northeastern stock of the offshore form has been reduced to a fraction of its original size by incidental kill in tuna purse seines since the early 1960s. Directed fisheries also exist or have existed in the Philippines, Laccadive Islands in the Indian Ocean, Solomon Islands, Indonesia, and St. Helena in the South Atlantic (Perrin and Hohn, 1994), and bycatches also occur in fishing nets of various types in the Philippines, India, Australasia, western North Pacific, coastal Peru and Ecuador, and Taiwan (Perrin *et al.*, 1994, 1996). The impacts of most of these takes on the populations have not been assessed.

Parasites

J. Antonio Raga, F. Javier Aznar, Juan A. Balbuena, and Mercedes Fernández
University of Valencia, Spain

Beyond their sanitary or economic importance, parasites are an integral part of the biosphere. Parasites are extremely diverse and of great importance to the health of their host. However, they are usually small and go unnoticed in biological studies. Parasites are also so pervasive that they virtually infect every free-living organism, potentially influencing, among other things, host behavior and population size, food web dynamics, and community structure. These effects are usually undesirable when human health or economy are at stake but confer parasites a paramount importance in many ecological and evolutionary studies.

This article presents an overview of the diversity of marine mammal parasites. Its aim is to explain concisely what they are and how they have become associated with their hosts. Other aspects, such as the impact of parasites on marine mammal populations, are covered only briefly as these topics are dealt with extensively elsewhere (Aznar *et al.*, 2001). Under the term "parasite," we will consider protozoans and metazoans (helminths and arthropods) which have adopted this trophic strategy.

I. Parasite Diversity

A. Cetaceans

Protozoan parasites have been reported rarely in marine mammals, perhaps due to insufficient sampling or because these organisms are actually rare. In fact, the number of protozoons detected and sampling effort seem clearly related. Three groups of coccidians occur in cetaceans: *Cystoisospora delphini* in bottlenose dolphins, *Tursiops truncatus,* causing enteritis; *Toxoplasma* sp., in bottlenose dolphins and striped dolphins, *Stenella coreuleoalba,* associated with toxoplasmosis; and *Sarcocystis* sp. in toothed whales, with little or no pathologic effect. The life cycles of these coccidians have not been elucidated, but they should be similar to those of their terrestrial counterparts. Regarding ciliates, *Haematophagus megapterae* is found

attached to the baleen plates of humpback whales, *Megaptera novaeangliae,* feeding on blood cells, and *Kyaroikeus cetarius* (Fig. 1b) (belonging to a genus exclusive to toothed whales) is sessile and dwells in the lungs of wild bottlenose dolphins. The latter has also been reported in captive toothed whales. Its transmission is believed to be direct, requiring perhaps repeated exposure to be successful. Finally, one unidentified flagellate and the sarcodinan *Entamoeba* sp. have been recorded in the contents of the colon of the bowhead whale, *Balaena mysticetus.*

Four families of flukes occur typically in cetaceans: Campulidae occur in whales and dolphins; Brauninidae and Pholeteridae occur in dolphins, and Notocotylidae occur in whales. In terms of diversity and geographic extension, the family Campulidae is the most important. It comprises some 41 species, 35 of which are distributed among the majority of cetacean families. Species of *Campula, Oschmarinella,* and *Zalophotrema* inhabit the hepatic and pancreatic ducts of TOOTHED WHALES; *Hadwenius,* the intestine; *Nasitrema* (Fig. 1c), the air sinuses; and *Hunterotrema,* the lungs. Baleen whales harbor species of *Lecithodesmus* in the bile ducts. The life cycles of the Campulidae are not known, but all digenean flukes possess heteroxenous cycles. The ciliated miracidium larvae of *Nasitrema* have eyespots and are active swimmers, whereas those of *Oschmarinella rochebruni* lack eyespots. These differences may indicate that the life cycle of the former occurs near the surface, whereas that of the latter occurs in deep water. The widespread occurrence of campulids in fish- or squid-eating cetaceans suggests that these prey may act as second intermediate or transport hosts. The family Pholeteridae includes two species, one of which, *Pholeter gastrophilus,* parasitizes many toothed whales (mainly delphinids) in the world. These flukes live in the wall of the main and pyloric stomachs, more rarely the duodenum, sometimes generating extensive fibrosis. Another fluke, with a strange ovoid morphology, *Braunina cordiformis* (Brauninidae), attaches to the stomach and the duodenal ampulla of small toothed whales. Baleen whales harbor, in the large intestine, several species of the genus *Ogmogaster* (Notocotylidae) (Fig. 1d), which have been found in many areas (Antarctic, Pacific, Atlantic, and Mediterranean). The life cycles are unknown, but information derived from other notocotylids suggests that the larval stage known as cercaria might not need a second intermediate host, encysting directly on the crustaceans that serve as prey for whales.

Cetaceans are infected with adult tapeworms of the families Tetrabothriidae (16 species of 23 in marine mammals) and Diphyllobothriidae (11 of 48 in marine mammals). These worms have small to very large sizes and occupy the intestine, from the duodenum (*Tetrabothrius forsteri*) to the terminal colon and rectum (*Strobilocephalus triangularis*). Tetrabothriidae have diversified morphologically in cetaceans [the genera *Trigonocotyle* (Fig. 1g), *Strobilocephalus, Priapocephalus,* and *Tetrabothrius;* only the latter two have representatives in baleen whales]. The diphyllobothriids belong to the genera *Diphyllobothrium* (Fig. 1f) (in toothed whales, more rarely in baleen whales), *Diplogonoporus* (in baleen whales and the sperm whale, *Physeter marcocephalus*), *Hexagonoporus* (in the sperm whale), and *Plicobothrium* (typical from pilot whales, *Globicephala* spp., rarely other dolphins). In general, tapeworms of marine homeotherms use zooplanktonic crustaceans as first intermediate hosts. Euphasiids act as intermediate hosts, and fishes as transport hosts, in the life cycle of some tetrabothriids. In contrast, the known cycles of members of the Diphyllobothriidae involve both copepods and fishes as intermediate hosts. Plerocercoids (larval stages) of the family Phyllobothriidae are encysted in the blubber and mesenteries of a number of cetacean species, being called *Phyllobothrium delphini* (Fig. 1h) and *Monorygma grimaldii,* respectively. Because the adult stages are not known, it is difficult to ascertain whether these designations actually correspond to species or to complexes of species. The definitive hosts are probably sharks that become infected by either preying or scavenging on cetaceans. This raises interesting questions about the evolution of these life cycles because no other tetraphyllideans use mammals as intermediate or transport hosts.

Among the nematodes, the family Anisakidae is probably the most successful in terms of potential for colonizing hosts in many environments. Studies of this family have revealed the existence of several complexes of sibling species. The anisakids of cetaceans belong to the genera *Pseudoterranova, Contracaecum,* and particularly, *Anisakis.* The latter is found mainly in cetaceans, hence its vernacular name of "whaleworm." Species of *Anisakis* (five defined morphologically, more based on isozyme analyses) have been reported in at least 35 species of marine cetaceans and occur also in river dolphins. Whaleworms favor the forestomach, where larvae can provoke ulcers by attaching in aggregates. The life cycle of *Anisakis simplex* is the best documented. Eggs shed with the feces hatch and release a free-living larva that is subsequently ingested by planktonic crustaceans. Fish and squid become infected by feeding on these crustaceans. Cetaceans acquire larva by consumption of infected prey. The worms molt to the adult stage and mate in the stomach, where females release the fertilized eggs. The large Crassicaudidae nematodes (a family containing about 11 species exclusive of cetaceans) are found in the kidneys and urigenital organs, placenta, mammary glands, muscles, and pterygoid sinuses, sometimes causing extensive damage. Species of *Crassicauda* (Fig. 1l) infect both whales and dolphins, whereas the up to 3.75-m-long *Placentonema gigantissima* dwells in the placenta of sperm whales. Life cycles are largely unknown. It has been speculated that *C. boopis* might infect fin whale calves, *Balaenoptera physalus,* either by ingestion of larvae shed in their mothers' urine or by prenatal (transplacental) transmission. Pseudaliids (about 17 species exclusive to toothed whales) are distributed among the genera *Pseudostenurus, Pharurus, Torynurus, Stenurus, Halocercus, Pseudalius,* and *Skrjabinalius* (Fig. 1k). They occur mainly in the lungs, air sinuses, and heart of phocoenids and monodontids, secondarily delphinids. Prenatal transmission of *Halocercus* in common bottlenose dolphins has been suggested. However, several authors consider that the life cycles of pseudaliids should also involve intermediate and transport hosts.

Only two genera of acanthocephalans (family Polymorphidae), closely allied to forms infecting aquatic birds, occur in the intestine and occasionally the stomach of marine mammals.

Whales and dolphins are the typical hosts for *Bolbosoma* (Fig. 1i) (some nine species). Pelagic euphasiids and copepods are postulated to act as intermediate hosts, and fishes as transport hosts. A few species of *Corynosoma* have also been described in cetaceans, but the bulk of diversity in this group is found in pinnipeds (see later).

Cetaceans harbor a specific, heterogeneous, and rather diverse fauna of parasitic and nonparasitic crustaceans; interestingly, such intimate associations are rare in sirenians and do not occur on pinnipeds. Whale lice (Cyamidae, about 26 species) (Fig. 1p) have diversified extensively and exclusively among dolphins and whales, becoming one of the few groups of parasitic amphipods. Whale lice attach to the skin (especially on natural openings, wounds, and scars), feeding on epidermic tissue and algal filaments. The life cycle takes place completely on the hosts and, therefore, females have developed a four-plated pouch that keeps the eggs and weak-legged young from being washed away. Transmission is by bodily contact. Likewise, around 6 *Pennella* species (Pennellidae) (Fig. 1o) have become established in cetaceans. The life cycles of these copepods are complex: after two free-swimming stages, they develop, mate, and attain sexual maturity on a cephalopod intermediate host and then females seek a suitable definitive host, e.g., cetaceans, where they burrow on the host's tissue (mainly on the back and belly) to get their head anchored, feeding on blood and body fluids.

B. Sirenians

Four species of Coccidia have been described in sirenians: *Eimeria manatus*, *E. nodulosa*, and *Toxoplasma gondii* in the West Indian manatee, *Trichechus manatus*, and *E. trichechi* in the Amazonian manatee, *T. inunguis*. The species of *Eimeria* have been detected as oocysts in feces. Nothing is known about their life cycles, but the oocyst of *E. nodulosa* bears peculiar nodules that are thought to serve for the attachment in the aquatic vegetation. Thus the cycle might be direct.

The metazoan parasitic fauna of manatees and dugongs is restricted to digeneans and nematodes, but it is fairly diversified, given the extant number of host species, and very specific. Except *Nudacotyle undicola*, which belongs to a genus typical from nonmarine mammals, all species and genera recorded so far (2 genera, 3 species of nematodes; 16 genera, 22 species of digeneans) are exclusive to sirenians (3 out of 6 families also are). Interestingly, the dugong, *Dugong dugon*, exhibits a distinct helminth fauna with greater diversity than the manatees (17 vs 7 species). The reason for this difference is a matter of speculation. It might simply result from differences in research effort. However, dugongs inhabit the Tropical Pacific, whose richer marine fauna may offer a larger selection of intermediate hosts and, perhaps more importantly, dugongs have remained longer in the marine habitat of ancestral sirenians. In contrast, the manatees entered freshwater habitats, which probably impoverished their helminth fauna.

The parasites of sirenians occur in a variety of sites within the host. The roundworms *Paradujardinia halicoris* and *Heterocheilus* spp. inhabit the stomach, more rarely the small intestine. Flukes exhibit a notable morphological variety, e.g., *Taprobanella bicaudata* (Fig. 1e), and are found in diverse locations. Species of Paramphistomidae (4), Rhabdiopoeidae (4), and Nudacotylidae (1) and most of the Opisthotrematidae (6) occur in different sites in the digestive system, including the stomach, pyloric ceca, duodenum, ileum, colon, pancreas, and liver. In some cases they form cysts, e.g., *Faredifex clavata* (Rhabdiopoeidae) or *Lankatrema mannarense* (Opisthotrematidae). In contrast, *Opisthotrema* (2), *Cochleotrema* (2), and *Pulmonicola* (1) species dwell in the ear system or the lungs, whereas *Labicola elongata* (Labicolidae) occurs in the upper lip of dugongs. The life cycles have not been determined for any of these parasites. Some authors have suggested that the nematodes of sirenians use crustaceans as intermediate hosts that would be consumed incidentally while feeding on vegetation. Alternatively, the nematode eggs might be ingested directly when the hosts feed on contaminated vegetation. Similar conjectures have been advanced for digeneans. *Chiorchis fabaceus* is thought to infect manatees through the incidental ingestion of snails containing metacercariae (larvae), whereas the cercariae of *Lankatrematoides gardneri* use a mollusk as an intermediate host, and perhaps then the larvae escape and encyst on aquatic vegetation, awaiting to infect dugongs.

C. Pinnipeds

The most common protozoons found in pinnipeds throughout the world are coccidians. Species of *Eimeria* have been detected in the intestine of seals, sometimes causing severe disorders. *Eimeria phocae* (Fig. 1a) is typical from harbor seals, *Phoca vitulina*, in the northwestern Atlantic. Although its life cycle is not clear, experimental evidence shows that oocysts sporulate in feces incubated in air, but not when suspended in seawater; this may suggest that transmission occurs on land. Another six species of *Eimeria* occur in Weddell seals, *Leptonychotes weddellii*, and crabeater seals, *Lobodon carcinophaga*. Species of *Sarcocystis* have been reported in harbor seals in California, northern fur seals, *Callorhinus ursinus*, in Alaska, and leopard seals, *Hydrurga leptonyx*, in Antarctica. *Isospora miroungae* and *Cystoisospora israeli* have been described in young Antarctic southern elephant seals, *Mirounga leonina*, and South African fur seals, *Arctocephalus pusillus*, respectively. Finally, toxoplasmosis associated with *Toxoplasma gondii* has been observed in a harbor seal pup. In addition to coccidians, the flagellate *Giardia* sp. has been found in ringed seals, *Pusa hispida*, from the western Arctic region of Canada. In fact, they have been considered as potential reservoir hosts for giardiasis in the Arctic.

Flukes are represented by 6 families. Within the Campulidae, 4 out of 5 species of the genus *Orthosplanchnus* infect Arctic and Subarctic phocids, and walruses, *Odobenus rosmarus*, whereas *O. antarcticus* is found in Antarctic seals. *Zalophotrema hepaticum* is associated with California sea lions, *Zalophus californianus*, in the Northeastern Pacific. Campulids of pinnipeds live in the bile ducts, gall bladder, and, rarely, the intestine of their hosts. The family Heterophyidae is widespread in pinnipeds from the Northern Hemisphere. About 10 intestinal species have been recorded so far, from the genera *Cryptocotyle*, *Phagicola*, *Rossicotrema*, *Galactosomum*, *Pricetrema*, and *Phocitrema*. Species of the two latter genera are particularly noticeable, as they are associated more specifically with pinnipeds (in the Pacific region). Nothing is known of the life cycles of these

heterophyids. Inferences made from other species strongly suggest that a gastropod would function as first and various species of fish as second intermediate hosts. Five species of opistorchiids from the genera *Opistorchis, Metorchis,* and *Pseudamphistomum* inhabit the bile ducts of seals from the Northern Hemisphere. Their life cycles are unknown, but, from other opistorchiids, it might be inferred that fish act as second intermediate hosts. Microphallids (3 species) from the genera *Microphallus* and *Maritrema* are intestinal flukes. For instance, *Microphallus orientalis* has been reported in immense numbers in walruses and bearded seals, *Erignathus barbatus,* from the Barents Sea. The majority of microphallid larvae encysts in benthic crustaceans, which may explain their occurrence in seals that feed on bottom invertebrates. Species of the genera *Echinostoma* and *Mesorchis* (Echinostomatidae) have been reported incidentally in seals. Finally, *Ogmogaster antarcticus* (Notocotylidae) is known from Weddell and crabeater seals. These hosts likely become infected when feeding on benthic invertebrates (see earlier discussion).

The tapeworm fauna of pinnipeds is rich. The majority of species belong to the family Diphyllobothriidae (37 species out of 48 in marine mammals). Species of *Diphyllobothrium* form the major component, being distributed in pinnipeds worldwide. In contrast, species of the genera *Baylisia, Baylisiella,* and *Glandicephalus* are exclusive to Antarctic seals, and those of *Diplogonoporus,* to boreal pinnipeds. Insights of the life cycles of diphyllobothriids have already been discussed. One genus of Tetrabothriidae, *Anophryocephalus* (7 species) is associated with Arctic and sub-Arctic pinnipeds. Euphasiids appear to be intermediate hosts, and fishes transport hosts in the life cycle of these parasites.

Pinnipeds harbor a diverse nematode fauna that comprises 6 families: Ancylostomatidae (2 species), Dipetalonematidae (2 species), Trichinellidae (1–2 species), Filaroididae (4 species), Crenosomatidae (1 species), and Anisakidae (14 species). To a great extent, this parasitic fauna is related to taxa found in land carnivores. Thus the cycle of some groups is land dependent and resembles that of their terrestrial counterparts. For instance, the eggs and the first three larval stages of *Uncinaria lucasi* (Ancylostomatidae) develop in the soil on the otariid rookeries in the North Pacific. Third-stage larvae infect adult northern fur seals through the skin (especially the flippers), migrating to host tissues, particularly the ventral blubber and mammary glands. Larvae use the milk of adult female seals to infect the pups, where worms become adult in the intestine. Transmission occurs only during the breeding period; infective larvae survive the severe winter on the rookery, awaiting the arrival of the fur seals in early June. The heartworm, *Dipetalonema spirocauda* (Dipetalonematidae), likely requires an athropod vector (a louse) to trigger development and to transmit the microfilaria to North Atlantic seals, although this cycle has yet to be proven. Transplacental or transmammary transmission to pups has been also suggested to occur. The species of *Trichinella* (Trichinellidae) are typical tissue parasites of terrestrial mammals. However, as discussed in the next section, a natural cycle of trichinosis involving pinnipeds seems to exist in the Arctic. With regard to nematodes with aquatic cycles, experimental research has demonstrated that the lungworm *Parafilaroides decorus* (Filaroididae) infects fishes that consume feces from Californian sea lions, contaminated with the larvae. These coprophagous fishes are, in turn, preyed upon by the sea lions. Recent experimental studies of the lungworm *Otostrongylus circumlitus* (Crenosomatidae), a species parasitizing boreal seals, have shown that fishes seem to be used as intermediate hosts. By far the most widespread nematode group in seals is the Anisakidae, dwelling in the stomach and duodenum. Pinnipeds are primary hosts for species of *Pseudoterranova* and *Phocascaris,* whereas species of the genus *Contracaecum* appear primarily in aquatic birds, having some representatives in phocids and otarids. In addition, there are records of *Anisakis simplex* maturing in some phocid species, particularly the gray seal, *Halichoerus grypus.* The complex life cycle of the sealworm, *Pseudoterranova decipiens,* is the best known. Experimental studies have shown that the sealworm is able to infect a wide variety of invertebrates. Under natural conditions, however, it utilizes only benthic and epibenthic organisms as intermediate and transport hosts. The exploitation of benthonic food webs can be traced to the early development of the parasite. The free-living larva emerging from the egg has negative buoyancy and adheres to the substrate by its caudal extremity. This behavior favors ingestion by benthic copepods, which, in turn, are consumed by benthic macroinvertebrates. At this point, the larvae have molted twice and are ready to infect the seal, but benthophagous fish, or their demersal predators, can be used as transport hosts, enhancing transmission.

Acanthocephalans of the genus *Corynosoma* (Fig. 1j) (Polymorphidae, some 20 species in pinnipeds) exhibit a protracted history of association with pinnipeds. They have a cosmopolitan distribution, appearing in the intestine of most species of seals, sea lions, and walruses. The complete life cycle for *C. strumosum* and *C. pseudohamanni* has been inferred from field collections. Nearshore amphipods acquire the cystacanth larvae, which, following ingestion, encyst in the body cavity of several fish species, awaiting seals to prey on these fish. Species of *Bolbosoma* have also been reported incidentally in Arctic seals.

Two main arthropod groups are associated with pinnipeds: sucking lice (Echinophthiriidae) (Fig. 1m) and mites (Halarachnidae) (Fig. 1n). The entire life cycle of sucking lice is spent on a single host and, therefore, these insects rely on direct contact for transmission. Each individual host must provide acceptable ecological conditions, such as hairs to glue the eggs. Echinophthiriids (four genera, nine species) are associated with all pinniped groups (otariids, odobenids, phocids) worldwide. They are especially adapted to the hosts' ecological conditions and are transmitted most likely on land. Mites (six species) inhabit the respiratory tract and belong to two genera: *Halarachne* (in phocids) and *Orthohalarachne* (in otariids and odobenids). The life cycle takes place in the same individual host and comprises four stages: a larva, two nymphal stages, and the adult. Transmission occurs on the terrestrial environment when active larvae are transferred by nose contact or are sneezed from the nostrils of infested animals. Acari typical of terrestrial mammals also have some representatives in pinnipeds. *Dermacentor rosmari* is the only species within the Ixodidae. These ticks appear between the fingers of walruses, especially in the hind legs on the skin, in the Arctic waters of Russia; nymphal stages are not known. *Demodex zalophi*

(Demodicidae) occurs in the hair follicles of the flippers and genital region of California sea lions. Each follicle usually contains one female and four males. All stages of development take place in the hair follicle, usually in the distal portion of the duct of the sebaceous gland.

D. Sea Otter

A total of 17–18 parasite species have been reported from sea otters, *Enhydra lutris*, throughout their range. The majority are acquired directly from sympatric pinnipeds: *Orthosplanchnus fraterculus*, *Pricetrema zalophi*, *Phocitrema fusiforme*, *Diplogonoporus* sp., *Diphyllobothrium phocarum*, *Pseudoterranova decipiens*, *P. azarasi*, *Corynosoma strumosum*, *C. villosum*, and *Halarachne miroungae*. Other parasites appear to derive from marine birds, namely *Microphallus pyrum* (Microphallidae), and three species of *Polymorphus* (Polymorphidae) occurring as immature. *Anisakis* larvae have also been recorded. Apparently, the only parasite specific to the sea otter is *Corynosoma enhydri*, the largest species in this genus.

E. Polar Bear

Polar bears, *Ursus maritimus*, have been relatively little analyzed for parasites. To our knowledge, the only helminth recorded thus far in wild animals is *Trichinella* spp. (Trichinellidae).

II. Patterns and Processes in Host–Parasite Associations

To understand how marine mammals and their parasites have become associated, we have to discuss first the principles that regulate the outcomes of host–parasite interactions. The evolutionary fate of every parasite species ineluctably depends on that of its hosts. To survive, parasites must track their hosts, switch to its hosts, or go extinct. Host tracking should result in congruent phylogenies of hosts and parasites (i.e., a perfect cospeciation pattern). However, incongruence often occurs because parasites speciate or go extinct whereas their hosts do not. Another reason for incongruence is host switching (also called "host capture"), i.e., parasites colonize phylogenetically unrelated hosts through ecological mechanisms. Colonization deserves more detailed comments because of its importance for the development of parasite faunas in marine mammals (Fig. 2).

The likelihood that a parasite successfully colonizes a new host depends on two factors: the probability of encounter and the compatibility between the new host and the parasite. Encounters depend on behavioral, ecological, or biogeographical factors. For instance, the transmission of sirenian parasites appears to be linked to sea vegetation or the organisms associated

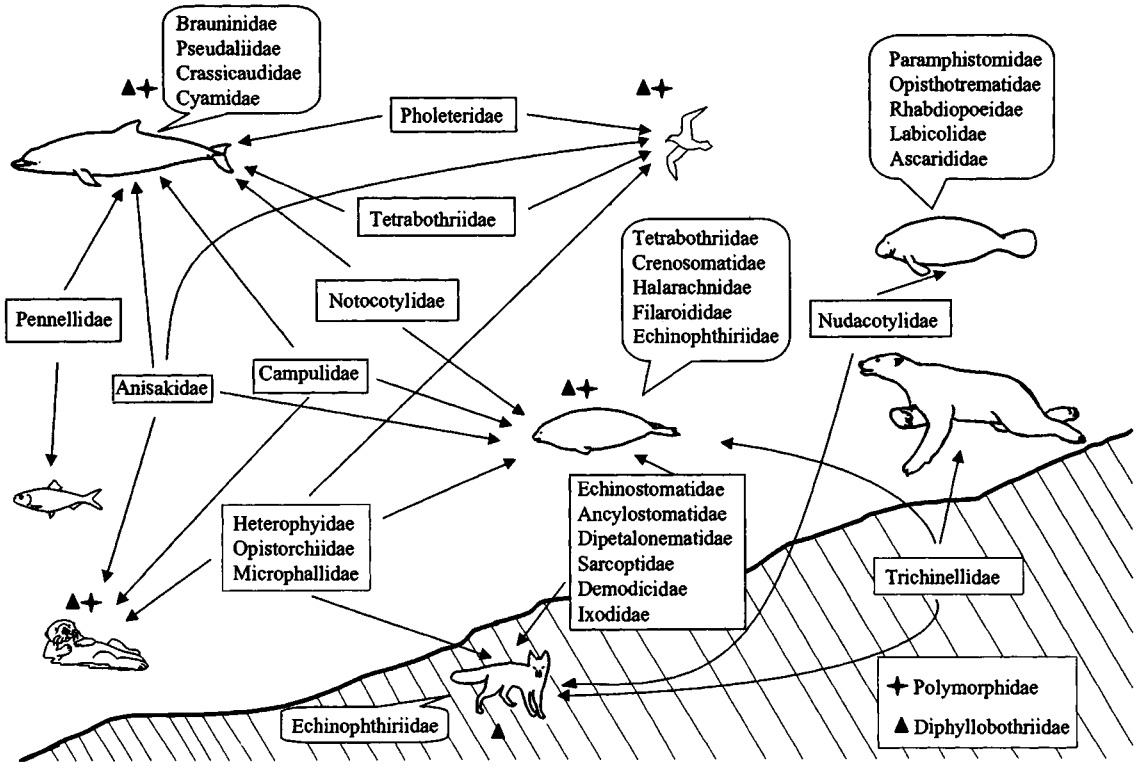

Figure 2 *Sharing patterns of parasitic helminth and arthropod genera. For simplicity, only the parasite families to which these genera belong are displayed. Balloons enclose families with genera exclusive to each host group, and rectangles those with genera common to several host groups (as indicated by arrows). For example, within the Tetrabothriidae, the genus* Tetrabothrius *is shared between marine birds and cetaceans, whereas the genus* Anophryocephalus *is exclusive to pinnipeds. Therefore, the Tetrabothriidae appear as both exclusive of pinnipeds and shared between birds and whales.*

to it. Therefore, the chances of infection to fish-eating marine mammals are very low. In this context, most marine mammal parasites exploit food webs for transmission and cannot exert strong host selection, being consumed by both "right" and "wrong" hosts. Whether a host is "right" or "wrong" depends on filter compatibility, i.e., those morphological, physiological, or immunological barriers that preclude that the parasite becomes established, matures, or reproduces in/on the contacted host. For instance, lice on pinnipeds require hair and a suitable surrounding climate to survive. Therefore, these lice have little opportunity to establish on cetaceans or sirenians. In another example, species of *Corynosoma* are mainly associated with pinnipeds worldwide, but their larvae frequently end up in sympatric seabirds or cetaceans. However, for unknown physiological and/or immunological reasons, these larvae rarely mature in nonpinniped hosts.

When encounters with "wrong" hosts are fortuitous, their ecological and evolutionary significance is minimal. For example, sea otters from California seldom acquire larvae of *Polymorphus* from aquatic birds. However, if encounters repeat predictably throughout time, true accommodation or SPECIATION of parasites in formerly "wrong" hosts can be promoted, providing that parasites are eventually able to overcome the compatibility filter. This is obviously easier as the target host is phylogenetically closer to the original host. However, we should bear in mind that the probability of encounter is always of paramount importance, e.g., carnivorous marine mammals have more parasitic taxa in common with piscivorous marine birds than with sirenians (Fig. 2).

A typical case of accommodation is that of the ecological facultative hosts, i.e., suitable hosts for a parasite species that originated elsewhere. For example, the tapeworm *Anophryocephalus ochotensis* originated in the Steller sea lion, *Eumetopias jubatus*, by colonization from *Anophryocephalus* spp. of seals. However, *A. ochotensis* also infects and reproduces now in sympatric northern fur seals. Facultative hosts are particularly important when they sustain a significant portion of a parasite population.

A. General Hypothesis on the Origin of Associations

Based on the above concepts, we can elaborate a general hypothesis on the origin of host–parasite associations. Let us consider the terrestrial ancestors of each marine mammal group (cetaceans, sirenians, pinnipeds, the sea otter, and the polar bear). These ancestors certainly harbored parasites in a variable number, but the subsequent host transitions from the land to the sea likely posed a barrier for these terrestrial parasites to track their hosts. In other words, parasites were phylogenetically constrained to either precisely adjust their life cycle and/or physiology to the new environment or go extinct. There are beautiful examples of such biological adjustment (e.g., the life cycle of *U. lucasi*, see earlier discussion), but extinction is thought to have occurred often, particularly in marine mammals, the cetaceans and sirenians, that eventually severed their ties with land completely.

When the ancestors of marine mammals made it to the sea, they became literally immersed in an ocean of infective stages of marine parasites. Then the mechanisms favoring colonization began to work. Some host captures involved marine mammals and parasites from nonmammalian hosts. However, due to compatibility limitations, these episodes should have been rare as compared to the parasite exchange between marine mammals themselves. An example can illustrate the intricacies of colonization events. The Campulidae, a family of digeneans occurring in marine mammals worldwide, is the putative sister group of flukes occurring in fish as adult. Apparently, the campulid ancestors amplified a cycle that formerly ended up in these fish by including their predators (some unknown ancestor of toothed whales) as new definitive hosts. This initial host switch opened the possibility of subsequent coevolution (host tracking) of campulids and toothed whales and, of course, of new host-switching events. Not surprisingly, the latter involved other marine mammals: baleen whales and pinnipeds acquired campulids from toothed whales, and sea otters from pinnipeds.

We therefore postulate that most parasite taxa infecting marine mammals have a marine origin, with coevolved products from land having remained in hosts with a permanent or close contact with this realm. The evidence available confirms that the arthropods and intestinal helminths of cetaceans probably rose from marine ancestors, whereas a sizeable part of parasites of pinnipeds has a clear terrestrial affiliation. To test this prediction thoroughly, we need robust phylogenetic hypotheses dealing with all parasite taxa.

B. Parasite Exchange in Ecological Scenarios

We have learned from the arguments described earlier that the distribution of parasites in marine mammals can be largely understood from patterns of exchange, either past or present-day, within communities of marine vertebrates. This section analyzes with more detail some major features of these patterns within each specific ecosystem.

1. Terrestrial Ecosystems For obvious reasons, we expect that most monoxenous parasites disappeared when the terrestrial ancestors of marine mammals entered the aquatic environment. In fact, whale lice, coming from free-living amphipods, appear to be the only aquatic forms that rely exclusively on direct transmission. However, some parasites of pinnipeds and polar bears, derived putatively from terrestrial counterparts, have cycles constrained to develop on land (interestingly, this does not occur with sea otters). Most of these land parasites have monoxenous life cycles and, to a great extent, are host specific. For instance, Echinophthiriid lice and halarachnid mites likely coevolved with the ancestor(s) of pinnipeds and are largely restricted to these hosts today. In this context, the occurrence of *Halarachne miroungae* in sea otters should be regarded as fortuitous. Perhaps the most interesting case is that of *Trichinella* species. These extremely generalist parasites occur worldwide in terrestrial CARNIVORES and other mammals. Bearded and ringed seals, walruses, and polar bears are known to serve as hosts of these nematodes in the Arctic. The infections can evidently be traced to a terrestrial origin, but patterns of transmission are intricate and have not been proven definitively. Crustaceans and birds have been suggested to acquire *Trichinella* larvae when feeding on mammal

carcasses. Then, seals would be infected by direct ingestion of these crustaceans or while feeding on grounds contaminated with bird feces. The nematode might then be transmitted to polar bears and some walruses that feed on seals. Polar bears could also acquire *Trichinella* independently by consuming carrion of terrestrial mammals.

2. Freshwater Ecosystems River dolphins, Baikal seals, *Phoca sibirica*, and manatees have secondarily colonized freshwater habitats, raising the interesting question of what parasites they are expected to harbor. Either parasites tracked these hosts from the marine realm or colonized them in freshwater or terrestrial habitats. The species of *Hunterotrema* and *Anisakis* infecting the Amazonian river dolphin, *Inia geoffrensis*, exemplify the first possibility. In contrast, many other parasites have been acquired more recently in nonmarine habitats. For instance, the fluke *Nudacotyle undicola*, from West Indian manatees, belongs to a genus whose species infect freshwater and terrestrial mammals, and Baikal seals, *Pusa sibirica*, are infected with the tapeworm *Diphyllobothrium dendriticum*, a typical freshwater species that usually infects aquatic birds and land mammals. Similarly, an echinostomatid fluke, *Ruffetrema indirae*, has been described in the Indian river dolphin, *Platanista gangetica*. Relatives of this fluke infect terrestrial birds and mammals. However, the Indian river dolphin infections seem accidental because no mature eggs were found in any worm.

Some parasites of these mammals have an uncertain origin. The digenean *Chiorchis fabaceus* and nematodes of the genus *Heterocheilus* are common to species of manatees from both freshwater and coastal habitats, but we do not know where these associations originated. The nematode *Contracaecum lobulatum* is exclusive to Indian river dolphins, and species of *Contracaecum* are typical of piscivorous freshwater and marine birds, pinnipeds, and cetaceans. Where might *C. lobulatum* have come from? In any case, river dolphins and manatees have a very poor, specific helminth fauna. Although we should bear in mind that these hosts have been poorly analyzed for parasites, the evidence suggests that parasite exchange with sympatric hosts seems to occur often at ecological time.

3. Coastal Ecosystems Coasts constitute probably the most important realm in terms of historical and current parasite exchange between carnivorous marine mammals, and between these hosts and other vertebrates. Perhaps the best illustration is the observation that the parasite fauna of sea otters is made up of parasites from either sympatric pinnipeds or seabirds. The influx of parasites through coastal food webs puts many parasites in contact with incidental hosts, in which, depending on the compatibility filter, parasites are able or not to reproduce at ecological time. Examples of apparent failure are, for example, *Pseudoterranova decipiens* in sea otters, *A. simplex* in many seals, or most *Corynosoma* spp. in nonpinniped hosts. In contrast, some parasites are notoriously unspecific with respect to the choice of their final hosts: heterophyid, opistorchiid, and microphallid digeneans found typically in terrestrial mammals or aquatic birds infect and reproduce in pinnipeds and the sea otter (rarely coastal cetaceans) in neritic and littoral waters. Most of these records are occasional, but in the Caspian seal, *Pusa caspica*, they represent an important portion of the helminth fauna: 16 of the 21 helminth species recorded so far are generalist parasites found in sympatric aquatic birds or terrestrial carnivores.

There are also many examples of recent accommodation or speciation of parasites in new hosts (although, in most cases, we are not certain of which were the donor and the target hosts). For instance, the campulid *Orthosplanchnus fraterculus* infects and reproduces readily in walruses, bearded seals, and sea otters, which share a similar diet on benthic invertebrates (sea otters probably acquired this fluke from pinnipeds). Likewise, diet similarity seems to be responsible for the occurrence of *Ogmogaster antarcticus* in fin whales, blue whales, Weddell seals, and crabeater seals in Antarctic waters. There are also many examples of apparent parasite speciation associated with recent colonization in the coastal environment. Species of *Corynosoma* in cetaceans (e.g., *C. cetaceum* in dolphins from the Southern Hemisphere), sea otters (*C. enhydri*), and seabirds (*C. shakletoni* in the Gentoo penguin *Pygoscelis papua*) appear to constitute independent host-switching events from *Corynosoma* of pinnipeds.

Finally, some cases represent more archaic colonization events followed by secondary diversification within the new association. It is postulated that the genera *Anophryocephalus* (Tetrabothriidae) and *Orthosplanchnus* (Campulidae), typical from pinnipeds of the Arctic and sub-Arctic waters, arose during the Quaternary from ancestors infecting toothed whales. After the initial host capture, a complex history of parasite diversification apparently occurred associated to pinnipeds themselves. One of the most striking examples is that of *Contracaecum* spp. in pinnipeds: it is believed that boreal seals and austral otariids independently acquired species of *Contracaecum* from seabirds.

4. Pelagic Ecosystems Despite the appearance of continuity between coastal and oceanic domains, the parasitic fauna of pelagic marine mammals is distinctive and comparatively poorer. Several factors appear to contribute to this singularity. First, some parasitic groups are underrepresented. The diversity of digeneans is probably constrained because they almost exclusively require gastropods or bivalves as first intermediate hosts, which are abundant in coastal habitats but not in pelagic waters. Indeed, the Campulidae are among the few flukes with representatives in pelagic marine mammals. Second, host communities are generally species poor as compared to coastal ones; therefore, the possibility of parasite exchange is decreased (note, for example, that there is little chance for terrestrial influence). Third, infective stages are much more "diluted" in the pelagic environment. Transmission rates are thus lowered, also reducing the likelihood of host captures.

Some parasitic groups infecting marine mammals are predominantly pelagic and probably originated in this ecosystem. Except for species of the genus *Anophryocephalus*, most tetrabothriid cestodes occur in pelagic birds and cetaceans. Seabirds have been considered as initial hosts for ancestral tetrabothriids, from which these tapeworms would have switched to cetaceans (seabirds, dolphins, and whales share the genus *Tetrabothrius*). There are two other interesting cases of host switch-

ing. Pelagic cetaceans seem to have acquired species of *Pennella* from oceanic fishes. There are even records of the same species, *P. crassicornis*, parasitizing both cetaceans and fishes. However, females of *Pennella* can actively select their definitive hosts, in contrast to the majority of examples discussed thus far. How did this host switch to cetaceans happen? However, some species of *Phyllobothrium* and *Monorygma* (Cestoda) appear to use cetaceans (mostly pelagic) as intermediate hosts. Evidently, a shift in the ancestral life cycle of these tapeworms had to occur as other relatives within the class Tetraphyllidea use only invertebrates and fish.

III. Effects and Applications

A. Parasitosis

The severity of the parasite-induced damage is related to the type of parasite, its abundance, the host's health status, and the concurrence of other pathogenic agents. The effects of parasites usually have little relevance on host health, such as only local reactions produced by the proboscis of *Bolbosoma* or *Corynosoma*. In other cases, the lesions can be more important, such as ulcers and hemorrhages caused by *Anisakis* and *Pseudoterranova*. On occasion, parasites can compromise the health of its host and even lead to its death: *Nasitrema* flukes can provide neuropathies that have been related to both single and mass strandings. Lungworms of cetaceans and pinnipeds cause bronchitis and pneumonia that may lead to mortality, particularly among the youngest individuals. Sometimes, the direct action of the parasite might not be severe, but propitiates viral, bacterial, and other parasite infections, e.g., sucking lice may transmit heartworms while feeding on their hosts.

Several authors have suggested that some parasites contribute significantly to marine mammal POPULATION DYNAMICS by affecting either host reproduction or survival. For instance, the mammary glands of many females belonging to a herd of Atlantic white-sided dolphins, *Lagenorhynchus acutus*, suffered from mastitis caused by *Crassicauda* nematodes. The parasites altered the secretory tissue, affecting the quality and quantity of the milk, which would ultimately compromise the survival of the calves and the reproductive output of the herd. In other instances, parasites can lead to direct mortality. *Crassicauda* sp. causes cranial damage in spotted dolphins, *Stenella attenuata*, from the eastern Tropical Pacific. A study of dolphins caught in a tuna purse seine fishery showed an increase of lesions among individuals up to 5 years old. In contrast, in animals older than 8 years, lesions diminished by 12.3% annually. Assuming that the lesions were irreversible, that there were no reinfections, and that dolphins with lesions had the same probability of being caught as those without, the mortality rate attributable to the parasite was estimated as 1.1%. Since the annual natural mortality rate for the Pacific spotted dolphin population is 10–13%, the study suggests that *Crassicauda* sp. accounts for 11–14% of that rate.

In some cases, parasites might regulate marine mammal populations. A density-dependent relationship between parasite-induced mortality and population size has been shown for the hookworm, *U. lucasi*, in northern fur seals from the North Pacific. These nematodes constitute the most important mortality factor among newborns by causing diarrhea, anemia, and intense intestinal hemorrhages. The population size of pups born in St. Paul Island (Alaska) peaked around 1940 and declined more or less steadily until the present. Data of hookworm mortality from previous surveys showed a decrease in pup numbers, which means that recent mortality is less than in the past. These data suggest a density-dependent relationship and, therefore, a possible regulatory effect.

B. Economic and Public Health Importance

The parasites of marine mammals can infect valuable animals in aquaria, causing lesions and diseases. For this reason, expensive prophylactic measures must be used routinely. The most important economic impact, however, is due to anisakid nematodes whose larvae use commercial fish and squid for transmission to marine mammals. These larvae also have public health repercussions (see Box), but from an economic perspective, the problem is cosmetic, rendering the fish unappealing to consumers. In 1982, the losses caused by *Pseudoterranova decipiens* in eastern Canada were valued $20 million, only in processing of cod fillets.

The parasites with repercussions on public health are those that can infect humans with food (Box 1), either by eating meat from marine mammals or, more frequently, raw fish or squid containing living infective stages.

C. Natural Tags

Many parasites are useful natural markers of biological and environmental phenomena because their transmission is linked intimately to features of the host and the ecosystem. Despite some limitations, marine mammal parasites have proven themselves as biological indicators of phylogeny, local migration, distribution, disease, stock identity, and social behavior of their hosts.

Regarding host behavior, differences in the occurrence of two whale louse (Cyamid) species on sperm whales were interpreted as evidence of spatial segregation between the bulls and the rest of the population off South Africa. Assuming that males leave their natal herd at attainment of sexual maturity, parasite information suggested that this should occur at 12 m of length. This estimation was validated later on by analyses of gonadal tissue. Another example is the comparison of intestinal helminth abundance between pods of North Atlantic pilot whales, *Globicephala melas*. Monte Carlo simulations revealed that adult males were more difficult to allocate into their pods than other individuals. This suggests male exchanges between pods, a conclusion that agrees with genetic studies that adult males do not breed within their natal pods.

Parasites transmitted through the food web have also provided information on past and present host feeding grounds. This has served to reveal geographical differences between areas for Antarctic whales, larga seal (*Phoca largha*), populations on both sides of the North Pacific, inshore and offshore forms of bottlenose dolphins in both the east coast of the United States and Peru, and geographical segregation of franciscanas, *Pontoporia blainvillei*, south and north of the La Plata River Estuary, between Argentina and Uruguay.

Main Parasitic Zoonoses

Trichinosis occurs mainly among people from the Arctic due to the consumption of raw or undercooked meat, particularly of polar bear, walrus, and some seals. *Trichinella* larvae are found in the striate muscle of many mammals, encapsulated inside individual nurse cells. When the muscles are ingested by another mammal, the larvae are released into the small intestine, where they penetrate the mucosa and develop to adult stage. The females give birth to numerous larvae, which migrate through the circulatory system to the skeletal muscles. The damage to the host is due to both penetration of adult females in the mucosa, migration of juveniles, and penetration in the muscle and nurse cell formation. Infections in humans can be fatal.

Diphyllobotriosis is caused by tapeworms of the genera *Diphyllobothrium* and *Diplogonoporus*. Human infections occur by ingestion of plerocercoids (larval stages) encysted in fish muscles. These larvae can develop into the adult stage in the human intestine. Usually the infections are not severe, but, in some cases, can lead to pernicious anemia due to a B_{12} vitamin deficit. Cases of marine-transmitted diphyllobothriosis are particularly common in Japan and Peru due to the ingestion of raw fish dishes such as ceviche.

Anisakidosis is produced by anisakid nematodes, particularly those of the genus *Anisakis*. Infections in humans occur when the larvae are eaten with either raw or lightly cooked fish or squid. The larvae cannot develop to the adult stage in the digestive tract of humans, but can cause considerable damage to the gastric or intestinal wall. They may produce ulcers and eventually peritonitis and other severe pathologies. Although anisakidosis has been traditionally common in Asian countries, especially in Japan, the popularity of raw fish dishes, as sushi, has resulted in human infections worldwide. Allergic reactions due to antigens released by the worms in the fish have been reported both among consumers and workers in fish-processing plants. This puts the problem of anisakidosis under a new light because the antigens are thermoresistant. Thus, common prophylactic methods to kill the larvae, such as cooking or freezing, cannot prevent allergies.

Parental Behavior

JANET MANN
Georgetown University, Washington, DC

Parental behavior in pinnipeds, sirenia, sea otters, polar bears, and cetaceans shares several features: paternal care is virtually absent, gestation and lactation periods are typically long, females give birth to and nurse one offspring at a

time (polar bears excepted), and many marine mammals fast during the early stages of lactation. In sum, marine mammal mothers invest extensively and exclusively in single offspring; this article reviews the diversity and nature of that investment.

Marine mammal maternal strategies vary in important respects. Polar bears (*Ursus maritimus*), sea otters (*Enhydra lutris*), and all three families of pinnipeds—Odobenidae (walrus, *Odobenus rosmarus*), Phocidae (earless or "true seals), and Otariidae (eared seals, sea lions, fur seals)—give birth on land or ice. Twenty-three species of pinnipeds breed on land and 13 breed on ice. Cetacean and sirenian females give birth in the water; this pattern favors precocial swimming and diving. Among many pinnipeds, maternal care is largely restricted to milk transfer, whereas the prolonged association characteristic of many cetaceans, sirenians, otters, polar bears, and some pinnipeds also involves protection and potentially extensive information transfer.

I. Feeding, Lactation, and Patterns of Association

Lactation strategies in marine mammals generally depend on trade-offs among foraging, predation risk, and reproduction. This trade-off is exemplified by many marine mammal species that fast during the early stages of lactation. That females forgo feeding by breeding on land (i.e., pinnipeds) or in warm coastal waters (i.e., baleen whales) suggests that benefits, such as reduced predation risk and rapid energy transfer from mother to offspring, outweigh the costs of fasting. Larger bodied mammals can withstand fasting for longer periods than smaller, thus able to afford longer fasting periods devoted to offspring care. Fasting and lactation coincide in many marine mammal species and only rarely in terrestrial mammals. Early-weaning marine mammals tend to have milk that is high in fat, investing heavily in offspring for a shorter period. Late-weaning marine mammals tend to have lower fat milk (although still much higher than for terrestrial mammals). This pattern is generally true for comparisons between phocids and otariids, or toothed and baleen whales (see Oftedal, 1997; Table I). Other factors, such as the development of pup or calf foraging skills, also contribute to late weaning ages and prolonged association (see Section IV).

Phocids tend to fast and remain near the ROOKERY until their pup is weaned; they rely on fat stores to nurse offspring. Phocid maternal strategies are generally characterized as *fasting*. A few phocids feed during lactation, notably the harp (*Pagophilus groenlandicus*), harbor (*Phoca vitulina*), ringed (*Pusa hispida*), and Weddell (*Leptonychotes weddellii*) seals. Most remarkable is the hooded seal (*Cystophora cristata*), which breeds on pack ice and nurses her pup for only 4 days, transferring approximately 748,000 J or 178,657 kcal to the pup in that time.

Predator and prey distributions are likely to influence breeding habitat (i.e., pack ice, fast ice, beach, cave, and water) and lactation length. Whether breeding habitat and lactation length are related is difficult to determine using the comparative method because species breeding in similar habitats tend to be close phylogenetically (and are thus nonindependent). However, some general comparisons are possible. Pack or floe ice is unstable compared to fast ice and could constrain the duration of lactation. Some species with protective lairs or caves [arctic Baikal ringed seal (*Pusa sibirica*), and Mediterranean monk seal (*Monachus monachus*)] wean late for phocids, at 2–3 months. Body size and fasting ability also influence the duration of nursing. Phocid

females tend to be larger than otariid females and can thus fast longer.

Otariid mothers leave their young after the first week to hunt for 1–14 days before returning to nurse their pups. When the mother is hunting, the pup is typically fasting. She returns for 1–3 days and fasts while she feeds her pup. The duration of her absence is correlated positively with the milk she provides per pup visit. If food is abundant, then mothers make shorter foraging trips than when food is scarce and feed their young more often. Thus, prey abundance is correlated positively with maternal body condition and pup growth rate. Some otariids, such as sea lions, nurse their pups for 6–11 months. The Galapagos fur seal (*Arctocephalus galapagoensis*) nurses her pup for as long as 3 years.

As pups grow, otariid mothers may spend three-fourths of their time at sea, but each foraging trip tends to vary in duration. Phocids are adapted to store energy and fast for the entire lactation period, whereas otariids must supplement stores with some food. Thus otariid mothers must find breeding breaches that are also near productive feeding grounds. Beach breeding can provide safety to pups, but also constrains how far and how often females can venture to hunt. Otariid pups grow more slowly than phocid pups, but tend to be weaned at larger weights, 40% of maternal mass compared with 30% in phocids. When food abundance is high, otariid mothers can transfer more milk to their offspring than when food is scarce. Phocid females concentrate on feeding offspring rather than expend energy traveling to and from feeding areas. In sum, most otariids wean their young within the year, but later than most phocids.

Of all pinnipeds, walruses appear have the longest average period of maternal care, nursing their young for up to 3 years. It is not known whether walrus mothers fast during the initial stage of lactation. They give birth on ice, but the mother nurses her pup in the water. Known for their sociability, females and pups spend most of their time in female herds. Daughters stay in their mothers' herd. Sons leave the herd when 2–3 years old and join all-male herds.

Similar to the fast vs feed pattern that distinguishes lactating phocids and otariids, the larger baleen whales fast for long periods and toothed whales little or not at all. Baleen whales have higher fat milk and nurse for shorter periods than toothed whales. Mysticete mothers, who typically migrate to warmer waters to birth and rear young, can devote their time and energy almost exclusively to milk transfer, much like phocid mothers. Like pinnipeds, baleen whales are characterized by annual breeding and feeding cycles, including cases of postpartum estrus. Among baleen whales and pinnipeds, females are often attractive to males soon after giving birth. Thus, intense competition between males over access to females could interfere with maternal care, but detailed behavioral studies are needed.

Little is known about the nature of the baleen whale mother–calf relationship. Humpback (*Megaptera novaeangliae*) and right whales (*Eubalaena* spp.) are the best-studied baleen whales, likely due to their tendency to visit protected coastal areas to breed. Interactions between more than one mother–calf pair are infrequent, especially between humpback mother–calf pairs, which appear to actively avoid each other. The explanation for avoidance is unclear. Association between mother–calf pairs may disrupt the development of maternal or calf recognition. Similar to some of the large ungulate species, mothers may avoid unrelated calves to avoid milk theft. Anecdotal reports of Southern right whale (*E. australis*) behavior indicate that calves occasionally attempt to nurse from another female. With such a tremendous energetic output, milk transfer may be difficult to inhibit if the "wrong" calf attempts to nurse. Additionally, fasting in warm water likely reduces the metabolic demands on the mother. (Warm water would also reduce metabolic demands on the calf.) Fasting terrestrial mammals convert body fat to fatty milk more easily than mammals that eat during lactation, and this pattern is likely to favor fasting in baleen whales that invest in rapid growth of a large calf. Consistent with this, fasting mammals (terrestrial and marine), including baleen whales, have milk low in carbohydrate, protein, and water, but very high in fat. The baleen whale mother can thus fatten in the feeding grounds, transfer that energy efficiently to her calf in the warmer breeding grounds, and assure a safer migration to higher latitudes. Larger calf body size would likely reduce predation risk and other somatic costs (e.g., metabolic). Four balaenopterids [blue, (*Balaenoptera musculus*), fin, minke, (*B. acutorostrata* and *B. bonaerensis*), and sei (*B. borealis*) whales] tend to wean early, before or soon after reaching the feeding grounds (at 6–7 months). Humpback, right, bowhead (*Balaena mysticetus*), and gray (*Eschrichtius robustus*) whales continue to nurse offspring to older ages and are typically feeding during the latter stage of lactation. Although bowhead whales migrate, they do not migrate to warmer waters to calve and apparently do not fast. Given this pattern, bowhead whales are predicted to have milk lower in fat, nurse offspring for longer periods, and have slower growth rates compared to other baleen whales. Existing data are too limited to make explicit comparisons.

Little is known about mother–calf behavior and associations during migration. Observations of Pacific humpback whales off the coasts of Australia and of gray whales off the coasts of North America indicate that adult males often accompany mothers and calves during the migration. This may reduce killer whale (*Orcinus orca*) predation risk, although the males are likely there to mate with the female, not protect the calf. Several studies have indicated that up to one-third of humpback whale calves bear killer whale tooth marks by the time they reach the feeding grounds with their mothers. Killer whale attacks on gray and humpback whale calves have been observed, but there is no evidence to suggest that males aid calves during such attacks.

Odontocete life history patterns are slow relative to baleen whales. The baleen whale usually reaches reproductive maturity in 4 or 5 years, but the typical odontocete takes 10 years or more, despite a much smaller body size. Only the smallest odontocetes, such as porpoises, tend to reach reproductive maturity by age 5. With a relatively long period of immaturity and calf vulnerability, odontocetes may benefit more by stable patterns of group living compared to mysticetes.

Odontocetes do tend to have stable groups and patterns of association compared to mysticetes. In contrast to the baleen pattern, odontocete mother–calf pairs tend to associate with

each other and stable associations with female kin are common. Adult male associations with mothers and young calves are more variable. For example, adult male killer whales consistently associate with female kin and their offspring. Female sperm whales (*Physeter macrocephalus*) and young spend most of their time with female kin and rarely associate with adult males. Shark Bay bottlenose dolphin (*Tursiops aduncus*) adult males associate with mothers and newborns (0–3 months) for only 5% of the time, although females are generally in larger groups during this period than when the calf is older. Larger group sizes may afford protection to the calf by reducing predation risk or harassment from conspecifics.

Close mother–calf association is characteristic of many toothed whales and dolphins, particularly in the delphinid family. Delphinid calves typically swim alongside the mother for the first few weeks in what is known as "echelon position." Within a few months, they begin to swim under the mother regularly in what is known as "infant position." In contrast, humpback and right whale calves tend to swim alongside the mother throughout development and separations are not common during lactation. Bowhead calves occasionally ride on the backs of their mothers during migrations. Odontocete mothers are presented with particular challenges baleen mothers do not face. Because they feed throughout lactation and hunt single prey, the mother must accelerate or dive deeply to hunt, often leaving her calf alone at the surface. Young calves are not very proficient divers, and they breathe more often, thus they sometimes "wait" at the surface while the mother forages below. This is especially pronounced in deep-diving species such as sperm whales. Mothers may dive for as long as between 30 and 50 min. The calf, often alone at the surface, has a tendency to swim toward any whale that comes up first. Some form of communal care in this deep-diving species may be an important selective force favoring matrilineal sperm whale units. A lone sperm whale mother would be at a distinct disadvantage if she had to abandon her vulnerable calf at the surface for long periods as she hunted for squid at depth. Among pantropical spotted dolphins (*Stenella attenuata*), lactating females feed on flying fish rather than squid (preferred by nonlactating females), which necessitates diving and separation from their calf. In bottlenose dolphins (*Tursiops* spp.), most mother–calf separations occur during the mother's foraging. When foraging, bowhead mothers and calves may separate 1–2 km for 30 min or more.

II. Protection and Predation

Otariids tend to breed on predator-free islands. Phocid pups can be vulnerable on fast ice, where polar bears and killer whales may feed on them. In the North Pacific, killer whales frequently catch harbor seal pups on their first forays into the ocean. South American sea lion (*Otaria flavescens*) pups are picked off beaches by killer whales. Great white sharks (*Carcharon charcharias*) are common predators of elephant seal pups (*Mirounga* spp.) and a variety of other pinniped prey. Mammal-eating killer whales will also prey on most pinniped species they encounter, including the largest species, Steller sea lions (*Eumetopias jubatus*). Maternal protection of pups from predation is not well documented. Adult male and female pinnipeds sometimes pursue predators, such as killer whales and sharks, but nothing about this behavior suggests that they are protecting offspring per se.

Mothers and other female whales and dolphins do protect offspring from predatory attacks. Sperm whale females may form a ring "marguerite formation" around a calf and sometimes they place their heads to the center and use their powerful tails to deter a predator. At other times they will face out in a circle, with their tails facing the calf. Indian Ocean bottlenose dolphin mothers and close associates have also defended calves from predation attempts by tiger sharks (*Galeocerdo cuvieri*) (Mann and Barnett, 1999). Gray whale mothers have been observed placing themselves between killer whales and their calves (Black *et al.*, 1999).

Bottlenose dolphin infanticide has been documented from retrieved carcasses at two Atlantic Ocean sites: the Moray Firth in Scotland and Virginia, United States. The perpetrators of calf killing are not known. If the pattern is similar to that found widely in felids, ursids, primates, and rodents, then it is likely that unrelated adult males are the perpetrators and might gain a reproductive advantage by monopolizing and mating with the mother of the victim. Polar bear mothers, like other ursid females, are known for their protectiveness and fierce defense of cubs from infanticidal males.

Among land-breeding SEXUALLY DIMORPHIC pinnipeds, offspring are occasionally killed incidentally by large patrolling males (e.g., elephant seals and sea lions). These killings appear to be by accident, e.g., when the male is preoccupied with defending the breeding beach. However, males also abduct and force matings on pups, sometimes resulting in the pup's death. Among ice-breeding pinnipeds, or when mating occurs in the water, pups are less vulnerable to patrolling males. In these species, sexual dimorphism is also less pronounced and the risk of being squashed is lower than for land-breeding species.

III. Mother–Offspring Recognition

Mutual vocal and olfactory recognition is common in a number of pinniped species, especially among otariids. This might be expected given that otariid mothers and pups often separate during the mother's foraging trips and the reunion depends on mutual recognition through repeated calling. Otariid pups are also fairly mobile, so the previous location of her pup would not be a reliable cue. In addition, otariids breed colonially, complicating the task of finding the pup or mother among hundreds. Phocid mothers would not necessarily need a recognition system if they remain close to their offspring, but some species that separate during lactation (e.g., harbor seals, *Phoca vitulina*) exhibit vocal recognition. After feeding trips, it is common for mothers to inspect several pups before finding her own.

Sea otter vocalizations have been compared to pinnipeds in structure and complexity. There is some evidence for short-range COMMUNICATION and vocal recognition between mothers and pups. Olfactory cues may also play a role.

Cetaceans have little or no sense of smell, but likely use vocal communication for individual identification. Little is known about mysticete mother–calf recognition and only slightly more

is known in odontocetes. Delphinids produce a diverse array of sounds, including echolocation clicks, burst-pulse sounds, and whistles. Dolphin calves are born able to whistle and will whistle often during the first days of life. Bottlenose dolphins and potentially other delphinids exhibit signature whistles, individually distinctive whistles in the first years of life. In bottlenose dolphins, simple whistles are present at birth, but the calf develops a more distinctive contour with age (although the calf may continue to produce simple whistles as well). Mechanisms influencing the development of SIGNATURE WHISTLE contours are not known. Although the calf's signature whistle is not present at birth, the young calf may learn to identify his or her mother's signature whistle soon after birth and mothers may be able to recognize the calf's simple whistle. Field studies suggest that whistles mediate natural separations and reunions between mothers and calves. Calves tend to whistle more than mothers, perhaps indicating the calf's greater motivation to reunite with the mother than vice versa. Experimental work with captive and temporarily captured animals suggests that dolphins can recognize the whistles of others. In the marine environment, depth (water pressure) and other habitat features may alter sound enough to make voice recognition difficult; thus, selection may favor individually distinctive whistle contours in an environment where individuals join and leave each other and frequently lose visual contact. Few studies have sufficiently examined cetacean mother–calf communication in captive or wild settings to elaborate further.

IV. Maternal Influence on Offspring Behavioral Development

Mothers influence offspring behavioral development by the experiences they provide, including migration and navigation, communication, social interactions, and foraging. To secure the transition from dependence to independence, marine mammal offspring must acquire necessary survival skills. Although data are limited, maternal influence on the development of foraging skills has received the most attention.

Some types of marine mammal foraging may not require learning, but other foraging skills clearly require experience. Marine mammal young may develop foraging skills by independent (nonsocial) learning or by social learning, including stimulus or local enhancement (e.g., exposure to foraging areas with the mother), observation of maternal foraging or prey caught, and rarely pedagogy. Teaching requires that the "teacher" modifies his or her behavior in the presence of a naïve observer (pupil) at some cost or without benefit to the "teacher," which results in or facilitates acquisition of some skill or knowledge by the "pupil" (Caro and Hauser, 1992). As such, a pup or calf can "learn" from another animal, without teaching occurring. There are good examples of extensive social and nonsocial learning in Cetacea, but only a few possible examples of teaching. There are no examples of teaching in pinnipeds and little evidence for learning from the mother. In sea otters, learning by observing from the mother appears to be important, but teaching probably does not occur.

Pinniped pups theoretically could learn some foraging skills by following and observing the mother. However, there is little evidence to suggest this. Phocid mothers fast for most of lactation and leave the rookery before their pups do. Otariid pups could accompany their mothers on foraging trips, but most studies find little evidence of this. Pup absence from the rookery often coincides with maternal absence (a pup does not leave the rookery while the mother is present), but mother and pup travel and forage independently at sea. Otariid pups have more opportunities to develop swimming, diving, and hunting skills while relying principally on their mothers nutritionally. In the late-weaning Galápagos fur seal, pups catch their own prey for a year or longer before weaning. Some phocid pups gain considerable diving and swimming experience independently before weaning [e.g., bearded (*Erignathus barbatus*) and ringed seals (*Pusa hispida*)]. Some harbor seals change haul-out sites during lactation. The pup, then, may follow the mother 30 km or more. Although research with captive pinnipeds indicates that they are adept learners, including vocal learners, there is little to suggest that learning in the context of the mother–pup relationship is particularly important except for mother–pup recognition.

Several studies clearly document that otter pups (*Lutra lutra* and *Enhydra lutris*) learn from their mothers. Mothers take their pups on foraging trips and the pup watches the mother as she dives and retrieves prey. Mothers share their catch with pups, and in sea otters, pups even develop the specific tool-using strategy of the mother (use of rocks, soft-drink bottles, or other objects) to open shellfish or other prey (Lyons and Estes, 1989). It takes time for pups to develop adequate diving and foraging skills, which may help explain the long dependence period in this small marine mammal. Other MUSTELIDS typically wean offspring at much younger ages (i.e., 2–3 months).

To become independent, cetacean calves must be able to forage successfully on their own. They must also catch their first prey on their own. Unlike other hunting species (e.g., felids, canids), cetacean mothers generally do not share prey with young. One exception is the killer whale, where prey sharing between mother and offspring has been well documented. Despite many thousands of hours of observation on bottlenose dolphin calves in Shark Bay by the author, prey sharing has not been observed. Delphinids exhibit a diverse range of foraging strategies and there is some evidence that these are learned. Whether calves learn foraging skills by simple trial and error, social learning, i.e., observing the mother and other conspecifics, or other mechanisms is generally not known. Shark Bay bottlenose dolphin calves begin capturing prey within 4–6 months, even though they continue nursing 3 years or more. Female bottlenose dolphin calves in Shark Bay, Australia, adopt the sponge-foraging tactic of their mother, and those without sponging mothers do not develop the trait. This unusual form of tool use, which is adopted by only a small subset of the population, may be transmitted socially (and culturally) from mother to offspring. Humpback whale juveniles in the North Atlantic have learned new foraging strategies, likely due to shifts in prey density and distribution. These tactics spread rapidly through the population, although data suggest that older animals generally did not adopt the behavior. The humpback example may provide evidence for learning (horizontal transmission), but not from the mother (vertical transmission).

The diversity of foraging strategies that humpback whales exhibit (e.g., bubblenet, cooperative lunge feeding) may help explain their relatively longer nursing period compared to other mysticetes; i.e., the duration of lactation may, in part, be determined by the ability of young animals to forage independently. This might also help explain the longer nursing periods of odontocetes relative to mysticetes. The odontocete's task of capturing single, elusive, and specialized prey is likely to require greater foraging skill than the gulp-feeding techniques characteristic of mysticetes.

Killer whales may provide the only reasonable cetacean example of teaching, but more observations are needed. Experienced beach-feeding whales (who beach to capture pinnipeds) actively help younger animals develop this risky technique by nudging them to shore, partially wounding prey for young to manipulate, and assisting their departure from the beach.

V. Parity

For many mammals, parity (number of pregnancies/live births experienced) is correlated negatively with offspring mortality. For example, sea otter pups born to older, more experienced mothers tend to have lower mortality than pups born to younger mothers. First-time (primiparous) elephant seal mothers have lower weaning success than experienced multiparous mothers. However, a number of factors may contribute to this difference, including maternal mass (young mothers are smaller than old mothers), experience, dominance, and placement of pups in the rookery. Young, subordinate females relegated to the peripheral area of a breeding beach may have more difficulty relocating their pup and their pup may be more vulnerable to harassment and death.

First-born dolphin calves in captivity have higher mortality than later-born calves, but the cause(s) for the difference is not known. Both maternal experience and body size may be factors. Patterns of first-born mortality in wild populations are not sufficiently well documented to draw conclusions.

VI. Sex-Biased Investment

Several pinniped studies have investigated whether, consistent with the predictions of Trivers and Willard (1973), mothers in good condition preferentially invest in sons over daughters. According to the Trivers-Willard model, in polygynous species, maternal investment is likely to have marginally greater genetic payoff in terms of grandoffspring if the mother can influence offspring quality and thus produce a "super-son" compared to a "super-daughter" because males have greater variance in reproductive success than females. This depends on whether mothers can confer benefits, such as increased body size, to their offspring. Biased investment generally takes two forms: sex ratio and differential investment or maternal care.

Data on biased maternal care or sex ratios are equivocal for both phocids and otariids. The sex ratio does not covary with maternal mass, a good indicator of maternal condition. For example, Northern elephant seal (*M. angustirostris*) males are born heavier than females and young mothers are less likely to successfully wean sons compared to daughters; however, there is little evidence that mothers differentially invest in sons compared to daughters. Males gain most of their size during the 3- to 5-year growth spurt, long after weaning. Maternal expenditure may not contribute significantly to male reproductive success. Gray seal data are similarly equivocal. Otariid males are born slightly heavier and appear to grow faster than female pups, but none of the pinniped data provides clear evidence that sons exact greater reproductive costs on mothers than daughters.

In cetaceans, much less is known about biases in either sex ratio or maternal care. However, one study found that humpback whales were more likely to give birth to sons than daughters following the close of a long (3-year) birth interval compared to a short (1- to 2-year) one, although they hypothesized that mothers were in better condition after a 3-year interval they were thus more likely to give birth to sons. However, the actual condition of mothers is unknown. Notably, adult female baleen whales are slightly larger than adult males. It thus remains unclear what benefit mothers in good condition might gain by biasing the sex ratio toward sons if larger body size relative to females or other males is unlikely to give them an advantage. Available growth data suggest that weanling males are slightly smaller than weanling females. Other potential cases supporting Trivers and Willard are findings suggesting that male teenage sperm and short-finned pilot whales (*Globicephala macrorhynchus*) are occasionally still nursing, but female offspring nurse no later than age 7. Because both species are markedly sexually dimorphic, these examples may be more likely to fit the Trivers–Willard model.

VII. Mother–Offspring Conflict and Weaning

In a number of pinnipeds, weaning can be initiated by either mother or pup. Otariid pups may leave the rookery while their mother continues to return from foraging trips. Phocid pups are typically weaned by the mother. She leaves the rookery permanently. Likely, the proximate cue for both the mother's and the pup's departure from land or ice is hunger. The mother leaves when her fat stores are depleted. The pup leaves when it is no longer receiving enough milk to sustain itself. Among some otariids, such as the Galápagos fur seal, the older sibling (1–2 years) may compete with the newborn for milk, providing one of the few examples of clear sibling competition among marine mammals. The size of the older sibling appears to influence the degree of competition with the younger sibling.

Little is known about the weaning process in whales or dolphins. Weaning may be fairly sudden in some baleen whales that separate feeding and breeding. Some baleen species wean during the migration to higher latitudes or soon after, but other species wean toward the end of the first year. Weaning in toothed whales is likely more gradual than in mysticetes. Evidence for mother–calf conflict comes from studies of Indian Ocean bottlenose dolphins in Shark Bay and southern right whales in Patagonia. At both sites, mothers are less responsible for maintaining proximity to their calves as they age and mothers appear to use the sea floor to prevent calves from nursing. A right whale mother may also roll belly up to prevent her calf from nursing.

VIII. Association Postweaning

Like humans and a few other mammals, mother and offspring may continue to associate postweaning and sometimes for life. Evidence for strong mother–offspring association in pinnipeds is weak. Phocids wean abruptly and separate. Among otariids, some postweaning association is possible but difficult to study. Many otariid and walrus females stay in or return to the same breeding areas, and thus may well recognize each other and interact. Few data on this are available.

However, among cetaceans, high group stability and patterns of preferential mother–daughter association in fission–fusion societies (fluid patterns of group association, often with some underlying stability) indicate that strong bonds may persist. For example, resident killer whale male and female offspring remain with their mothers for life, a pattern unique to this species. Pilot whale daughters remain with their mothers postweaning, but sons may disperse temporarily or permanently. Sperm whale daughters remain in their matrilineal unit for life, much like elephants. Bottlenose dolphin daughters associate with mothers more postweaning than sons. In contrast, few daughter or son associations postweaning persist in mysticete whales. Among delphinids, the significance of such long-term kin associations is not known, but given the diversity of prey, the complexity of some delphinid social relationships, and other selective pressures on odontocetes, continued association is likely to offer the benefits of group living. Such benefits include protection from predators or conspecifics and sharing of information and/or tasks, such as calf care.

Pathology

DANIEL F. COWAN
University of Texas Medical Branch, Galveston

This article focuses on naturally occurring diseases of marine mammals and how their behavioral, physiologic, and anatomical adaptations to life spent mainly or entirely in the water influence those disease processes. Pathology is the study of diseases, including their mechanisms, manifestations, and diagnosis. One of the fundamental principles of pathology is that *every disease is a reaction to injury.* This means that an organism responds to an injury within its anatomical and physiological capacity, and that the way the organism responds, i.e., the way the disease process shows itself, will be determined or at least influenced by the organism's adaptation to its environment. Thus, a fish can develop an infectious disease of the gills, but cannot get pneumonia, a disease of the lungs. This seems obvious enough, but it may easily be forgotten when making assumptions about marine mammals. For example, the presence or absence of a thick coat of hair makes a difference in the way mercury is handled by an animal. In hairy species, a large portion of the mercury burden accumulated in the diet is eliminated by binding to HAIR, which is later shed. Cetaceans, however, which may be exposed to at least as much environmental mercury as their hairy fellow marine mammals, the pinnipeds, otters, and polar bears, have no hair to bind mercury and must find some other way of dealing with it. Their protective mechanism appears to be to combine it with selenium, rendering it insoluble and inert, and tucking it away in storage sites. This seems to serve the cetacean well, but it can be totally misleading to the researcher who finds large tissue burdens, even "lethal levels" of mercury in a healthy dolphin, and immediately casts about for a polluter to blame.

"Injury" is understood broadly to mean any noxious influence, which may include physical trauma; action of physical agents such as heat and cold; infection; intoxication; metabolic disease; nutritional deficiency; genetic disorders; and developmental malformations. To this list some would add "stress," the often (but not always) injurious effects of the attempts of an organism to adapt to environmental influences not directly injurious themselves. This idea allows us to think of concepts of, for example, deleterious effects of excess population density (crowding), even in the presence of an adequate food supply. We can also think of an animal living at the margin of its nutritional support, with enough food available to support day-to-day functions, but unable to respond to an event, such as pregnancy, exposure to unaccustomed cold, and exposure to toxins, among many others, that places an increased energy demand on it. In such circumstances, the factors that comprise immune resistance may be too feeble to prevent heavy parasitic infestation or infection. With this perspective, we can readily understand that the environment in which an organism lives has a profound, if not determining, influence on the things that make the organism ill or cause it to die. By studying the specific diseases and patterns of occurrences of diseases in a group of animals, we can gain insight not only into the hazards of the environment, but also the basic physiology of the organism. We also have to consider that animals differ even within species and that they may differ in their reactions because of experience so that two animals that seem nearly identical might exhibit wide differences in their response to apparently identical environmental situations or stressors.

Because environments vary, it may be expected that patterns of disease might vary among populations of a single species of animal living in different places, and because physiology and anatomy vary, patterns of disease may also vary among different species living in the same environment. Indeed, this phenomenon is well known in the world of experience. Human populations living in temperate climates and industrialized societies have very different patterns of disease than people living in tropical agricultural societies, even though both populations would be susceptible to the same noxious agents if only they were exposed to them. Conversely, dogs, cats, and humans all living in the same house will have their own separate infectious diseases, and only rarely do they infect each other.

From the foregoing, it can be seen that study of the diseases of wild marine mammals can offer insights into anatomy, physiology, and environment that might be gained in no other way. Disease represents an interaction between an individual animal and its environment, which demands an understanding of complex, often intricate processes involving several different organisms. For example, it is not enough to simply measure the level of a toxin in water to gauge its effects on animals living in the water, as the toxin itself can be changed not only by the presence of other chemicals in the water or by bacterial action, but also by sequential processing through metabolic systems of different organisms and ultimately by the physiology and chemistry of the marine mammal itself. Observations indicate, for example, that adaptation to environmental mercury over millennia makes it possible for dolphins to tolerate tissue burdens of mercury that would be fatal to cattle (Turnbull *et al.*, 1998). Animals with high tissue mercury burdens may show no sign of the tissue lesions associated with mercury toxicity in land animals (Siebert *et al.*, 1999). Diseases may appear as a secondary effect of some primary phenomenon; e.g., a population with inadequate food supplies may become debilitated, with lowered resistance, and so be overwhelmed by parasites that ordinarily are held in check. In this instance, the load of parasites is obvious, the lowered resistance to parasitism may be inferred, and the lack of appropriate nutrition recognized by other factors, such as body condition, serum protein levels, and measurements of specific nutrients in body fluids.

It is remarkable that until relatively recent times, almost nothing was known about the diseases of free-ranging marine mammals, and even today not much is known about the diseases of sea otters (*Enhydra lutris*), polar bears (*Ursus maritimus*), manatees (*Trichechus* spp), and walruses (*Odobenus rosmarus*) in the wild. Even though many tens of thousands of large whales were taken in the whaling industry, only a few reports of pathology resulted. Simpson and Gardner (1972) compiled a detailed discussion of the histology and histopathology of marine mammals based mainly on their own experience and an appraisal of the scattered reports then available in the literature. This work

remained the standard resource and reference for two decades and is still very valuable. For practical purposes, systematic study of the pathology of marine mammals in the wild is limited to pinnipeds, dolphins, and, to a lesser degree, manatees and did not begin until the mid-1960s. The current literature contains many reports of findings in single animals, or small groups of animals, but relatively few investigations resulting from long-term, detailed studies. The state of the art and science of pathology of marine mammals is such that new and important observations may still be made using dissection and light microscopy, techniques developed and applied to many species in the 19th century, supported by the latest developments in molecular biology and molecular diagnostics.

I. Sources of Information

All marine mammals are protected by law in most developed countries with notable exceptions being Canada and Japan, which allow commercial hunting of some species. In countries with protective laws, access to marine mammals is carefully limited and experimentation, with rare exceptions, is prohibited. This means that apart from animals maintained in marine aquaria and under the care of specialized veterinarians, all information is derived from animals that strand on beaches, are killed accidentally as by-catch in the fishing industry, or taken by approved subsistence hunters, who may make arrangements with researchers for access. Not much scientific use is made of animals in commercial hunting operations. Apart from the occasional stranding near a population center or accidental death associated with fishing, it is rare for an animal to be found in an undecomposed condition by a trained observer with appropriate equipment and supplies. Therefore, what we know is based mainly on case reports, often incomplete, and a few studies involving at most a few dozen animals, often of several different species. Stranding and rehabilitation centers are the main source of information. These obviously can describe only what they see, which is mainly coastal species and the occasional pelagic animal that is cast up on the beach.

Despite these limitations, observations made in stranding centers may be the source of powerful insights into the state of the free-ranging, otherwise unaccessible wild populations. Phocine distemper virus, a morbillivirus responsible for the deaths of at least 18,000 harbor seals (*Phoca vitulina*) in Europe in 1988, was first isolated from stranded seals in that year. Phocine herpes virus (PhHV1) was identified in 1985. The highly toxic domoic acid, a product of the diatom *Pseudo-nitzschia australis*, was recognized as a cause of death in over 400 California sea lions (*Zalophus californianus*) examined in a rehabilitation center in 1998.

It is not clear just how representative beach-stranded animals are of the population at large, but for the time being this issue is of lesser importance than simply building a reliable database of descriptions of pathological findings and relating these to age, sex, reproductive status, incidence, and type of trauma sustained, identification of infectious diseases, toxin and parasite burdens, and so on. Continuing, detailed pathological studies of stranded dolphins are currently taking place in a number of areas, most notably on the North Sea coast of Germany, the St. Lawrence River and estuary in Quebec, coastal New Zealand, the United Kingdom, Italy, Peru, the Canary Islands, and the Texas and Florida coasts of the Gulf of Mexico, among other locations. Pinnipeds are studied in central California, and manatees in Florida. Important but non-continuing studies of strandings have been done in southern California, in which the focus was solitary strandings, and in the eastern United States, involving mass strandings. Mortality events in which unusually large numbers of deaths of marine mammals, sometimes accompanied by substantial mortality of fish, seabirds, and turtles, occur over a period of days to months, are under a special program conducted by the U.S. National Marine Fisheries Service.

II. Differences between Pathology of Strandings and By-Caught Animals

Spontaneous strandings of single animals are believed to be caused by sickness or some other impairment, such as injury, and are therefore a selected and perhaps nonrepresentative element of the population from which they come, whereas by-catch animals are snatched from their daily lives and may be presumed to be healthy, or at least representative of the general condition of the population. Diseases seen in these may be a better indicator of the disease status of the population or of disease in an early stage, whereas strandings might represent a late stage. This is mostly presumption, based on logic rather than observation, although accumulating experience suggests it is true.

"By-catch" is the term used to refer to animals that are caught by accident during the course of trying to catch something else. In the case of marine mammals, it usually means ENTANGLEMENT of the animal in fishing nets. Commonly this involves one or a few animals, but in the early days of the purse-seine tuna fishery in the eastern tropical Pacific Ocean, it might mean hundreds or even thousands of animals. At least two episodic studies of pathology have been conducted on this group of animals, and a continuing study of by-catch is taking place in northern Germany.

III. Mass Strandings vs Mortality Events and Solitary Strandings

Mass strandings, the more or less sudden appearance on a beach of large numbers of whales or dolphins, remains a problem to explain. Various theories have been put forth, such as bad luck of animals swimming inshore in being caught by an ebbing tide. This presupposes several things: complex bottom topography, a gently sloping bottom, a rapidly moving tide, failure of echolocation in shallow water, interference in echolocation by extraneous noise, and perhaps distraction of attention by feeding. Other theories implicate an impaired leader who misjudges the tide and leads the herd into a strand or, more likely, fails to lead them away from the beach at the right time. One or two observers even see similarities to lemming migrations and postulate a mass suicide. All of these theories lack supporting experimental evidence. What is known from the few pathological studies of mass-stranded animals is that sub-

stantial disease is found, mainly parasitism, which would have been present for some time. Some of this may have been severe, but most is of a tolerable level. If the disease causing the strand was present yesterday or the day before, why did they strand today?

Geraci and St. Aubin (1977) examined the naturally occurring diseases in 41 of a herd of approximately 150 stranded Atlantic white-sided dolphins, *Lagenorhynchus acutus*. The most prevalent lesions were associated with parasites: mastitis associated with the nematode *Crassicauda grampicola* and biliary and pancreatic fibrosis associated with biliary flukes *Oschmarinella laevicaecum*. In these conditions, the parasite enters the duct system and provokes inflammation and scarring. Other parasites commonly found were *Phyllobothrium delphini* and *Monorygma grimaldi* cysts in the blubber and abdomen, *Crassicauda* sp. in the fascia, all of which were encysted, and long-term infestations. A roundworm, *Stenurus globicephalae*, was present in the cranial air sinuses and lungs, where it caused minor inflammation, and the tapeworm *Tetrabothrius forsteri* was found in the duodenum. These findings are all typical of wild dolphins in the North Atlantic and cannot be invoked to explain the stranding. This is generally the story of mass strandings; many clues, but little definitive evidence.

"Mortality event" is the term applied to excess deaths (over that known to occur in an average period of time) in a relatively limited geographic area. The difference between a mass stranding and a mass mortality is the time scale and circumstances. Mass stranding is an event of a day or so, whereas mass mortality evolves slowly over days, weeks, or months. In contrast to mass strandings, animals involved in a mortality event are very likely to suffer from infectious disease (e.g., Schulman *et al.*, 1997) affecting some segment of the local population or a toxic event such as the brevitoxicosis associated with red tide (e.g., Bossart *et al.*, 1998) or domoic acid toxicity associated with bloom of a particular diatom (Scholin *et al.*, 2000). One obvious difference between an infection and an environmental toxicosis is that the infection, typically viral, tends to be limited to one kind of animal, whereas the toxicosis may affect mammals, birds, fish, and turtles alike. Epizootic infection can occur among terrestrial animals as well, but an environmental biotoxicosis is a uniquely aquatic event.

Solitary strandings of dolphins, which may be taken as representative of coastal marine mammal strandings, reflect a variety of causes, from trauma (boat strikes), intra- and interspecific aggression, accidents, and a wide variety of disease causes (Haubold *et al.*, 1999). This tends to apply more to juvenile and adult animals, whereas young calves seem to strand more for social reasons, such as separation from the mother, and although debilitated, are less likely to be sick. This observation does not apply to pinniped pups, however, which tend to be suffering from infection, septicemia, dehydration, starvation, or trauma when found stranded.

IV. Parasitism

Infestation by parasites is nearly universal in wild animals, and marine mammals are no exception. Indeed, the parasites found in pinnipeds and cetaceans are so widespread and bear such a consistent relationship to their hosts and their environments that they have been used as "tags" to study specific mammal populations (Dailey and Otto, 1982). Parasitism is probably the best recognized disease factor in free-ranging marine mammals, and the variety of lesions caused may be illustrated by a few examples.

Parasitism is by far the leading cause of pathology associated with stranding in wild pinnipeds and cetaceans, affecting the BRAIN and lungs as well as the GASTROINTESTINAL TRACT, liver, and pancreas. Large (baleen) whales may suffer KIDNEY damage from *Crassicauda*, and seals may carry heavy, often fatal, burdens of heart worm. While parasites occur in other sites, such as in the blubber and under the peritoneal membranes, they are not usually of any particular significance and apparently are not an important mortality factor.

The great majority of small cetaceans, approaching 100%, have nematode lung worms. These seem to be relatively innocuous as long as they remain in the airways, but provoke an inflammatory reaction on entering the alveolar spaces, the distal sites of air exchange. These delicate tissues lack the defenses of the airways, which are covered by a cell layer adapted to a passageway and have a thin coat of protective mucin. The parasite in the alveolus, perhaps associated with bacteria, provokes the formation of small abscesses, which rarely may rupture into the pleural space, but typically subside into fibrous nodules (granulomas), which may mineralize. At this stage, they are inert and probably of no further consequence, except as a marker of past events. In some delphinids, notably the harbor porpoise, *Phocoena phocoena*, in the North Sea, the airways may be filled to occlusion by large nematodes of several species (Siebert *et al.*, 1995).

The effect of parasites in the lungs illustrates very well the influence of adaptation of the lung to diving on the disease process. The cetacean lung differs from the lung of a typical land mammal in that the diving mammal has structural adaptations designed to keep air in the gas exchange spaces, the alveoli, while also tending to eliminate or reduce "dead space." Dead space is the functional compartment of the lung in which gas exchange does not take place; for practical purposes, the airways. In diving, compression of the animal by surrounding water, which increases with depth, forces incompressible blood into any compressible space. This is familiar to human divers as the "squeeze effect." In the lung, the alveoli can be collapsed by compression of the chest wall, but the airways are held open rigidly by cartilage bars. It appears that the reduction of airway dead space and the prevention of the forcing of alveolar air back into airways are accomplished by the action of a series of muscular valves or sphincters within the airway. All of this extra tissue (compared with the lung of a terrestrial mammal) makes the cetacean lung dense and heavy. When an agent such as a lungworm, bacteria, or aspirated contaminated water reaches the distal airways and provokes an inflammatory reaction, it appears that the muscular sphincters go into spasm, preventing movement of air, and evacuation of secretions.

The effect of the peculiar anatomy of the cetacean lung is to cause nearly all infections to form abscesses with focal destruction of tissue. The density of the lung tissues in general prevents spread of the inflammation beyond the local focus. In

contrast, bacterial infections of the terrestrial mammalian lung may resolve without destruction of tissue but may spread in an unconfined fashion to involve large regions of the lung.

Delphinids of many species harbor flukes of the genes *Nasitrema* in the pterygoid air sinuses of the skull. These sinuses connect with the external environment by way of the nasal passages and by way of the eustachian tubes, with the specialized structures of the ear, the ossicles or acoustic bullae. Bullae are connected to the brain by the staticoacoustic nerve, concerned with both balance and hearing, which passes into the skull within a dense fibrous sheath. Characteristics of the anatomy of the air sinus, the acoustic bullae, and the staticoacoustic nerve permit invasion by the worm into the subarachnoid space of the brain, in which the spinal fluid circulates. Taking advantage of this space, they migrate over the surface of the brain until they reach a point of penetration, at which they burrow through the cortex or gray matter deep into the white matter, laying large numbers of eggs (ova). This migration produces destructive tracts or galleries in the white matter, with hemorrhage and necrosis. It is not clear what induces the migration of the parasite into the brain, as it is a dead end for the worm as well as damaging to the host. It is a complex problem, seen mainly in beach stranded dolphins in both the Atlantic and the Pacific Oceans. Dolphins of the same species caught as bycatch in the eastern tropical Pacific tuna fishery also have infestations of the same fluke in the air sinuses, but apparently without invasion of the nervous system (Walker and Cowan, 1981). Why this difference should occur is not known. It is possible that a third factor is involved, such as some agent in the inshore water that influences the worm, i.e., makes it "sick" and disoriented. There is clearly a differential species susceptibility among dolphins, as the air sinus infestation occurs with great frequency in stranded Atlantic bottlenose dolphins, *Tursiops truncatus*, but without nervous system invasion.

Flukes of several species (*Campula rochebruni, C. oblongata,* among others) infest the bile duct and pancreatic duct of dolphins and porpoises. The effect may be a relatively low-grade irritation or inflammatory reaction ranging up to chronic active inflammation with fibrosis and occlusion of the duct. This results in inflammation and fibrosis of the affected organs, a form of hepatitis (cholangitis), and pancreatitis. Serious disease is relatively uncommon but may be life-threatening when it occurs.

The stomach and intestine of marine mammals are the frequent site of infestation with nematodes, trematodes, and cestodes. A light infestation may be relatively innocuous, but occasionally the stomach or intestine may be perforated by parasites, resulting in peritonitis. In some geographic areas, gastric ulcers associated with the nematode *Anisakis simplex* are common in stranded cetaceans (Abollo *et al.,* 1998). Sea lions may carry heavy burdens of hookworm.

Massive infestation of the heart and great vessels of elephant seals by nematodes (*Otostrongylus circumlitus*) is described from strandings on the central California coast (Gulland *et al.,* 1997). Heavy burdens in the right atrium, right ventricle, and pulmonary artery were associated with pulmonary thromboembolism (blood clots in the lungs) and pulmonary arteritis, an important cause of mortality. Death of infested juvenile elephant seals (*Mirounga angustirostris*) before the parasite reaches maturity suggests that the host–parasite association is relatively recent. Similar heartworm infestation occurs in seals in the Atlantic Ocean. This disease is very much like the heart worm infestation of dogs seen in parts of the United States.

V. Neoplasia

"Neoplasia" is the process of the formation of autonomous new growths in a tissue. The mass of tissue formed is called a tumor. Some of these are benign, meaning limited in capacity to harm, and some are malignant (cancer), having the ability to invade adjacent tissues and to set up colonies in remote organs and tissues. Some tumors have been shown to be caused by viruses, some by chemicals, and a rare few are associated with parasitic infestation. For most, a definitive "cause" is not known; we can only speak of "associations."

Once thought to be rare in marine mammals, neoplasms were found to occur at an incidence of 2.5% in a large surveyed population of marine mammals (Howard *et al.,* 1983a). As of 1987, there were probably only 41 confirmable reports of tumors in cetaceans. Then, in 1994, 21 additional tumors, some benign and some malignant, were reported in 12 of 24 animals from the small, isolated, and highly contaminated population of beluga whales (*Delphinapterus leucas*) in the St. Lawrence River in Quebec (De Guise *et al.,* 1994). Seven of these animals had more than one tumor; one had as many as three tumors, two malignant. One was as young as 1.5 years, another 3.5 years. The ages ranged up to over 29 years. This particular environment, the estuary of the St. Lawrence River, suffers heavy industrial pollution, with the waters containing polycyclic aromatic hydrocarbons. High concentrations of organochlorines, heavy metals, and benzo[a]pyrene were found in the tissues of the belugas. Thirty-seven percent of all tumors reported from cetaceans to that time were found in this small population of belugas, suggesting the direct carcinogenic effect of the pollutants or an impairment of resistance to the development of tumors.

Gulland *et al.* (1996) reported an incidence of 66 transitional cell carcinomas in a population of 370 (18%) California sea lions (*Zalophus californianus*) examined over a 15-year period. Transitional cell carcinomas are a particular type of cancer that arise from the lining epithelium or membrane of part of the urogenital tract. The original site and cause of this extraordinary incidence of a particular tumor type was a mystery for a number of years due to the advanced state of the disease when recognized. Typically, it had spread to involve most of the lower abdominal lymph nodes and viscera, and the primary site could not be determined. Environmental pollution with a variety of industrial chemicals was speculated to be the cause. Using a variety of modern analytical techniques, strong evidence has been found that the cause of the malignancy is infection with a gamma herpesvirus and not chemical pollution (Lipscomb *et al.,* 1999). This virus is implicated in the etiology of several animal cancers.

These two studies are very instructive in that they emphasize that a presumed low incidence of tumors in wild populations may be merely an artifact of not looking. When popula-

tions of wild animals are studied carefully over a long time, clusters of disease may be revealed. They also illustrate the value of modern technology in evaluating cause. In the case of transitional cell carcinomas, the cause, a herpesvirus, is demonstrated as well as it can be, whereas tumors in belugas are associated with pollution on epidemiological grounds but have not been proven conclusively to be caused by pollution.

VI. Infectious Disease

In their life in the oceans, marine mammals are exposed to a very great array of infectious agents, including dozens, if not hundreds, of species of bacteria, viruses, fungi, and protozoa. Because these are not distributed randomly, actual infection will vary with features such as location, water temperature, contamination from terrestrial sources, river effluents, food species, and exposure to other marine mammals. Most organisms are resisted successfully, and a state of more or less peaceful coexistence is maintained. Occasionally, however, an individual's defenses are so weakened or breached that one of these microorganisms can gain effective entry and set up a disease state. Sometimes an otherwise perfectly healthy animal comes into contact with a particularly virulent strain of organism or simply a novel one to which there is no natural or acquired immunity conferred by previous exposure. Under these circumstances, the organism can sweep through a population, causing epizootic disease with high death rates. Some isolated, small populations may be seriously threatened with extinction by new infections.

Bacterial, viral, and mycotic (fungal) infections are important morbidity and mortality factors in marine mammals, often appearing in outbreaks, such as one that occurred in the endangered New Zealand sea lion (*Phoctarctos hookeri*), involving both adults and pups (Gales *et al.*, 1999). At least 53% of the pups born during the 1998 breeding season (total number was not known) had died within the first 2 months of life, with acute necrotizing inflammation of the blood vessels of the skin and lungs in adults and pneumonia and abscesses in the pups. The causative agent was determined to be a pleomorphic gram-negative bacterium, most likely *Campylobacter* sp., an organism not previously associated with this kind of mortality.

Several viral diseases are well known among pinnipeds, including seal pox virus and the San Miguel calcivirus, which produce contagious crusted lesions on the skin and oral mucosa. These are serious but not fatal diseases, much like human chicken pox. Seals, sea lions, and dolphins are known to be infected with herpesviruses, and dolphins are susceptible to a pox virus, which produces transient "pinhole" lesions of the skin. Rabies virus is uncommon, but has been observed in ringed seals. Herpesvirus is familiar to most people in the context of the infections known as shingles and cold sores. This virus occurs in many types and strains, some relatively innocuous, with others capable of producing severe disease of many organs, including the brain, lungs, liver, and heart as well as the skin. Several outbreaks of herpes infection have been recognized among marine mammals, usually producing skin lesions and sometimes pneumonia, as well as the spectacular incidence of cancer in California pinnipeds.

Morbilliviruses, which comprise a large group of viruses that cause measles in humans, and distempers in dogs and many other species also produce respiratory disease, immune deficiency, and neurological injury in seals, dolphins, porpoises, and a wide range of other cetaceans.

Marine mammals are quite susceptible to infection with morbillivirus. Morbillivirus infections, which were not documented in aquatic mammals until 1988, have caused at least five epizootics in these species since the early 1990s (Kennedy, 1998). Disease has been recognized in seals from Europe (*P. vitulina*) and Siberia (*Pusa sibirica*), striped dolphins (*Stenella coeruleoalba*) in the Mediterranean Sea, and bottlenose dolphins in the northern Atlantic Ocean and the Gulf of Mexico, and seropositivity, indicating previous exposure to the virus, has been found in many species of seal, dolphin, porpoise, and whale from the Antarctic to the Arctic circle, in Florida manatees (*T. manatus*), and in polar bears in Russia and Canada. The disease in marine mammals is much like distemper in dogs, with destructive and inflammatory lesions in the brain, gastrointestinal tract, lungs, and lymph nodes, with immune suppression, and frequently superinfection of immune-impaired animals with fungi. Lung lesions include bronchointerstitial pneumonia, with filling of alveolar spaces by exudates, hyaline membranes formed by protein exudate covering gas exchange surfaces, and hemorrhage. Brain lesions are typically in the form of nonsuppurative encephalitis (nonpus-forming inflammation of the brain), with neuronal and glial necrosis, microgliosis, the brain equivalent of scar, and focal demyelination, or loss of the insulating covering of nerve processes. Necrosis of the cerebral cortex is also sometimes found (Kennedy, 1998).

It is not entirely clear whether the observed increase in cases of the morbillivirus distempers is due to actual spread of the infection or to improved case finding permitted by clear descriptions of the lesions in the literature, accompanied by the development of advanced methods of laboratory diagnosis.

Many bacterial species are found in marine waters and may be recovered from marine mammals, either as primary pathogens or as part of a complex normal flora. Bacterial infection is thought to be the main cause of disease and death in marine mammals, especially in captivity (Howard *et al.*, 1983b). Certain marine organisms are known to produce severe or fatal infections. These include the halophilic or salt water *Vibrios*, of which there are many species, and *Edwardsiella tarda*. These organisms are common in the marine environment and are frequently encountered in cetaceans and less often in pinnipeds. The exact means by which these organisms are acquired by marine mammals is not known, but experience with humans indicates that they can be inoculated directly, infect wounds, and be ingested with food items, such as shellfish. It is reasonable to assume these routes of entry in marine mammals as well.

Clostridia are obligate anaerobic bacilli, ubiquitous in the environment in soil, sewage, marine sediments, decaying animals and plant products, and the intestinal tracts of many animals. More than 80 species are known. Some species are potent toxin producers, causing botulism and gas gangrene. Many species of *Clostridia* have been cultured from blood, lesions, and intestinal tract of stranded dolphins in the Gulf of Mexico,

but are less common in California pinnipeds. Some *Clostridia* may be merely part of the normal intestinal flora, whereas some species have been recovered from lungs in cases of pneumonia.

Many species of bacteria have been recovered from cultures of respiratory tract, kidney, and intestinal tract, as well as lesions of captive and stranded marine mammals. The majority of these species are known to be pathogenic or potentially pathogenic. There may be a differential distribution of bacteria in different kinds of marine mammals, as in cetaceans *Vibro, Clostridia, Pseudomonas,* and *Edwardsiella* tend to predominate, whereas in pinnipeds from the California coast, for example, the major pathogens encountered in sea lions, elephant seals, and harbor seals are organisms usually associated with the intestine, mainly *Escherichia coli, Klebsiella pneumoniae, K. oxytoca, Proteus* spp., *Pseudomonas* spp., *Enterococcus* spp., and *Salmonella*. Leptospirosis occurs in harbor seals, California sea lions, and northern fur seals (*Callorhinus ursinus*).

Brucella infection of the placenta with abortion has been reported in dolphins. The organism, *Brucella delphini,* appears to be readily transmissible among dolphins and has also been cultured from the lung of a bottlenose dolphin at necropsy. Brucella infection occurs in other cetaceans and seals. A substantial percentage of marine mammal serum samples (about 30%) react positively on tests used to detect antibody to *Brucella* spp., and a number of *Brucella* isolates have been obtained from marine mammals. However, only *B. delphinus* has been associated with reproductive failure.

Mycobacteria include organisms that cause tuberculosis and leprosy. They are hardy organisms and may produce infection across a wide array of warm- and cold-blooded animals. *Mycobacterium marinum,* originally described from fish, was first recognized as a human pathogen in 1951. *M. marinum* infection has been transmitted to a handler by a dolphin bite. The lesions, when localized, resemble abscesses, but are very slow to heal. Infection of deeper tissues and organs, such as heart valves, brain, eye, and joints, is very serious. *Mycobacterium bovis,* the agent of bovine tuberculosis, was transmitted from seals to their trainer. It caused similar lesions in both. Six cases of tuberculosis were observed over a 4-year period in stranded sea lions and fur seals from the coast of Argentina (Bernardelli *et al.,* 1996). Disease was widespread, involving lungs, lymph nodes, liver, spleen, pleura, and peritoneum. The lesions were typical granulomatous inflammation, from which organisms belonging to the *Mycobacterium tuberculosis* complex were isolated. This organism complex was similar to both *M. bovis,* the agent of bovine tuberculosis, and *M. tuberculosis,* the agent of human tuberculosis, but with enough molecular differences to be judged different from both. This suggests that the seals and sea lions did not acquire their infection from contact with humans or cattle. Organisms associated with the pinniped cases all had similar genetic features, suggesting that seal tuberculosis in that geographic area is caused by organisms belonging to a distinct grouping within the *M. tuberculosis* complex. An instance of disseminated *Mycobacterium chelonei* infection in a manatee (*Trichechus inunguis*) has been reported, and cases of cutaneous mycobacteriosis in a manatee and its handler have been attributed to *M. chelonei.* This organism was first identified in a reptile.

Marine mammals are subject to infection with a wide variety of fungi and filamentous bacteria (*Actinomyces, Nocardia, Dermatophilus,* which produce lesions similar to those caused by fungi) (Migaki and Jones, 1983; Reidarson *et al.,* 1999). Some of these are opportunistic, meaning that they occur in the context of debility or other disease, and some are primary pathogens. Both opportunists and pathogens are species that are familiar in human and veterinary medicine and are not peculiar to the marine environment.

Animals suffering immune suppression from morbillivirus disease may suffer severe, disseminated fungal infection, frequently from molds such as *Aspergillus* spp., as a terminal event. These organisms may produce disease in one of two patterns: superficial infections of skin that cause mild disease or indolent, very chronic processes; and the deep or systemic mycoses, which produce severe pyogranulomatous lesions. A pyogranulomatous lesion is a mixture of granulomatous inflammation, which is produced by persistent infection, with a pus-forming acute inflammation, indicative of a more active injury. Deep infections may involve any organ, especially the lungs and respiratory tract, and the brain. They may produce bulky lesions, which displace normal tissues ("mass lesion") as well as destroy tissues. Some organisms tend to permeate tissues and invade and block blood vessels.

Dermatophytosis, ringworm-like lesions, occur in manatees and pinnipeds, caused by the same organisms that cause ringworms in land animals and humans. Because infection with fungi requires spores from the environment rather than the vegetative stages found in marine mammals, direct transmission from animal to animal seems unlikely. Lobo's disease, caused by a fungus, *Loboa loboi* (syn. *Lacazia loboi*), is a very unusual disease recognized only in dolphins and humans and no other species. One instance of transmission from dolphin to human has been reported. Lobo's disease (once called keloidal blastomycosis) is a skin infection producing chronic, treatment-resistant, thick nodular swellings of the superficial dermis and epidermis, occasionally with ulceration. While the lesions in humans and dolphins are quite similar, there are subtle morphological differences in the organisms in the lesions, which may represent separate species (Haubold *et al.,* 2000). In humans, Lobo's disease is a disease of the Central and South American tropics, while in dolphins it ranges from the Gulf of Mexico, mainly Florida, to South America.

A number of protozoal infections, similar to those seen in land animals, are known to occur in marine mammals. These include toxoplasmosis, infection with *Toxoplasma gondii,* found in a West Indian manatee; pinnipeds; stranded Atlantic bottlenose dolphins, *Tursiops truncatus;* a Pacific spinner dolphin, *Stenella longirostris;* beluga whales, *Delphinapterus leucas;* and a killer whale, *Orcinus orca.* The animals were found in both Atlantic and Pacific Oceans, were captive and free ranging, and the lesions ranged from incidental to disseminated and fatal. The mode of transmission in these animals is not known. *Cryptosporidium* morphologically, immunologically, and genetically indistinguishable from those obtained from infected calves have been recovered from feces of California sea lions (*Zalophus californianus*), suggesting that the sea lion could serve as a reservoir for the environmental transmission of this organism.

Giardia have been isolated from fecal material from harp seals (*Pagophilus groenlandicus*), gray seals (*Halichoerus grypus*), and harbor seals in eastern Canada waters and ringed seals (*Phoca hispida*) from western arctic Canada and from California sea lions from northern coastal California. The widespread occurrence of these organisms in both terrestrial and marine mammals suggests transmission via rivers and streams, and perhaps carrier species taken as food.

VII. Chronic Diseases of Undetermined Cause

Several chronic diseases of unknown cause have been recognized in dolphins and small whales stranding along the Texas coast of the Gulf of Mexico. These are arthritis, pulmonary angiomatosis, and amyloidosis.

A high incidence of arthritis of the synovial joints (neck and flipper joints) was found in several cetacean species, including 10 of 49 (20%) bottlenose dolphins (*T. truncatus*), 1 of 2 (50%) striped dolphins, 1 Fraser's dolphin (*Lagenodelphis hosei*), and 1 pygmy sperm whale (*Kogia breviceps*) (Turnbull and Cowan, 1999a). Some of these cases were associated with infection of the joint, whereas others showed features typical of degenerative or osteoarthritis, commonly thought of as a disease of aging. Two such cases, however, were in immature animals. The severity of disease ranged from a relatively minor loss of articular cartilage to complete destruction and fusion of the joint.

Angiomatosis is a newly recognized and bizarre disease, to date reported only in bottlenose dolphins from the Texas coast (Turnbull and Cowan, 1999b). This disease was first recognized in 1991 in a minor form but has since increased in incidence and severity to involve all adult bottlenose dolphins. It is characterized by the proliferation of small blood vessels in the lungs to form small clusters. It involves all parts of both lungs equally and to the same degree and is not associated with inflammation. These vascular clusters progressively enlarge and fuse. In advanced stages of the disease, the walls of the new vessels thicken and lumens are reduced. Proliferation of vessels in the bronchial-lining mucosa erodes the bronchial cartilages and severely constricts airway diameter. The normally very thin and pliable pleura is similarly involved and becomes thick, stiff, and opaque, reaching a thickness of 3 mm. The effect on respiratory physiology has not been measured, but the gross and microscopic appearance suggests marked impairment of lung ventilation and restriction of circulation. One animal with advanced disease had massive thickening of the right ventricle of the heart, suggesting a marked increase in pulmonary artery blood pressure (pulmonary hypertension). Lymph nodes associated with the lungs in advanced cases may also show a pronounced vascular proliferation, and hemangiomas (tumors of blood vessels) are a common finding in the lymph nodes and an occasional one in the lungs. The cause of this disease is not known.

Amyloidosis, a disease characterized by deposition of a dense amorphous waxy proteinaceous material in the interstitial tissues of various organs, occurs in bottlenose dolphins stranding along the Texas coast of the Gulf of Mexico at an incidence of about 20%, a remarkable figure considering that the disease has not been reported from any other cetacean species (Cowan, 1995). This deposition occurs consistently in the kidneys, but also in small arteries in the spleen, heart, and lungs and around the acini of the thyroid gland and the palatal salivary gland. In the amounts present, the amyloidosis likely did not result in death, but experience in humans and other animals is that it can progress to organ failure. Several causes and associations are known for amyloidosis in humans and other animals, including chronic infection and disorders of the lymphoreticular system, but the cause of dolphin amyloidosis remains obscure.

VIII. Conclusions

There is much to be learned from the study of the pathology of marine mammals. Work by many observers since the mid-1970s has done much to reveal the causes of sickness and death among these heretofore mysterious animals. We are coming to understand how similar the diseases of marine mammals can be to those of terrestrial mammals and how different they can be. This is well illustrated by the evolution of inflammatory processes in the lung, which are strongly influenced by the special anatomy of the diving lung, and by the phenomenon of cerebral parasitism, which appears to depend not only on the special anatomy of the nasal passages, air sinuses, the specialized inner ear, and their relations to the brain, but also exposure to a very specific parasite.

Recognition of similarities in tissue structure and diseases can be treacherous if we approach the study of the diseases of marine mammals as if they are just like land animals, only wet. What we see, or think we see, may mean something very different than it would mean if we saw it in a land animal.

A great deal has been learned about the anatomy and physiology of pinnipeds and cetaceans in particular, and especially about cetaceans, who have taken typical mammalian systems, inherited from what many believe to be terrestrial forbears, back into the water and made them work there. The adaptive changes in the anatomy of the lungs in particular, which influence the development of disease processes in that organ, are plain and obvious. These are the adaptations we can see and are relatively easy to puzzle out. We are only now gaining insight into the unseen adaptations, such as the metabolic management of mercury, a protoplasmic poison. The vast majority of mercury (and most other toxic metals) in the environment is from natural, not industrial, sources and comes from rocks and the soil. It is leached out by rain and reach streams, rivers, and ultimately the OCEANS. These metals have always been present in the environment, perhaps not in the levels now recognized in some geographic regions. However, the adaptive experience of animals who spend their entire lives in the water and whose food consists of other organisms that spend their entire lives in the water has endowed them with startling abilities. These natural toxins cannot be avoided; they must be dealt with within the metabolic capacities of the animal who is inevitably exposed to them. Who could have predicted that a dolphin can carry a burden of mercury in its tissues sufficient to kill a cow four times over and still be healthy? The next task is to better understand these unseen adaptations so that we do not misread or misunderstand the message that Nature is sending us about the state of our oceans, written in the tissues of marine mammals.

Peale's Dolphin

Lagenorhynchus australis

R. Natalie P. Goodall

Centro Austral de Investigaciones Científicas, Tierra del Fuego, Argentina

Peale's dolphin (*Lagenorhynchus australis*) is common in inshore waters of southernmost South America, but because it seldom strands, its life history is not well known. Nearly a century passed before the first descriptions of its pigmentation and skull were discovered to be of the same species.

Accounts of only five specimens had been published by 1974; many of the 80 specimens now available were beach pick-ups.

I. Taxonomy

This species was first described as *Phocaena australis* Peale, 1848 and *Sagmatias amblodon* Cope, 1866. Although lumped with *Delphinus obscurus* and *L. cruciger* at different times, the present combination *Lagenorhynchus australis* was proposed by Kellogg in 1941. *Tursio chiloënsis* is a synonym. New work with DNA shows that the genus *Lagenorhynchus* needs revision and that the genus name of one Northern Hemisphere species and the three Southern Hemisphere SPECIES should revert to *Sagmatias*. Although there have been several common names in English, Peale's dolphin is now standard. *Delfín austral* (southern dolphin) is the common name in Argentina and Chile, although *llampa* is sometimes used in the latter.

II. Diagnostic Characters

A. Pigmentation

Peale's dolphins are dark gray or black on the dorsal surface, with two areas of lighter pigmentation on the sides (Fig. 1). A curved white-to-gray flank patch angles forward from the vent, narrowing to a single line ending below or in front of the dorsal fin. The posterior curves of the flank patch almost meet above the tail stock. The larger thoracic patch is light to medium gray, outlined with a narrow dark line on its lower surface. Both patches may be flecked with darker gray. A double black eye ring extends forward onto the snout, which is inconspicuous. The black chin or throat patch varies individually in the shape of its posterior border, usually extending backward on the sides to leave a white point in the middle. The white flipper patch is also delineated with gray and may extend onto the lower part of the flipper. The flippers and dorsal fin are dark with lighter posterior edges. Flippers in older animals may have a series of small knobs on the leading edge. The ventral surface behind the throat patch is white, with a few dark streaks in the genital area. Young animals are lighter gray than adults and have less definition between thoracic and flank patches than in adults.

Peale's dolphins can be confused with dusky dolphins, *L. obscurus*, through much of their range. The latter are usually a lighter gray and have white on the sides of the face and two light lines running forward from the flank patch.

B. Size and Shape

This is a stocky dolphin with the barest indication of a beak. Total length for 35 specimens ranged from 98 to 218 cm. Females (n = 20) measured 130–210 cm, males (n = 9) from 138 to 218 cm, and animals of unknown sex (n = 5) from 172 to 213 cm. The collections to date probably do not represent the total size range for the species. The heaviest animal (n = 5), a sexually mature female, weighed 115 kg.

III. Distribution

Peale's dolphin is a southern South American species commonly found from 59°S (the Drake Passage south of Cape Horn) northward to Valdivia, Chile (about 38°S), on the west coast and Golfo San Jorge, Argentina (44°S), on the east, including the Falkland (Malvinas) Islands, with exceptional records to 33°S in the southeastern South Pacific and 38°S in the southwestern South Atlantic (Fig. 2). Sightings of animals similar to *L. australis* in 1988 near the Cook Islands, in tropical waters thousands of miles from its normal distribution, have been considered an anomalous occurrence by some authors or perhaps a new species by others.

IV. Ecology

A. Habitat

Peale's dolphins occupy two major habitats; open coasts over shallow continental shelves to the north and deep, protected bays and channels to the south and west. In the channels, this is an "entrance animal" found in tide rips at the entrance to fjords. They often swim shoreward of or through channels in kelp beds (*Macrocystis pyrifera*). Although their distributions overlap, Peale's dolphins are usually coast hugging, while the similarly pigmented dusky dolphin occurs a few miles seaward. There is no information on abundance, stocks, or population size.

B. Prey, Predators, and Parasites

Peale's dolphins are noted for feeding in the kelp, where divers have observed them taking small octopus. They also feed

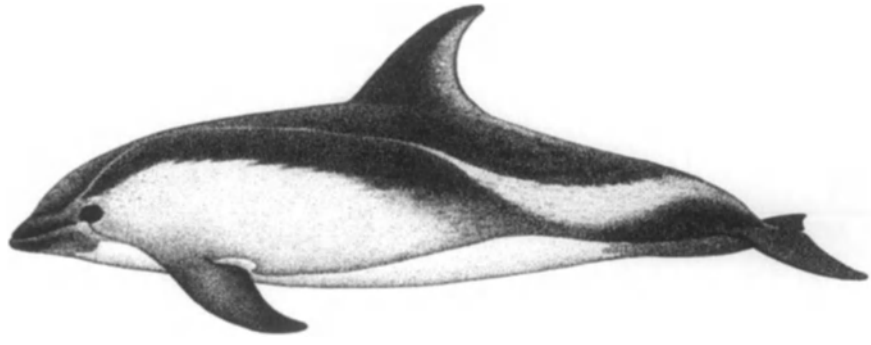

Figure 1 *Peale's dolphin,* Lagenorhynchus australis. *Pieter A. Folkens/Higher Porpoise DG.*

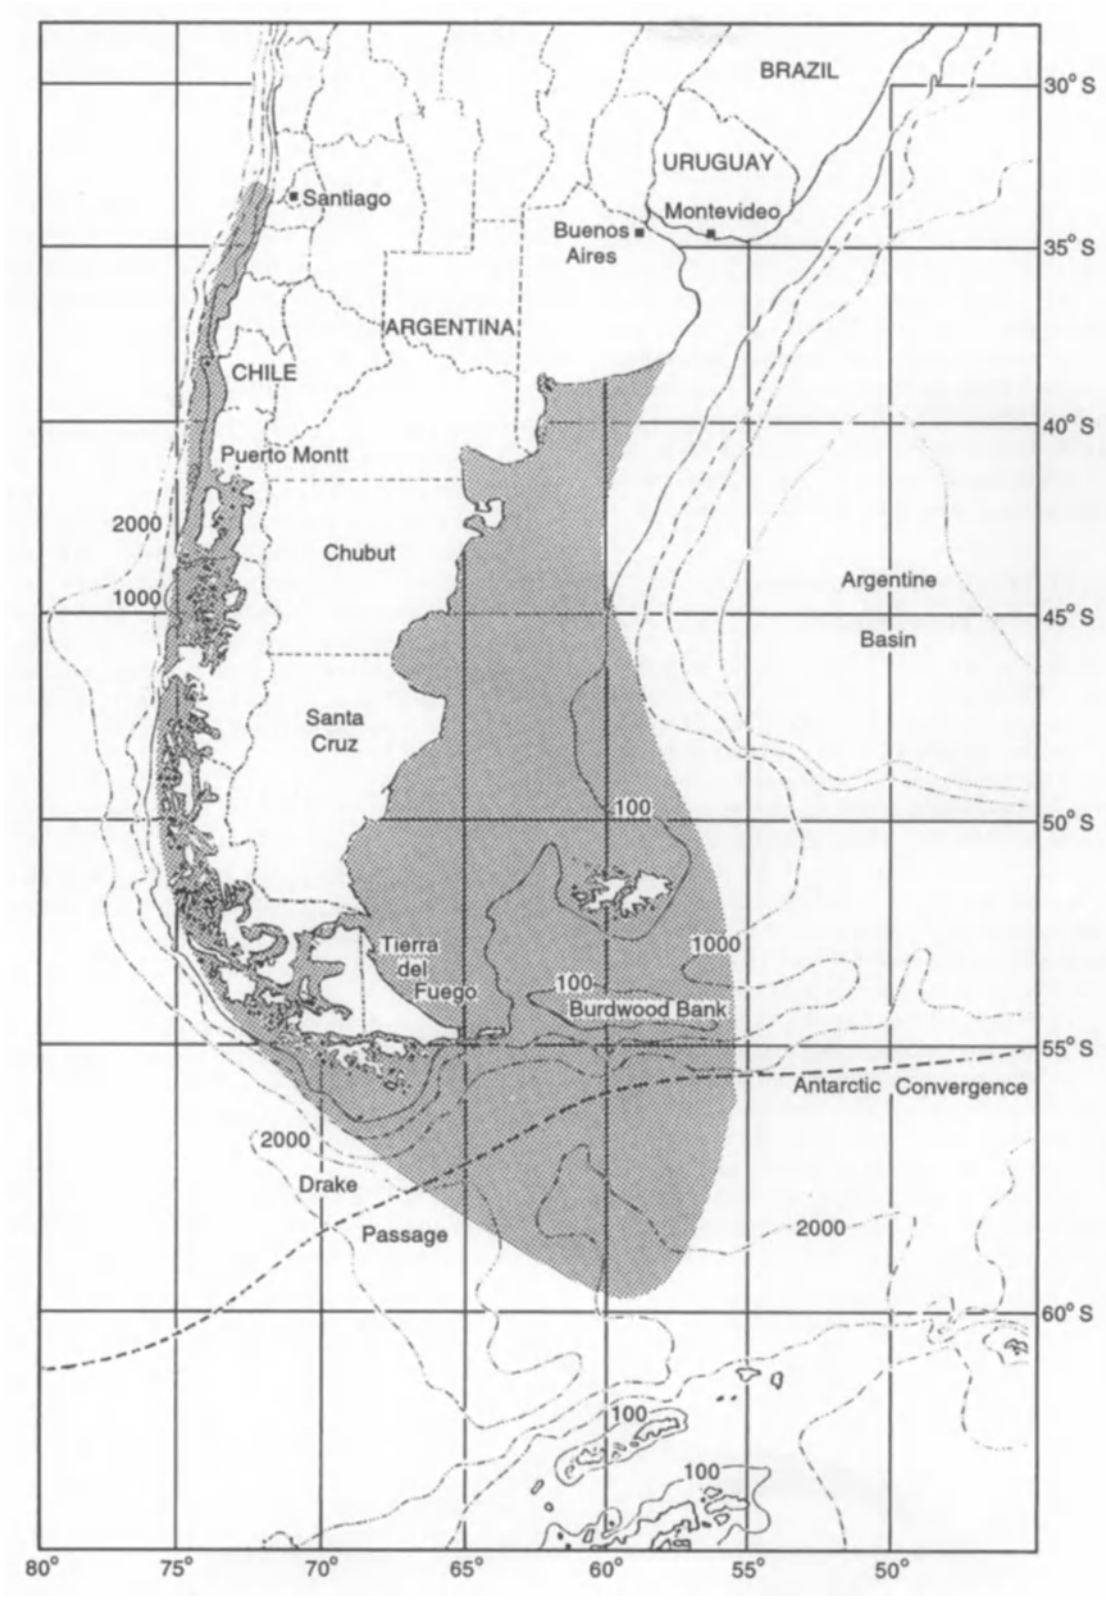

Figure 2 *The distribution of Peale's dolphin, based on sightings and strandings from 1839 to 1997.*

in open waters beyond the kelp on fish, often using the "sunburst" formation for herding. Few stomachs have been examined (n = 16), and those only from the southwestern South Atlantic. About 20 prey taxa have been identified, mainly demersal and bottom fish, octopus, and squid species common over the continental shelf or in kelp beds.

No predators but humans are known, although killer whales and leopard seals are a possibility. Parasite fauna are under study; *Anisakis simplex* was present in three females.

V. Behavior

A. Migration

Near Isla Chiloé and in the Strait of Magellan, resident groups have been noted throughout the year, although more animals were present during summer. In southern Tierra del Fuego, animals also seem to move inshore during summer, possibly following fish migrations. It is not known if the dolphins in different parts of the range belong to different populations or stocks.

B. Swimming and Schooling

Peale's dolphins are most often seen swimming slowly in or near the kelp. Dive times range from 3 to 157 sec, with an average of 28 sec (n = 723), with three short dives followed by a longer one. They commonly BOW RIDE, with much head movement, rolling, BREACHING, spy hopping and spinning. They produce a wide splash when surface swimming, earning the name "plough-share" dolphins. They associate closely with other dolphins, especially *Cephalorhynchus commersonii*.

Group size is usually small, from 2 to 5 animals, but aggregations of up to 100 have been seen. Little else is known of their behavior.

C. Sounds

Pulsed sounds were recorded in the Chilean channel region, revealing broadband clicks at 5–12 kHz and narrowband clicks at 1- to 2-kHz bandwidths. Whistle-like squeals were not recorded, but may have been above the limits of the recording equipment used.

VI. Internal Anatomy

The condylobasal lengths of 27 skulls ranged from 352 to 359 mm. The number of teeth is variable, with up to 37 upper and 34 lower teeth in each jaw. The mouth is unusual in having a wide lip outside the tooth line. The vertebral count is CV7 with the first two fused, T14, L13–16, Ca 31–34 for a total of 66–70, normally 67–68. The Peale's dolphin is larger and more robust than the other two southern *Lagenorhynchus*, with larger vertebrae. The phalangeal number is I = 2–3, II = 6–9, III = 5–6, IV = 2–4, V = 0–2.

Few tissues have been examined. Skin thickness was 1–2 mm, and blubber thickness was 15–25 mm. The gonads and uterus of three specimens have been described, and organ weights are known for three others. Eye pigments were reported for one animal. Residues of organochlorine contaminants were found in the blubber of one animal.

VII. Life History

A. Growth and Reproduction

There is little information on reproduction. A female of 185 cm was sexually immature, one of 193 cm was pubescent, and one of 210 cm was mature. There is no information on sexual maturity in males. Calves have been reported from spring through fall, October to April.

Physical maturity, on the basis of epiphyseal fusion, has been recorded for 24 specimens. Neonates measured 98–130 cm, juveniles 138–176 cm, subadults 142–210 cm, and adults 190–199 cm. The oldest animal was a physically mature female with 13 GLGs (growth layer groups) in the teeth.

VIII. Interactions with Humans

A. Captivity and History

No Peale's dolphins have been kept in CAPTIVITY. Prehistorically, Peale's dolphins were exploited for food by the canoe peoples of the channels of southernmost South America; remains have been found in kitchen middens dated at 2500 and 6000 years before present. More recently, a few dolphins were taken for scientific research.

B. Fisheries

1. Chile Peale's dolphin have been heavily exploited for crab (*centolla, Lithodes antarctica*) bait in southern Chile since at least the early 1970s, with highest exploitation in the 1980s. Overfishing, resulting in greatly reduced populations of crabs, has led to other types of fishing that do not need bait. The full extent of the exploitation of dolphins for crab bait at present is unknown, but is thought to be less than formerly. Although common, Peale's dolphins are rarely taken incidentally in the northern part of their range between Valdivia and San Antonio. A few dolphins have been caught in anti-pinniped nets near the salmon pens in the Isla Chiloé area.

2. Argentina A few Peale's dolphins were taken for crab bait in eastern Beagle Channel in the late 1970s and early 1980s, but this has not continued. A small incidental take occurs in shore-set gill nets off Tierra del Fuego, but fishermen claim that Peale's dolphins are usually strong enough to fight and release themselves from the net. Likewise, a few Peale's dolphins die in off-shore fishing activities south of Golfo San Jorge, but not as many as other species. The extent of this exploitation is unknown; it represents a potential danger that should be monitored.

Pelvic Anatomy

Peter J. Adam
University of California, Los Angeles

With the development of tail flukes for producing propulsion in whales, manatees (*Trichechus* spp.), and dugongs (*Dugong dugon*), the pelves and hind limbs became vestigial structures that now associate only loosely with the spine. The major role of the pelvic apparatus in these forms, when present, is to serve as attachment points for muscles acting on the genitalia and the abdominal body wall. Marine carnivores, which still maintain close ties with the terrestrial environment, have not had such a dramatic reduction in the pelvis and hind limb structures. Both pinnipeds and the sea otter (*Enhydra lutris*) have united the toes to form flippers. Phocids, which use the hind limbs to generate swimming thrust and which cannot rotate the hind feet under the body while on land, have highly modified hind limbs. Phocid adaptations include increasing the surface areas available for muscles that flex the leg, modification of limb muscles to aid in undulatory movements of the spine, and a general increase in the muscle mass operating on the hind limb (in particular the muscles acting to flex the limb).

I. Cetaceans

The known fossil record documenting cetacean evolution shows a progressive reduction and loss of hind limb skeletal elements and disassociation of the pelvic girdle from the vertebral column as whales became less dependent on nearshore environments and developed tail flukes to generate swimming thrust. This trend is most marked with the origin of the basilosaurine whales, in which the tibia and fibula became fused with each other and tarsal elements co-ossified into a single immobile mass. Basilosaurines also mark the point during which the pelves became disassociated from the vertebral column. Among modern forms, only vestiges of the hind limb skeleton can be found, and these are contained within the body wall. Mysticetes typically posses only vestigial pelves, whereas the occurrence of hind limb and pelvic elements is more variable among both individuals and species of odontocetes. When present, the pelves bear little resemblance to those of terrestrial mammals and, when undeveloped, may exist only as a band of connective tissue connecting spinal muscles to those of the genitalia and abdominal wall. If present as a bony element, each pelvis is typically cigar or sickle shaped, with only the pelvic bone proper contributing to its structure (Fig. 1). Atavistic femora and occasional tibiae have been described from numerous (mysticete and odontocete) taxa, although occurrence of these elements is infrequent. Hind limb buds are present during early embryogenesis of all whale species documented so far, although the mesodermal cells that usually form the internal limb structures die or are reallocated to other functions as limb buds are resorbed later in ontogeny. Retention of a rudimentary pelvis is associated with the attachment of numerous muscles acting on the reproductive organs of both sexes. In males, the pelvis is usually larger relative to that of females. It serves as the site of origin for muscles acting on the genitals and anal region (e.g., the penis retractor and levator ani muscles) and may also serve as a site of attachment for posterior fibers of the rectus abdominis muscle. When present, the pelvis is isolated from the spine (sacral vertebrae are absent) but maintains a soft tissue attachment to the hypaxial spinal musculature. Rearrangements of spinal and pelvic muscles in association with tail-based locomotion have led to considerable controversy over specific identities of muscles in these regions.

II. Sirenians

The evolutionary loss of the hind limb in sirenians closely parallels that of cetaceans (Fig. 1), with modern forms possessing only a vestigial pelvis composed of iliac and ilium bones. In dugongs, each pelvis is long and stick like in appearance, and the ilium and ischium are of subequal length, fusing by 5 years of age in both sexes. In manatees, the pelves are more

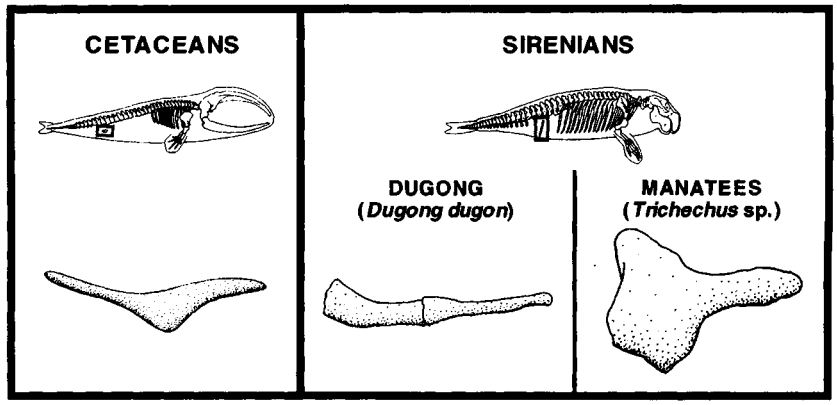

Figure 1 *Line drawings of the right pelvis of a cetacean (left) and sirenians (right) in lateral view (anterior toward the right). Position and orientation of the pelvis are indicated by boxes on the skeletal outlines.*

plate like and cross shaped in lateral view. The ischium is the largest portion of the manatee pelvis, with the ilium forming a small cap on the anterior surface of the bone complex. As in whales, sirenian pelves lack osseous attachment to the vertebral column. In dugongs, the pelves join with the anterior caudal vertebrae by an aponeurosis thought to be homologous with the m. coccygeus, as well as by the retractor ischii and ischiococcygeus muscles to caudal chevron BONES. The pelves serve as the origin for muscles acting on the genital organs (e.g., in females, the constrictor vulvae, constrictor vestibuli, and urethralis muscles) as well as some muscles inserting into the skin of the abdominal region [e.g., the transversus abdominis (in part)]. The atavistic appearance of femora has been reported for manatees.

III. Marine Carnivores

A. Pinnipeds

The earliest known pinniped, *Enaliarctos* from the late Oligocene of California, possessed a well-developed hind flipper, and intermediate stages in the anatomical progression from a limb used for terrestrial locomotion to one specialized for swimming are undocumented. Anatomical adaptations of the hind limbs of extant pinnipeds largely reflect strategies adopted by each family for swimming and terrestrial locomotion. Phocid seals and walruses (*Odobenus rosmarus*) primarily use the hind limbs to generate thrust while swimming and have relatively more muscle mass in the pelvic region relative to the pectoral region and forelimb. Otariids propel themselves with the forelimbs and have relatively lower pelvic muscle mass. On land, otariids and walruses are able to rotate their hind feet under their body and progress with modified walking motions; phocids lack the ability to rotate their feet under their body and move along the ground with undulatory movements of the body.

Externally, the hind limbs of pinnipeds extend beyond the body contour from the approximate middle or end of the crus. In walruses and phocids the middle digit is the shortest, and digits increase in length both laterally and medially, giving the flipper a crescent shape (more marked in phocids). A thin, extensible interdigital webbing stretches between adjacent digits in these forms. In otariids, the interdigital areas are occupied by thick layers of connective and other tissues, making the hind flipper a much more rigid structure. Emargination of the distal interdigital regions of the flipper confers a scalloped shape to its trailing edge. Claws are reduced in all pinnipeds, although those of the middle three digits tend to be better developed than those of the first and fifth digits. Claws are positioned terminally in phocids and subterminally in walruses, but are located considerably farther proximally in otariids due to the development of distal cartilaginous rods on the ungual phalanges. The presence of these cartilaginous extensions gives the ungual phalanges an hourglass shape and roughened distal ends. The plantar surface of otariid and walrus flippers is hairless, with moderately developed foot pads related to their ambulatory terrestrial locomotion. Foot pads are lacking on phocids. With the exception of interdigital regions, which are hairless or have only sparse hair, the dorsal pedal surface typically has a hair density subequal or slightly lower than that of the body.

Departures of the skeletomuscular anatomy from the condition observed in typical terrestrial carnivores are most prevalent in phocid seals due to their highly modified (undulatory) terrestrial locomotion and specialized hind limb swimming. The iliac region of the phocid pelvis is expanded laterally, particularly among phocines. This confers a mechanical advantage to the gluteus muscle complex, which inserts onto the greater trochanter of the femur and functions to flex the leg against the water. The ischiopubic region of phocid pelves, posterior to the acetabulum, is elongate relative to otariids and the walrus. This increases the surface area available for attachment of the strong muscles acting to medially flex the leg during the power stroke of the swimming cycle (e.g., the adductor, gracilis, gemelli, obturatorius, and semimembranosus muscles). The ischial tuberosity, often misidentified as the "ischial spine," is greatly enlarged in phocids, but undeveloped in otariids and the walrus. It serves as the site of origin for the biceps femoris muscle, which inserts broadly onto the tibia. The orientation and widening of the biceps femoris in phocids indicate that it is

primarily responsible for lifting the hind limb off the ground during terrestrial locomotion, as well as medially flexing the limb during swimming. The pinniped femur is short and stout, and the distal condyles are inclined relative to the long axis of the shaft. The fovea capitis of the femoral head is lacking. This indicates the loss of the teres ligament, which normally maintains the femoral head within the acetabulum of the pelves in terrestrial mammals that have weight-bearing hip joints. In phocids, the lesser femoral trochanter is either reduced or absent, and the two muscles typically inserting onto it have undergone major changes from their usual orientation and function: (1) the iliacus muscle inserts onto the more distal femoral epicondylar crest or proximal tibia and (2) the psoas major muscle, arising from the posterior thoracic, lumbar, and sacral vertebrae, inserts onto the medial surface of the ilium and thus aids in lateral undulation of the spine during swimming rather than acting on the limb. Proximally, the tibia and fibula of most pinniped species become fused prior to maturity. The posterior tibial fossa is deep in phocids, reflecting enlargement of the tibialis caudalis muscle, which originates from this region and inserts onto the tarsus and first metatarsal, acting to plantar flex the pes during the swimming power stroke. The tendon of the flexor hallucis longus muscle passes over a posterior projection of the astragalus that is unique to phocids, limiting dorsal flexion of the pes. This, in combination with the elongated ischiopubis (which limits anteroventral bending of the spine when phocids are on land), limits the ability of phocids to assume a four-legged stance. Additionally, the tibioastragalar joint of phocids is nearly spherical and would unlikely bear the weight of the animal. This is in contrast to the more rigid, hinge-like joint found in other pinnipeds and terrestrial carnivores. Inserting tendons of the large plantar flexing muscles (i.e., the flexor digitorum longus, flexor hallucis longus, and flexor digitorum superficialis muscles) often combine together in a com-

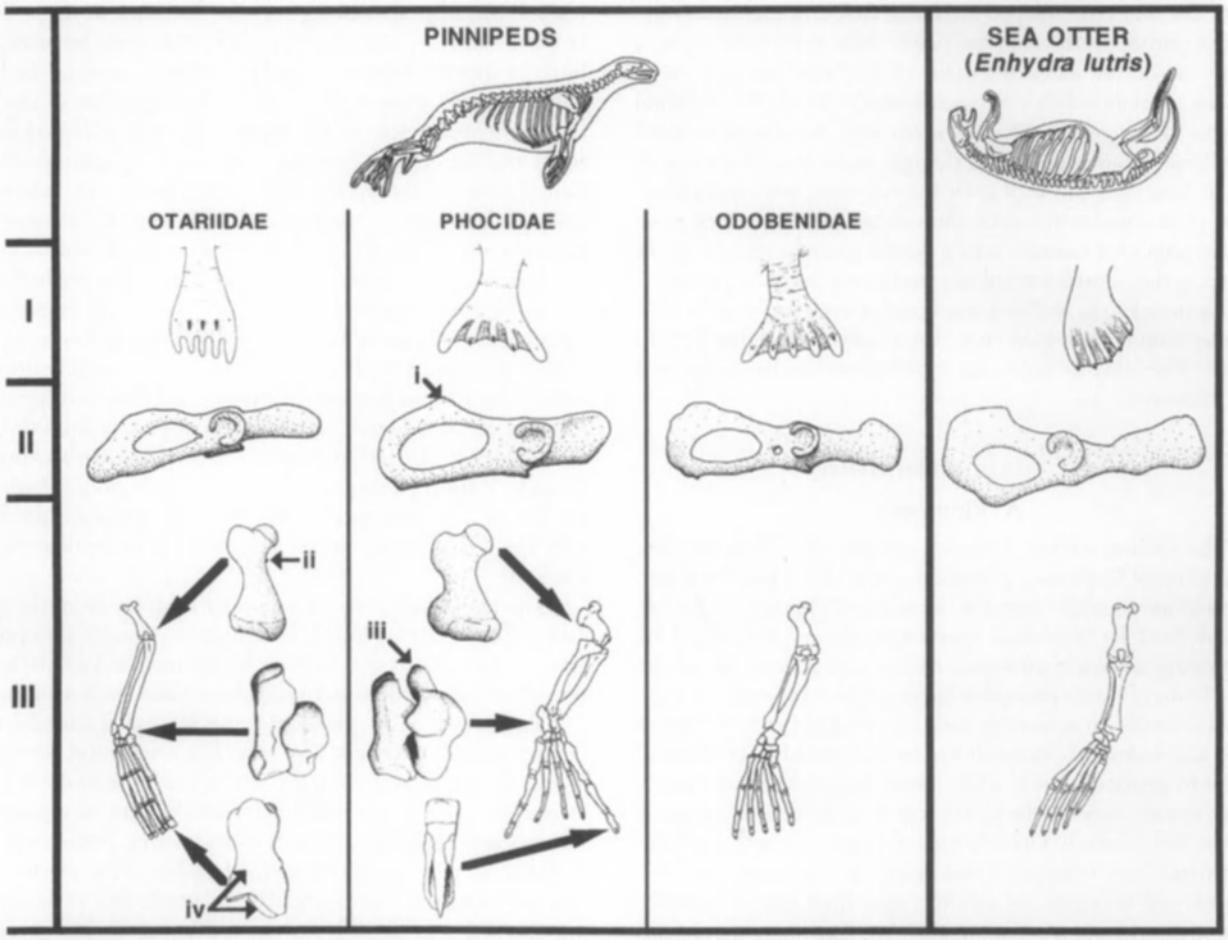

Figure 2 *Line drawings of external flipper morphology (row I), right pelvis (row II, lateral view, anterior is toward the right), and right hind limb skeleton [row III, anterior (dorsal) view] of representative species of pinnipeds (left; Otariidae,* Callorhinus; *Phocidae,* Monachus; *and Odobenidae,* Odobenus*) and the sea otter (right). Indicated features of the otariid and phocid hind limb are as follows: i, enlarged ischial tuberosity of phocids; ii, presence of a lesser femoral trochanter in otariids and walrus (absent or reduced in phocids); iii, posterior projection of the phocid astragalus, over which the tendon of the flexor hallucis longus muscle passes; and iv, first ungual phalanx of the otariid pes showing the lack of a claw and distal roughened surface to which cartilage is attached in life.*

plex manner at the level of the tarsals. A united tendon of these muscles sends branches out to the digits, although slips extending to the first and fifth digits tend to be larger in phocids. The pedal formula of all pinnipeds is 2-3-3-3-3, the primitive condition for all mammals. In phocids and the walrus, metatarsals and phalanges of the first and fifth digits are more robust than those of the middle three digits. This is associated with hind limb swimming, where both digits may act as leading edges of the flipper during the complex power stroke. Metatarsal–phalangeal and interphalangeal joints tend to be of the tongue-and-groove type in phocids and hinge-like in otariids and the walrus. However, all pinnipeds have reduced trochleation of the metatarsals and phalanges (Fig. 2).

Available evidence indicates that blood supplying the crus and pes of phocids passes primarily through the external iliac, femoral, and sapheneous arteries. Maintenance of this primitive condition is related to the efficiency of the system for supplying oxygen and nutrients to the heavily used hind limb musculature. In contrast, otariids have adapted the blood vessels such that most of the blood supplying the distal limb regions passes through the internal iliac and gluteal arteries. The passage of blood via this route is believed to enhance heat dissipation. The walrus is intermediate to these conditions, although detailed description of its anatomy is lacking. The presence of a circulatory countercurrent heat exchange system (*rete mirabile*) in the hind limbs has been reported for several phocid and otariid species. Anatomy of the spinal nerves serving the hind limb of pinnipeds is poorly known. Available evidence suggests that the lumbosacral plexus has shifted posteriorly by one vertebra, being composed of ventral rami arising from the third through fifth lumbar, first through third sacral, and first caudal vertebrae. Division of this plexus into lumbar and sacral plexi is not possible.

B. Polar Bears and Sea Otters

Adequate descriptions of polar bear (*Ursus maritimus*) pelvic and hind limb anatomy have not yet been made, but there is little indication that the morphology of this species has diverged appreciably from that of other species of *Ursus*. Departures of sea otter hind limb anatomy from that of other mustelids, however, are seen more readily. Externally, the leg is enclosed within the loose body skin to the approximate level of the ankle. The digits are bound together by interdigital webbing, although the fourth and fifth digits are bound more closely together than other adjacent digital pairs. The sea otter is unusual in that in overall length the digits decrease in size from the fifth to the first: V > IV > III > II > I. While swimming, sea otters use the hind feet to generate thrust and sweep the leg through the water such that the fifth digit forms the leading edge of the pes. The hair densities for the ankle and interdigital webbing have been estimated at 107,000 and 3300 hairs/cm^2, respectively, compared to a density of 125,000 hairs/cm^2 for the back. Pads are present on the phalangeal portion of each toe and are variably found ventral to the metatarsals. As with pinnipeds, the fovea capitis is absent from the femur, marking the absence of the teres ligament. The biceps femoris muscle inserts onto the middle of the tibia and maintains the leg in a posterior position. The flexor digit V muscle is very large in the sea otter (relative to other mustelids). This enlargement corresponds to the use of the lateral surface of the pes to lead during the power stroke of the limb. The remaining hind limb anatomy of the sea otter corresponds well with that of terrestrial mustelids (Fig. 2).

Perissodactyla

J. G. M. Thewissen
Northeastern Ohio Universities College of Medicine, Rootstown

I. Overview

The perissodactyls (odd-toed ungulates) are an order of land mammals that comprise, in modern times, horses (including zebras and asses), rhinoceroses, and tapirs. Perissodactyls are mainly characterized by their feet. There is an odd number of toes, and the axis of symmetry of each fore- and hindfoot runs through the middle (third) digit (this is called mesaxony). The third digit is the largest in all perissodactyls and is the only digit in horses. The toes immediately adjacent to the third digit (the second and fourth) are similar to each other and smaller than the central toe. Rhinos have three toes per foot and tapirs have three on their hindfeet and four on the forefeet. The fourth toe in a tapir is medial to and smaller than any other toe. All toes bear a hoof in perissodactyls, just like in the even-toed ungulates (artiodactyls), where there are two or four toes per foot and the axis of symmetry runs between the third and the fourth digit (paraxony).

II. Relation to Marine Mammals

The earliest perissodactyl fossils known date from the early Eocene, approximately 52 million years ago, and are close temporally to the earliest cetaceans and sirenians. Perissodactyls are related to marine mammals. Studies of morphological data (Thewissen and Domning, 1992; Fischer and Tassy, 1993) commonly find that perissodactyls are close relatives to sirenians, proboscideans, and hyracoids. Molecular data disagree with that, instead finding that certain insectivores are related more closely to sirenians (Stanhope *et al.*, 1998). A minority opinion is that perissodactyls are closely related to whales, but most evidence instead points to a close relationship between whales and artiodactyls.

Pilot Whales

Globicephala melas and *G. macrorhynchus*

Paula A. Olson and Stephen B. Reilly
Southwest Fisheries Science Center, La Jolla, California

Pilot whales are large dolphins, among the largest members of the family Delphinidae. They are widely distributed in the world's oceans. Two species are recognized: *Globicephala melas* (long-finned pilot whale) and *G. macrorhynchus* (short-finned pilot whale). Notable aspects of pilot whale natural history include sexual dimorphism and mass strandings. Pilot whales are among the most gregarious of the cetaceans.

The name "pilot whale" originated with an early theory that a school is piloted by a leader. Other common names for these whales include pothead (after the whales' bulbous melon) and blackfish (a term also used for melon-headed whales, pygmy killer whales, and false killer whales). The genus name, *Globicephala*, is derived from the Latin word *globus*, meaning round ball or globe, and the Greek word *kephale*, meaning head. *Melas* is a Greek word for black. *Macrorhynchus* is likewise derived from Greek words: *macro*, meaning enlarged, and *rhynchus*, meaning snout or beak. For many decades, *malaena* was used as the trivial name for the long-finned pilot whale. However, in 1986 the name was revised to *melas*.

I. Physiology

A. Morphology

Long-finned and short-finned pilot whales are difficult to distinguish at sea (Fig. 1). The morphological differences between the two species are subtle: length of flippers, differences in skull shape, and number of teeth. On average the pectoral flippers of long-finned pilot whales are one-fifth the body length, whereas on short-finned whales they are one-sixth the body length. However, overlap exists between the two species. Long-finned flippers exhibit a noticeable "elbow" whereas short-finned pectorals have a more curved appearance.

Adult pilot whales reach an average length of approximately 6 m. Males are larger than females. Most pilot whales appear black or dark gray in color. The body is robust with a thick tailstock. The melon is exaggerated and bulbous, and there is either no beak or a barely discernible one. A wide, broad-based falcate dorsal fin is set well forward on the body. The flippers are long, slender, and sickle shaped. A faint gray "saddle" patch may be visible behind the dorsal fin as well as a faint postorbital blaze (Fig. 2). A gray midventral line extends anteriorally into an anchor-shaped chest patch and widens posteriorally into a genital patch. Calves are paler than adults.

Because most size, shape, and color pattern distinctions between the two species are so variable, the shape of the skull is the only definitive characteristic for identification to species. The long-finned pilot whale has a narrower skull, with the premaxil-

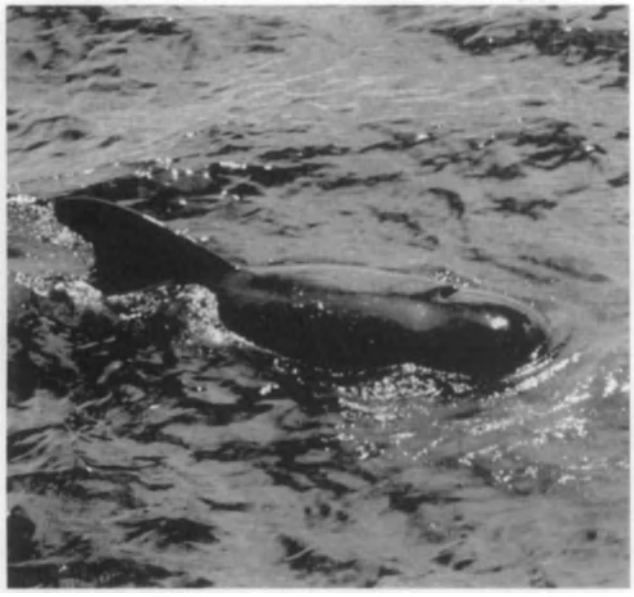

Figure 1 *Long-finned and short-finned pilot whales exhibit similar external morphology, including a large, bulbous melon and a broad-based dorsal fin. Photo by J. Carretta.*

lae leaving uncovered 1 cm of the lateral borders of the maxillae (Fig. 3A). There are 9 to 12 teeth in each row. The skull of the short-finned pilot whale is shorter and broader, and the premaxillae cover the maxillae (Fig. 3B). There are 7 to 9 teeth in each row. Pilot whales have notably fewer teeth than most other delphiniids. This is similar to the evolutionary reduction of teeth found in Risso's dolphins (*Grampus griseus*) and sperm whales (*Physeter macrocephalus*), two other heavy squid consumers.

B. Sexual Dimorphism

Pilot whales exhibit striking sexual dimorphism in size, similar to that observed in sperm whales and killer whales (*Orcinus orca*). Adult males are longer than females, develop a more pronounced melon, and have a much larger dorsal fin (Fig. 4). The function of sexual dimorphism in pilot whales is unknown, although several have been hypothesized. The males' enlarged features may be used for display to other males or females or for increased agility when maneuvering for mate access or for herding females. The males' large size may aid in defense of their school from attacks by killer whales or sharks.

C. Disease

Pilot whales in the western Atlantic have been affected by the morbilliviruses that have plagued other marine mammals in recent decades. Although to date no large-scale outbreak of disease has been reported in pilot whales, high percentages of both species sampled during the 1980s and 1990s carried virus-neutralizing antibodies. It appears that most individuals are immune. Due to their wide-ranging movements and their propensity to mix with other species, pilot whales may act as a vector for morbilliviruses in other cetaceans, such as bottlenose dolphins (*Tursiops truncatus*).

II. Distribution

Pilot whales are wide ranging (Fig. 5). Generally, short-finned pilot whales have a tropical and subtropical distribution and long-finned pilot whales are distributed antitropically. There is little overlap in the range of the two species. Areas of marginal overlap include the temperate waters of the North and South Atlantic, in the Pacific off the coast of Peru, and off South Africa. Pilot whales are found in both nearshore and pelagic environments.

A. Geographical Variation and Subspecies

Long-finned pilot whales inhabit the cold temperate waters of both the North Atlantic and the Southern Ocean. The two populations are isolated. There are slight morphological differences between the populations and they are accorded subspecies status: *G. melas melas* in the North Atlantic and *G. melas edwardii* in the Southern Hemisphere.

In the North Atlantic, the range of *G. melas melas* includes the waters of Greenland (Denmark), Iceland, and the Barents Sea south to the Tropic of Cancer. This species is present in the western Mediterranean Sea. *G. melas edwardii* is circumglobal in the Southern Hemisphere, with records as far north as 14°S in the Pacific and further south than the Antarctic Convergence. Long-finned pilot whales do not occur in the North Pacific.

Short-finned pilot whales are found worldwide in tropical, subtropical, and warm temperate waters. Their northern range in the Atlantic extends to the midcoast area of the United States and to France. Short-finned pilot whales are not found in the Mediterranean. Latitude 25°S marks the southernmost record for the Atlantic and the Pacific coasts of South America. Elsewhere in the Pacific, the range of the short-finned pilot whale continues north to Japan and to the west coast of the United States.

Pacific short-finned pilot whales in higher latitudes are generally larger than those in lower latitudes. Two distinct populations of short-finned pilot whales are found off northern and southern Japan. These populations exhibit morphological differences in external and cranial features. The populations are segregated geographically and genetically. However, their exact taxonomic status is still undetermined and for the time being they are both classified as *G. macrorhynchus.*

B. Abundance

Estimates of abundance for pilot whales have generally been undertaken in response to management issues. Survey areas are typically determined by management goals rather than natural population boundaries. Most of the quantitatively derived estimates of abundance are for nearshore populations. Estimates using line-transect methods have been made for Newfoundland/Labrador (Canada), the northeast Atlantic, the Antarctic, the U.S. West Coast, northern and southern Japan, and the eastern tropical Pacific (Table I).

III. Fossil Record

The extant delphinid groups (to which *Globicephala* belongs) appeared in the Middle to Late Miocene Epoch. Fossils of the genus *Globicephala* dating from the Pleistocene Epoch have been uncovered in Florida (*G. baerreckeii*). Odontocete remains from the Pliocene Epoch uncovered in Tuscany, Italy, have been designated as *Gobicephala? eturiae.*

Although the long-finned pilot whale does not currently inhabit the North Pacific, skulls dated to the 8th to 12th centuries have been recovered in Japan. Short-finned pilot whales now inhabit those waters.

IV. Ecology

Pilot whales are found on the continental shelf break, in slope waters, and in areas of high topographic relief. In gen-

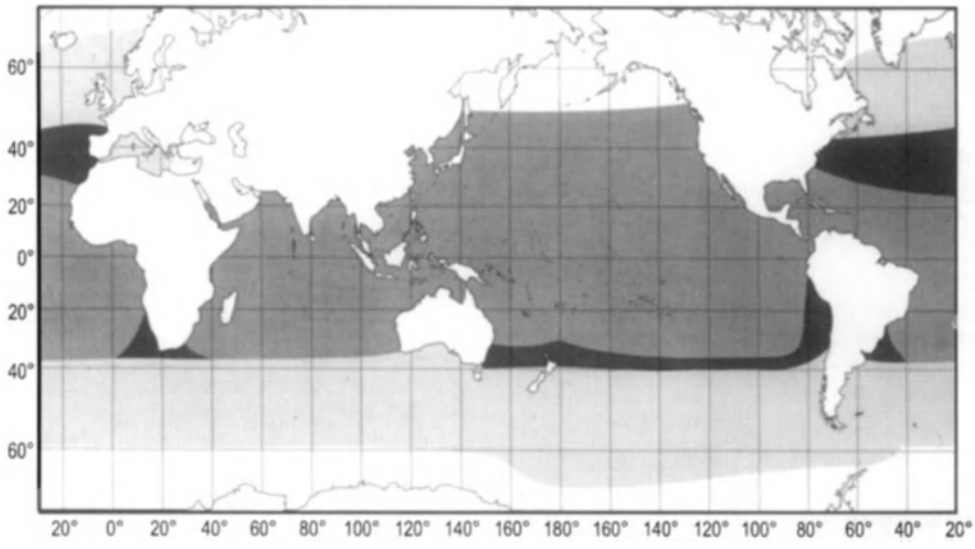

Figure 5 *Worldwide distribution of pilot whales. The distribution of long-finned pilot whales is indicated by light shading and the distribution of short-finned pilot whales by medium shading. Dark shading indicates regions where the species overlap.*

eral, pilot whales are nomadic, but resident populations have been documented in a few locations such as coastal California and Hawaii. Seasonal inshore/offshore movements of pilot whales are related to the distribution of squid, their favorite prey. Studies in Newfoundland and California correlated the seasonal abundance of pilot whales with spawning squid.

The pilot whale diet consists primarily of squid, with lesser amounts of fish. Fish prey in the northwest Atlantic include Atlantic cod (*Gadus morhua*), Greenland turbot (*Rheinhardtius hippoglossoides*), Atlantic mackerel (*Scomber scombris*), Atlantic herring (*Clupea harengus*), hake (*Urophycis* spp.), silver hake (*Merluccius bilinearis*), and spiny dogfish (*Squalus acanthias*). Pilot whales in the northeast Atlantic have been known to take Atlantic Argentine (*Argentina silus*) and blue whiting (*Micromesistius poutassou*).

The ecosystem changes brought about by a strong El Niño event in 1982–1983 affected the distribution of pilot whales off southern California dramatically. With the influx of warm water during the El Niño, squid did not spawn as usual in the area. Pilot whales were virtually absent from the region that year and remained so for another 9 years. It is not known where the whales went during this time or whether the whales sighted there now are returning or are new individuals.

V. Life History

Pilot whales share several features of life history with other large odontocetes: long life span, delayed maturity, different rates of maturation for males and females, seasonal MATING, and the production of a single calf in multiyear intervals.

TABLE I
Estimates of Pilot Whale Abundance Using Line-Transect Methods

Species/Subspecies	*Area*	*Population*	*Reference*
Globicephala melas melas	Newfoundland/Labrador	6,731–19,603	R. Hay (1982). *Rep. Int. Whal. Commn.* **32,** 475–480.

G. macrorhynchus	Southern Japan	53,000	T. Miyashita (1986). Int. Whal. Comm. Scientific Committee Meeting Document SC/38/SM17.
G. macrorhynchus	Eastern tropical Pacific	160,200	P. W. Wade and T. Gerrodette (1993). *Rep. Int. Whal. Commn.* **43,** 477–493.

Short-finned pilot whales have a slower growth rate than long-finned pilot whales and reach a shorter body length. The pattern of growth for both species is similar. Rapid neonatal growth is followed by a less rapid but continual growth phase during the juvenile years. Growth slows even further after the attainment of sexual maturity and ceases some years later. Short-finned females become sexually mature at 9 years, males at age 13 to 16. Long-finned females reach sexual maturity at 8 years, males at about 12. Males become socially mature, e.g., mate successfully, several years after reaching sexual maturity.

In the Northern Hemisphere, mating generally occurs in spring or early summer and parturition in summer or early autumn. An exception to this is the population of pilot whales off northern Japan. Their peak breeding season is autumn with parturition in winter. Gestation is estimated to be 12 months for long-finned pilot whales and 15–16 months for short-finned whales.

The birth interval in pilot whales is one of the longest of all the cetaceans. Lactation lasts for at least 3 years, often longer. Such an extended lactation period probably serves a social rather than nutritional purpose in later years. The capability of a short-finned female to lactate years past final ovulation has been reported. This supports the theory that females may invest more in present offspring as their likelihood to bear more offspring diminishes. Sizable numbers of postreproductive females have been found in populations of both species.

Estimates of natural mortality for pilot whales are based on data from the directed fisheries in the Faeroe Islands (Denmark) and Japan. These data indicate that male pilot whales have a higher mortality rate at all ages than those of females. Females are known to be longer-lived. Females live past 60 years; males reach 35–45 years.

VI. Behavior

A. Social Organization

Pilot whales are highly social and are usually found in schools, or pods, averaging 20–90 individuals. A variety of GROUP BEHAVIORS have been documented. Commonly reported are traveling or foraging in a loose chorus-line formation or collective logging at the surface.

The social structure of pilot whale pods is similar to that of killer whales. Pilot whales form stable pods composed of individuals with close matrilineal associations. All age and sex classes are included, although there is a female bias in adults. The groups are stable; pilot whales grow to maturity in their natal group and most remain there for life. Genetic evidence supports the theory that males breed outside their family group.

Pilot whales are polygynous. Huge aggregations of pilot whales are occasionally reported and it is believed that males move between family groups to mate during these temporary aggregations. This type of social structure where adult males stay with their female kin and mate elsewhere is unusual among mammals.

B. Sound Production

Pilot whales echolocate with a precision similar to that of bottlenose dolphins. Pilot whales also vocalize, the primary purpose probably being to maintain contact among school members. Vocalizations are more complex with active behavior and simpler with calmer behavior.

Significant differences have been found between the calls of long-finned and short-finned pilot whales. The calls of long-finned pilot whales are of a lower frequency and a narrower frequency range than those of short-finned pilot whales. The mean frequency for long-finned pilot whales is 4480 Hz, for short-finned pilot whales the mean frequency is 7870. Short-finned pilot whales were also found to have distinct group-specific call repertoires, as would be expected for a species with stable matrilineal kinship groups.

C. Interspecific Associations

Pilot whales are often observed in mixed species aggregations. They are most commonly sighted in association with common bottlenose dolphins (*Tursiops truncatus*), but have also been seen with short-beaked common dolphins (*Delphinus delphis*), Atlantic white-sided dolphins (*Lagenorhynchus acutus*), Pacific white-sided dolphins (*Lagenorhynchus obliquidens*), striped dolphins (*Stenella coeruleoalba*), Fraser's dolphins (*Lagenodelphis hosei*) killer whales, fin whales (*Balaenoptera physalus*), sperm whales, and gray whales (*Eschrichtius robustus*). There are accounts of pilot whales behaving aggressively toward humpbacks (*Megaptera novaeangliae*), sperm whales, common dolphins, and dolphins of the genus *Stenella*. Pilot whales have also been reported carrying the carcasses of dead California sea lions (*Zalophus californianus*) and towing a human diver.

D. Mass Stranding

Pilot whales are one of the most frequently reported cetaceans in mass strandings. Strandings of pilot whales are dramatic events because they usually involve groups of animals and because live whales that are assisted back into the ocean often return to the beach. Pilot whales strand singly as well as in groups; often these animals are diseased.

Curiously, most of the whales in a group event do not show any pathology. It is not known why apparently healthy animals strand, although there are a variety of hypotheses. The whales may become confused or trapped in shallow areas; geomagnetic anomalies may disorient whales if they are using the earth's magnetic field for navigation; or if an ill animal strands it may be followed by members of its pod. The strong social bonds within a pilot whale pod are likely to play a role in stranding events, whatever the other underlying reasons may be.

VII. Interactions with Humans

A. Directed Catches

Because of their cohesive social structure, pilot whales are susceptible to herding by humans. Meat, blubber, and oil are the desired products. Historically, there have been a number of directed fisheries for pilot whales. In the North Atlantic, drive fisheries for long-finned pilot whales were conducted in Newfoundland, Cape Cod, Norway, Iceland, Orkney Islands (Scotland), Hebrides Islands (Scotland), Greenland, and the Faeroe Islands. The intensive drive fishery in Newfoundland (1947–1971) is es-

timated to have taken 54,000 animals and to have reduced the local population substantially. The population may be recovering, but more information is needed. Fisheries for short-finned pilot whales have operated in the Caribbean and in Japan.

The drive fishery in the Faeroe Islands and the drive and harpoon fisheries in Japan continue today. These fisheries have been in existence for several hundred years. In 1996, the catch of long-finned pilot whales in the Faeroes was 1524 animals; in 1997, Japan reported a catch of 347 short-finned pilot whales.

B. Bycatch

The INCIDENTAL BYCATCH of cetaceans in fisheries is a worldwide phenomenon. Most bycatch goes unreported because this information is not recorded in many countries. Pilot whales are particularly susceptible to entanglement in driftnets. The effect of such mortality on pilot whale populations is unknown.

In northeast U.S. waters, pilot whales have been taken incidentally in a variety of fisheries: mackerel and squid trawls, pelagic drift gill nets, pelagic long lines, and pelagic pair trawls. Some of these fisheries are now closed, and none of the current fisheries exceed the allowable annual take for pilot whales under U.S. law.

Pilot whales off California and Mexico are taken incidental to driftnet fisheries targeting swordfish and sharks. It is likely that these takes are from the same population of short-finned pilot whales, and the per-set mortality rate reported from both countries is similar. In the United States the take exceeds the allowable annual limit and a take reduction plan has been implemented. Prior to the El Niño of 1982–1983, pilot whales were taken incidentally in the Californian squid purse seine fishery. Pilot whale redistribution in response to El Niño is the likely reason no mortality was reported for this fishery during the following years. Currently the squid fishery is not monitored, but there have been anecdotal reports of pilot whales seen near squid fishing operations in recent years.

C. Contaminants

Long-finned pilot whales from both sides of the north Atlantic carry high levels of organochlorine contaminants (pesticides such as DDT and PCB) in their tissues. Concentrated organochlorines may impair reproduction or increase susceptibility to disease. Studies are continuing on the effects these compounds have on marine mammals.

Accumulations of cadmium and mercury are also present in the tissues of long-finned pilot whales from the Faeroe Islands. As top predators, pilot whales are a repository of these heavy metals accumulating through the marine food chain. Pilot whales seem unusually tolerant to elevated levels of these metals, as studies have not yet revealed a major toxicity problem in these species.

D. Captivity

Numerous short-finned pilot whales have been captured for training and/or display in the United States and other parts of the world. Whales have been taken from northeast United States, California, Hawaii, and Japan by means of direct capture, incidental to drive fisheries, or stranding salvage. The most recently published North American marine mammal display census dates from 1990. At that time, four pilot whales were on exhibit in United States and Canadian aquaria. Stranded pilot whales have occasionally been kept for rehabilitation and subsequently released.

Pinnipedia, Overview

ANNALISA BERTA
San Diego State University, California

Pinnipeds have always been understood to represent a group distinct from other aquatic mammals. They are recognized as members of the mammalian order Carnivora and include three monophyletic lineages; the Otariidae (fur seals and sea lions), the Odobenidae (the walruses), and the Phocidae (true or earless seals). Pinnipeds comprise slightly more than one-fourth (28%) of the species level diversity of marine mammals. Thirty-three to 37 living species of pinnipeds are distributed throughout the world: 18 phocids, 14–18 otariids, and the walrus. One additional species of modern phocid and a modern otariid are reported extinct in historical time (Rice, 1998).

I. Systematics and Distribution

A. Otariidae: Fur Seals and Sea Lions

Of the two groups of seals, otariids are characterized by the presence of external ear flaps or pinnae, and for this reason they are often called "eared" seals (Fig. 1). Otariids can turn

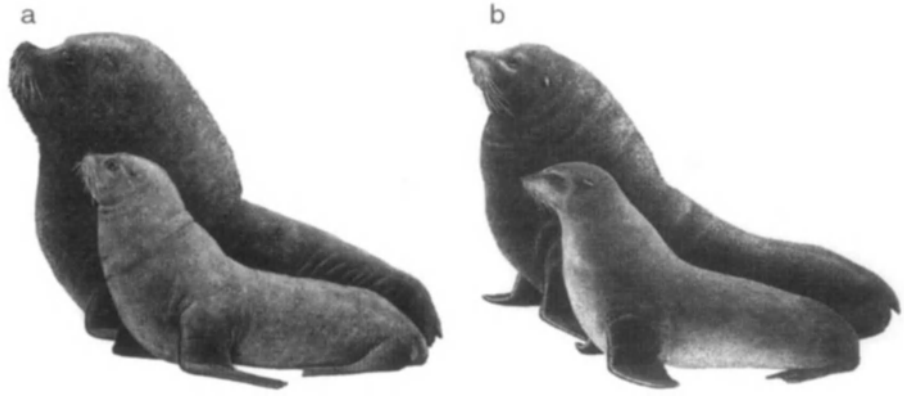

Figure 1 *Representative otariids, (a) southern sea lion,* Otaria flavescens, *and (b) South African fur seal,* Arctocephalus pusillus, *illustrating pinna. Note also the thick, dense fur characteristic of fur seals. Males are shown behind smaller females. Illustrations by P. Folkens. From Berta and Sumich (1999).*

their hind flippers forward and use them to walk. Otariidae typically are divided into two subgroupings: Otariinae (sea lions) and Arctocephalinae (fur seals). Five living genera and seven species of sea lions are recognized, occurring in both the Northern and Southern Hemispheres: *Eumetopias jubata* (northern sea lion), *Neophoca cinerea* (Australian sea lion), *Otaria flavescens* (southern sea lion), *Zalophus californianus* (California sea lion), *Z. japonicus* (Japanese sea lion), *Z. wollebacki* (Galapagos sea lion), and *Phocarctos hookeri* (New Zealand sea lion; Fig. 2). Fur seals, named for their thick, dense fur, are divided into two genera. The genus *Arctocephalus*, or southern fur seals, consists of eight species: *A. australis* (South American fur seal), *A. forsteri* (New Zealand fur seal), *A. gazella* (Antarctic fur seal), *A. galapagoensis* (Galapagos fur seal), *A. philippii* (Juan Fernandez fur seal), *A. pusillus* (*A. p. pusillus* South African fur seal and *A. p. doriferus* Australian fur seal), *A. townsendi* (Guadalupe fur seal), and *A. tropicalis* (sub-Antarctic fur seal). The genus *Callorhinus* is monotypic; a single extant species is recognized, *C. ursinus*. All of the fur seals except the northern and Guadalupe fur seals are found in the Southern Hemisphere. The northern fur seal is found in sub-Arctic waters of the North Pacific, with the exception of a small population on San Miguel Island off California (Fig. 3).

The monophyly of otariids is based on a combination of cranial, postcranial, and soft anatomical characters (Berta and Sumich, 1999). Relationships among otariids based on morphology conflict with those based on molecular data, although as yet the latter is based on an incomplete taxonomic sample (Fig. 4). Morphologic data indicate that only the sea lions (Otariinae) are monophyletic with a sister group relationship

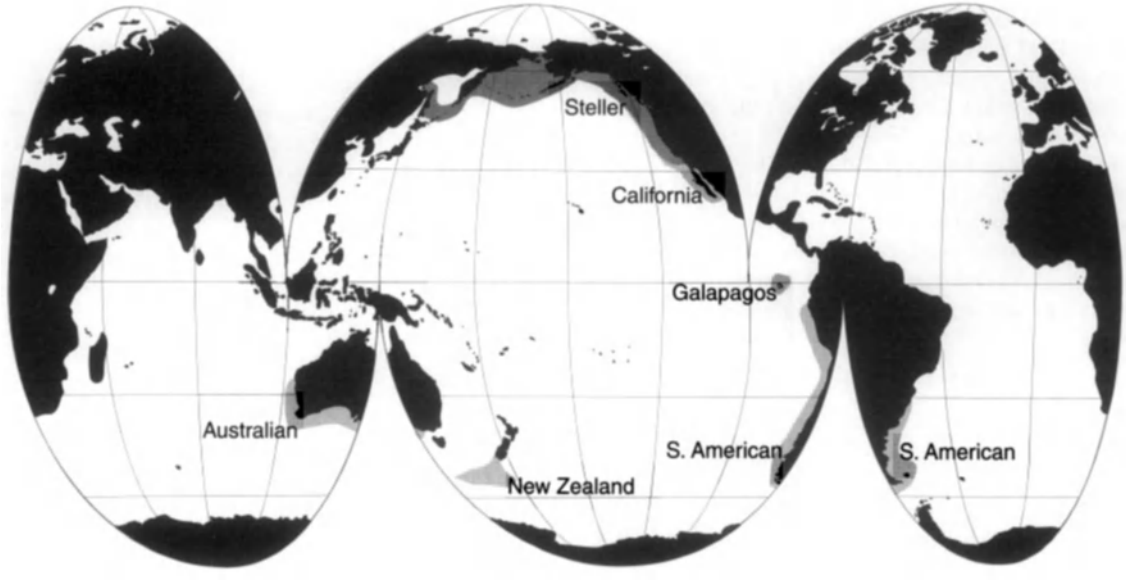

Figure 2 *Distribution map of sea lions. From Berta and Sumich (1999) based on Riedman (1990).*

Figure 3 *Distribution map of fur seals. From Berta and Sumich (1999) based on Riedman (1990).*

suggested with only some fur seals (i.e., *Arctocephalus* spp.). Thus far, morphologic data have been unable to resolve relationships among *Arctocephalus* species. Relationships among sea lions based on morphology suggest a pairing of *Otaria* and *Phocarctos* with *Neophoca, Eumetopias,* and *Zalophus* as successive outgroups. *Callorhinus* and the extinct taxon *Thalassoleon* are positioned as sequential sister taxa to this clade. Molecular studies have revealed that neither fur seals nor sea lions are monophyletic. In support of these results is evidence for hybridization of various species (e.g., *Arctocephalus gazella/A. tropicalis, Zalophus californianus/Otaria flavescens*). Additionally, the violent sexual behavior by male sea lions toward females of different species may have resulted in more hybridization and introgression that has been typically recognized for the evolutionary history of otariids.

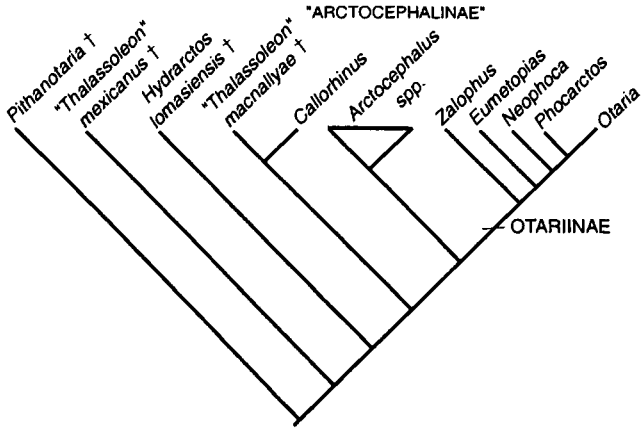

Figure 4 *Phylogeny of Otariidae based on morphologic data showing monophyletic Otariinae and paraphyletic "Arctocephalinae." From Berta and Sumich (1999).*

One modern species of sea lion is probably extinct, *Zalophus japonicus* (Japanese sea lion); its last well-documented record of occurrence was in 1951.

B. Odobenidae: Walruses

Although tusks are arguably the most characteristic feature of the modern WALRUS, *Odobenus rosmarus,* a rapidly improving fossil record indicates that these unique structures evolved in a single lineage of walruses and "tusks do not a walrus make." The living walrus is the sole survivor of a what was once a diverse radiation of at least 10 genera and 13 species of walruses that lived from the early Miocene to the end of the Pliocene (Deméré, 1994). Two subspecies of the modern walrus are recognized: *O. r. rosmarus* (Atlantic walrus) and *O. rosmarus divergens* (Pacific walrus). Pacific walruses are more abundant, are larger, and have longer tusks than Atlantic walruses (Fay, 1981). Walruses inhabit the Northern Hemisphere in areas with pack ice over shallow water of the continental shelf (Fig. 5). Like phocids, walruses lack external ear flaps. A unique feature of members of the modern walrus lineage are enlarged upper canine tusks that function primarily in breeding and social contexts. Walrus locomotion combines elements of phocid and otariid locomotion.

Monophyly of the walrus family is strongly supported, although there is controversy regarding whether walruses are related more closely to otariids or to phocids (Berta and Sumich, 1999). The modern walrus belongs to one of two monophyletic clades of walruses, the Odobeninae, and is most closely related to *Valenictus,* from the late Miocene to late Pliocene of southern and central California (Fig. 6). Several uniquely derived features of *Valenictus* indicate that it diverged from a common ancestry with *Odobenus* prior to pursuing its own evolutionary path toward toothlessness.

A survey of genetic variation among Atlantic and Pacific populations of the walrus suggests separation of the subspecies

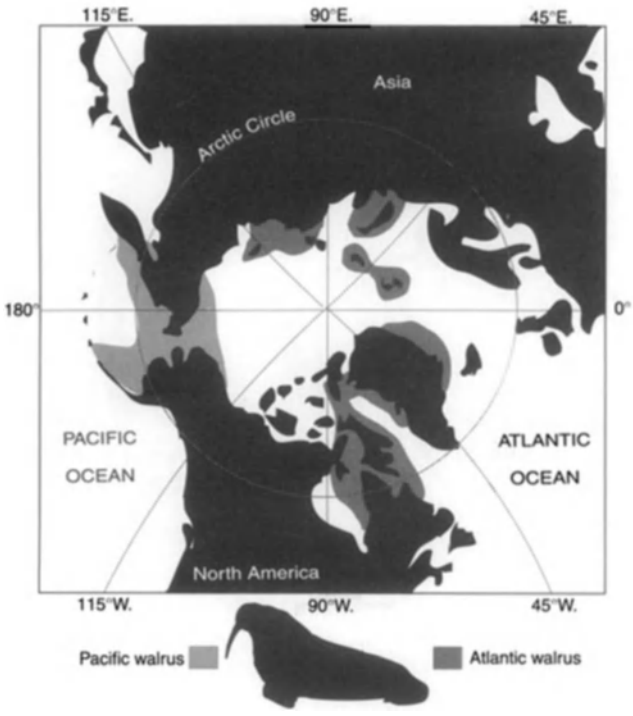

Figure 5 *Distribution of modern walrus subspecies,* Odobenus rosmarus divergens *(Pacific walrus) and* Odobenus rosmarus rosmarus *(Atlantic walrus). From Berta and Sumich (1999).*

about 500,000–750,000 years ago, supporting the suggestion that *Odobenus* evolved in the Pacific and reached the North Atlantic early in Pleistocene time (Cronin *et al.,* 1994).

C. Phocidae: Seals

The second major grouping of seals, the phocids, often are referred to as the "true" or "earless" seals for their lack of visible ear pinnae, a characteristic that readily distinguishes them from otariids as well as the walrus (Fig. 7). Among the most distinguishing phocid fur seals is their inability to turn the hindlimbs forward to support the body, resulting in a peculiar crawling locomotion on land. Phocids inhabit both Northern and Southern Hemispheres, although they are largely restricted to polar and subpolar regions (Fig. 8). Among pinnipeds, phocids are unique in their ability to survive in estuarine and freshwater habitats (e.g., Caspian and Baikal seals inhabiting land-locked lakes).

Traditionally, phocids have been divided into two or four major subgroups (including the Monachinae, Lobodontinae, Cystophorinae, and Phocinae). Only the Phocinae is universally accepted as being monophyletic (Berta and Sumich, 1999; Fig. 9).

The "Monachinae" subgroup of "southern seals" typically includes *Monachus* (monk seals), *Mirounga* (elephant seals), and the Lobodontini (Antarctic seals). Monophyly of the Monachinae is disputed (Wyss, 1988; Bininda-Emonds and Russell, 1996). Basal phocids have been identified as being *Monachus* spp. (not recognized as a monophyletic taxon by all workers) or alternatively as *Mirounga.* Three species of *Monachus* have been described: *M. schauinslandi* (Hawaiian monk seal), *M. monachus* (Mediterranean monk seal), and the recently extinct *M. tropicalis* (Caribbean monk seal). According to Wyss (1988), *Monachus* is a paraphyletic taxon, and based on morphology of the ear region, *M. schauinslandi* is basal to the other two species (Fig. 9a). Bininda-Emonds and Russell (1996) argue that *Monachus* is monophyletic and, on the basis of other morphologic characters, position *M. monachus* as the basal taxon (Fig. 9b). Molecular sequence data for species of *Monachus* are currently available only for *M. schauinslandi* and thus offer no resolution of relationships among this species group. Elephant seals, named for their enlarged proboscis, are represented by two species: *Mirounga angustirostris* (northern elephant seal) and *Mirounga leonina* (southern elephant seal).

There is also disagreement regarding monophyly of the Lobodontini, which include *Leptonychotes weddellii* (Weddell seal), *Lobodon carcinophaga* (crabeater seal), *Hydrurga lep-*

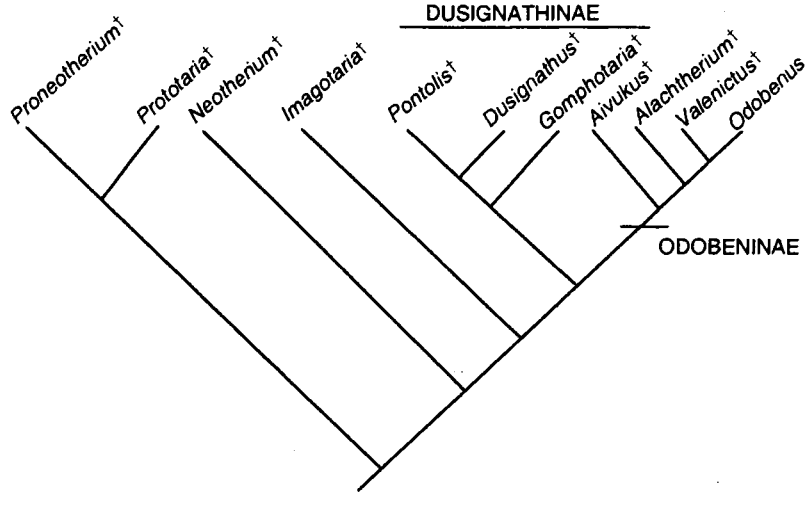

Figure 6 *Phylogeny of Odobenidae. From Deméré (1994) and Deméré and Berta (2001).*

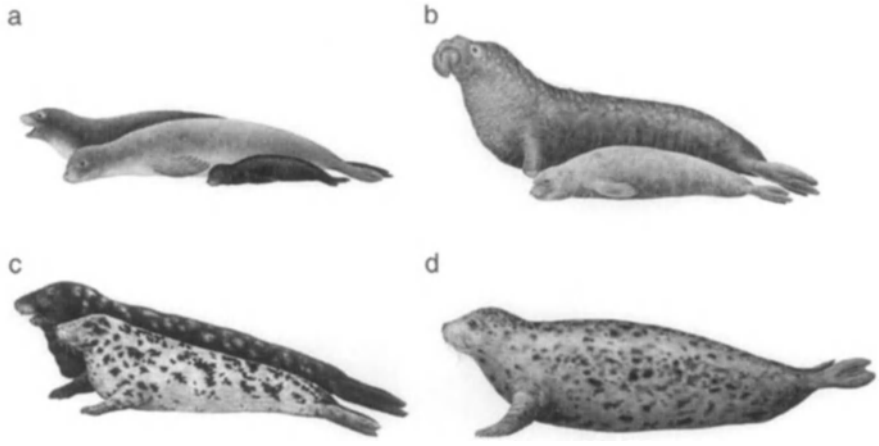

Figure 7 *Representative "monachines" (a) Hawaiian monk seal,* Monachus schauinslandi, *and (b) northern elephant seal,* Mirounga angustirostris, *and phocines (c) harbor seal,* Phoca vitulina, *and (d) gray seal,* Halichoerus grypus. *Males are shown behind smaller females. Illustrations by P. Folkens. From Berta and Sumich (1999).*

tonyx (leopard seal), and *Ommatophoca rossii* (Ross seal). Although Wyss' data support monophyly of this group, relationships among taxa were unresolved. According to Bininda-Emonds and Russell (1996) the Lobodontini are paraphyletic. Their most parsimonious tree (bootstrap analysis) supports a *Lobodon–Monachus* pairing with *Ommataphoca, Leptonychotes,* and *Hydrurga* forming successive outgroups to this clade (Fig. 9b).

Traditionally the Phocinae subgroup of "northern seals" includes *Erignathus barbatus* (bearded seal), *Cystophora cristata* (hooded seal), *Halichoerus grypus* (gray seal), *Phoca* (including among others harbor and spotted seal), *Pusa hispida* (ringed seal), *Histriophoca fasciata* (ribbon seal), and *Pagophilus groenlandicus* (harp seal). Wyss' cladistic analysis supports *Erignathus* and *Cystophora* as successive sister taxa to the Phocini (*Pusa, Histriophoca, Pagophilus, Halichoerus,* and *Phoca*). Although Bininda-Emonds found support for the basal position of *Cystophora*, this was not the case for *Erignathus*, which moved to a sister group relationship with *Pagophilus* + *Histriophoca* (Fig. 9b). There is disagreement about recognition of the Phocini; paraphyly of several taxa has been proposed based on both morphologic and molecular data. According to Arnason *et al.* (1995) molecular data, Phocini are divided into an earlier diverging lineage consisting of *Histriophoca* and *Pagophilus* and the other composed of various species of *Phoca* (rendering the genus paraphyletic) and *Halichoerus* (Fig. 9c). Bininda-Emonds and Russell (1996) acknowledge weak support and poor resolution among Phocini.

The harbor seal (*Phoca vitulina*) has the most extensive geographic distribution of any seal, with a range spanning over 16,000 km from the east Baltic, west across the Atlantic and Pacific Ocean to southern Japan. The population structure of the harbor seal studied by Stanley *et al.* (1996) revealed that populations in the Pacific and Atlantic Oceans are highly differentiated. Mitochondrial data are consistent with the ancient isolation of populations in both oceans coincident with the development of continental glaciers and extensive sea ice. In the Atlantic and Pacific Oceans, populations appear to have been established from west to east, with the European populations showing the most recent common ancestry.

II. Anatomy and Physiology

Pinniped aquatic specializations include their STREAMLINED shape, reduced external ear pinnae, paddle-like limbs and feet, small tail, and genital organs and mammary glands that are retracted beneath the skin. In comparison to most terrestrial carnivorans, pinnipeds are large, which helps conserve warmth. Pinnipeds, particularly phocids show tremendous diversity in size, ranging from the smallest pinniped, the Baikal seal, *Pusa sibirica,* reaching a length of just over a meter and a weight of 45 kg to the largest pinniped, the elephant seals, nearly 5 m in length (adult males) and up to 3200 kg (Bonner, 1990). Pinnipeds are ecologically diverse with habitats ranging from shelf to surface waters in tropical and polar seas, with some species living in freshwater lakes, whereas others move freely between rivers and the ocean.

Phocids and the walrus have lost much of their HAIR (fur) and are characterized by thick layers of blubber under the skin. Otariids, especially fur seals, have retained a thick fur coat. Color patterns in the pelage of pinnipeds occur almost exclusively among phocids. Ice-breeding seals (e.g., ribbon seal, harp seal, hooded seal, ringed seal, crabeater seal, Weddell seal, and leopard seal) show contrasting dark and light or disruptive color patterns (Fig. 10). The uniform coloration of some pinnipeds (e.g., white harp seal pups) allows them to blend readily into their arctic environment. Pinnipeds come ashore for birthing and molting. All phocid seals undergo an annual molt. Fur seals and sea lions instead renew their pelt gradually all year.

Vibrissae, or whiskers, are stiff hairs that occur on the face. Most prominent are the mystacial whiskers, which range in size from the short stiff bristles of the walrus to the very long, fine bristles of fur seals (Fig. 11). Vibrissae function as sensitive

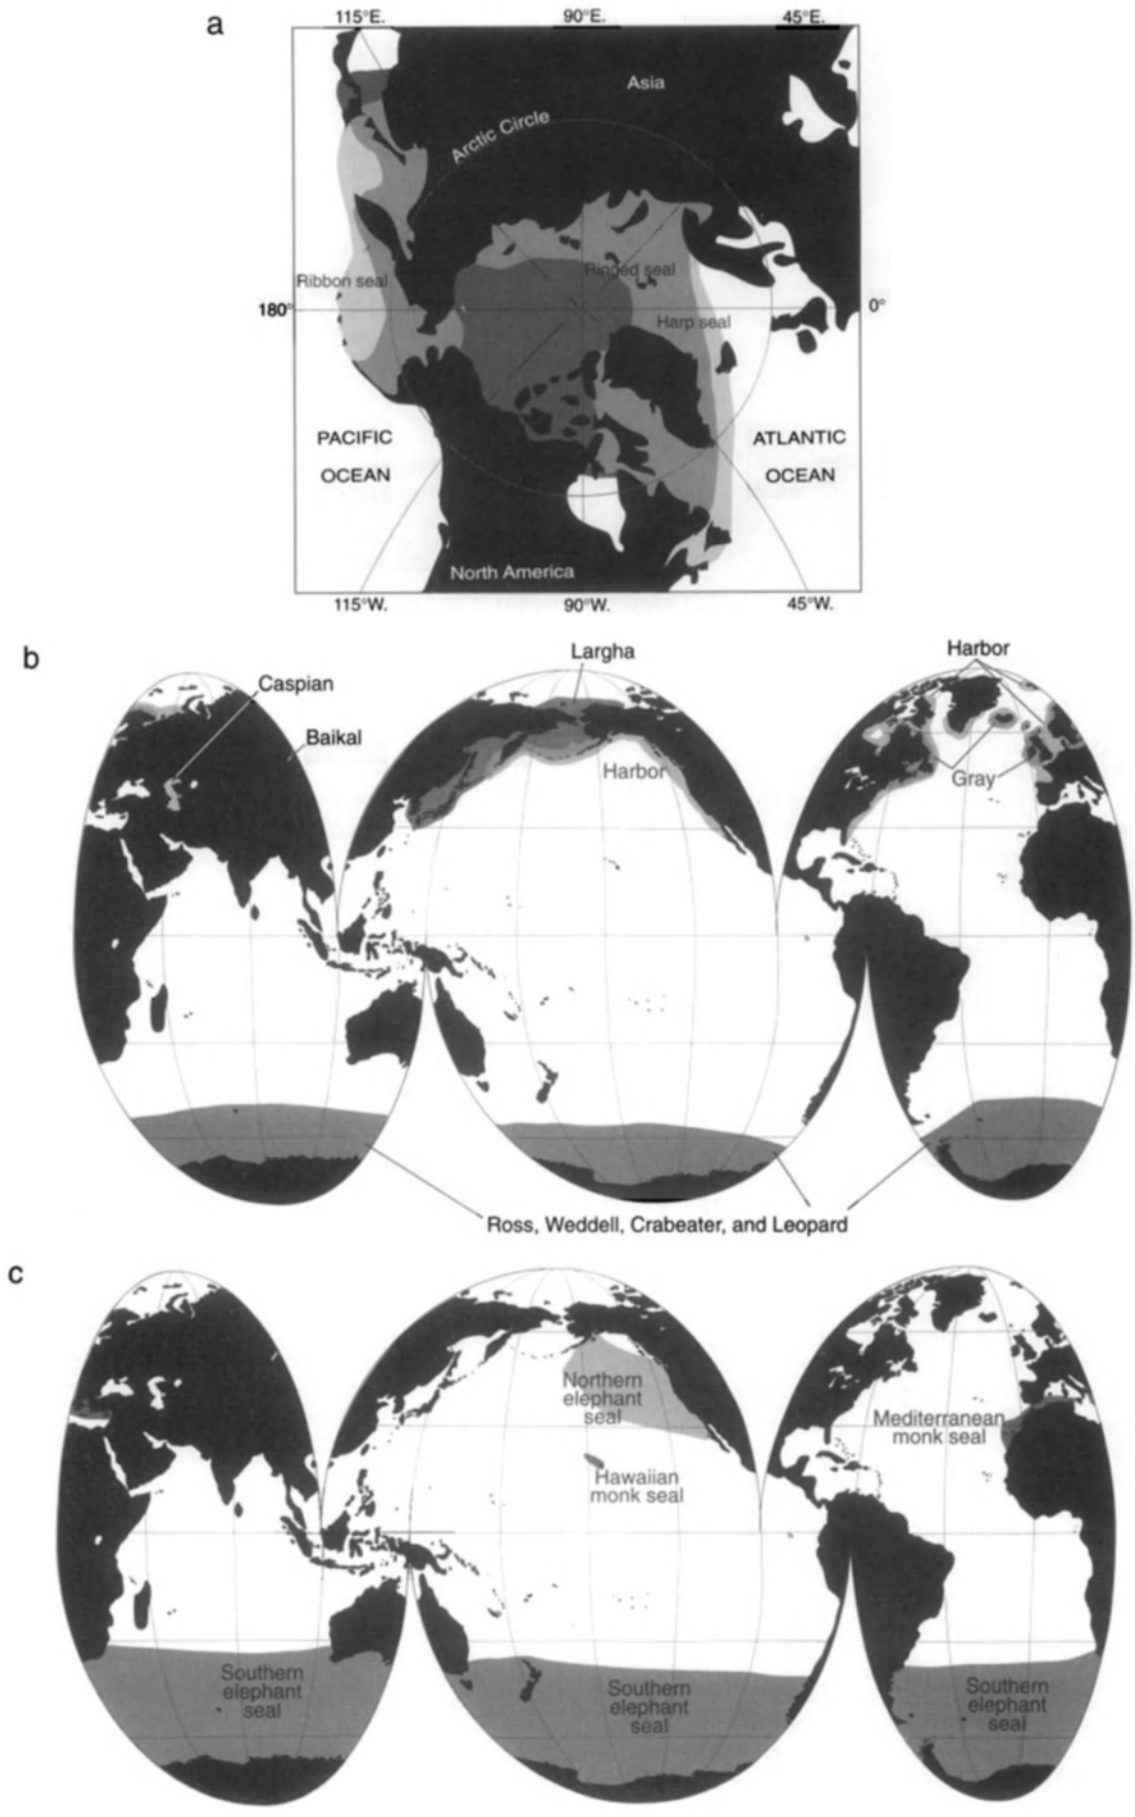

Figure 8 *Distribution of some Arctic phocines. (a), Antarctic lobodontine and phocines (b), and "monachines" (c). From Berta and Sumich (1999) based on Riedman (1990).*

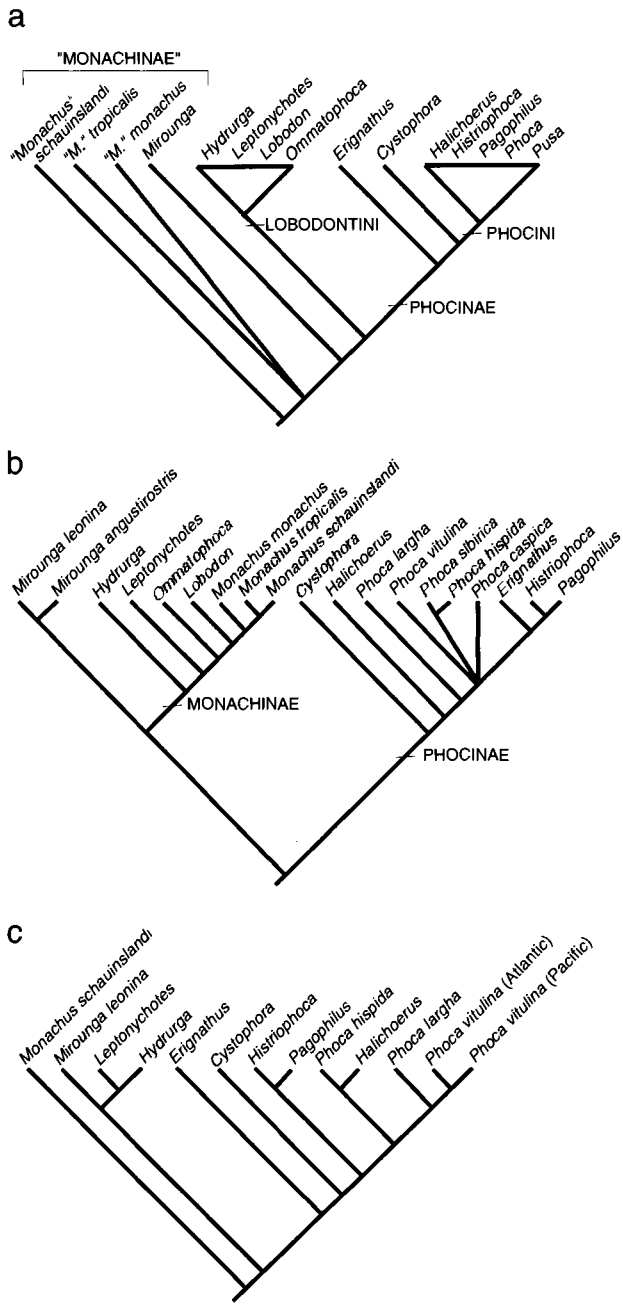

Figure 9 *Alternative phylogenies for Phocidae based on morphologic data (a) from Wyss (1988) and Berta and Wyss (1994); (b) from Bininda-Emonds and Russell (1996); and (c) molecular data from Arnason* et al. *(1995).*

touch receptors. Research on the Baltic ringed seal (*P. hispida*) has shown that they have exceptionally well-developed vibrissae, which help them find their way in the dark and often cloudy water beneath the ice (Hyvarinen, 1995). A single vibrissae of the Baltic ringed seal contains more than 10 times the number of nerve fibers typically found in that of a land mammal.

Pinnipeds, like other marine mammals, have evolved ways to accommodate the immense heat loss that occurs in the water. Among these solutions are a spherical body and a resultant decreased surface-to-volume ratio and increased insulation (thick BLUBBER or fur). In addition, heat exchange systems occurring in the flippers, in the fins, and (as discovered recently) in the reproductive tracts of pinnipeds conserve body heat.

Among modern pinnipeds, aquatic and terrestrial locomotion are achieved differently. Three distinct patterns of SWIMMING are recognized: (1) pectoral oscillation (forelimb swimming) seen in otariids where the forelimbs are used in a "flapping" manner to produce thrust, (2) pelvic oscillation (hindlimb swimming) seen in phocids where the hindlimbs are the major propulsors, and (3) a variant of pelvic oscillation exhibited by the walrus where the hindlimb are the dominant propulsive force and the forelimbs are used as rudders or

paddles. There is a major difference in locomotion on land between phocids on the one hand and otariids and walruses on the other. The inability of phocids to turn the hindlimbs forward results in forward progression by vertical undulations of the trunk, which do not involve the hindlimbs. In walruses, as in otariids, the hindlimbs can be rotated forward in terrestrial locomotion.

Pinnipeds are carnivores; most are generalists feeding predominantly on fish and squid. Several pinnipeds, notably crabeater and leopard seals, have highly modified cheek teeth with complex cusps to trap and strain krill. Leopard seals also possess well-developed canines for preying on birds and other pinnipeds. Walruses are specialists that feed almost exclusively on clams using a suction-feeding strategy in which the muscular tongue acts as a piston, creating low pressure in the mouth cavity. Some pinnipeds, e.g., elephant seals, rival gray whales (*Eschrichtius robustus*) in the distances traveled in migration (18,000–21,000 km) to forage offshore between breeding seasons. The advent of microprocessor-based time and depth recorders and satellite telemetry has enabled the documentation of details of the foraging behavior of these deep-diving seals.

Among pinnipeds are found the most extraordinary of marine mammal divers. Average dives of small species such as the Ross seal are just under 10 min in duration, increasing to over 1 hr for the northern elephant seal and the Weddell seal. Maximum depths vary from less than 100 m in the Guadalupe fur seal to more than 1500 m in northern elephant seal males. Some seals (in addition to sperm whales *Physeter macrocephalus*, sea turtles, and some penguins) are "incredible diving machines" with unique ways of budgeting their oxygen supply and responding to pressure.

Sounds produced by pinnipeds include air-borne and underwater vocalizations. Air-borne sounds vary from grunts, snorts, or barks identified as either mother–pup calls or threat calls among seals to the distinctive gong-like sounds produced by male walruses striking throat pouches with their flippers as part of a courting display during the breeding season. Pinnipeds produce a variety of underwater sounds that appear related to breeding activities and social interactions. Among these are the whistles, trills, chirps, and buzzes of Weddell seals that are used in territorial defense. These contrast with the soft lyrical calls of leopard seals that may be related to their solitary social system. In contrast to toothed whales, pinnipeds have not been found to use ECHOLOCATION in their natural surroundings.

The pinniped eye is adapted for VISION both above and under water. The spherical lens, thick retina, and the well-developed tapetum lucidum increase light sensitivity. With the exception of the walrus, which has small eyes, seals and sea lions have large eyes in relation to body size. The question of whether pinnipeds have color vision is still debated, although behavioral experiments and the presence of both rods and cones in the retina have been documented in some species (e.g., California sea lion, spotted seal, walrus).

III. Behavior

Unlike other marine mammals, pinnipeds differ in their need to return to land (or to ice) to give birth. Many pinnipeds (e.g., elephant seal) are extremely polygynous, with successful males mating with dozens of females in a single breeding season. Species that are polygynous tend to breed in large colonies on land where males compete for breeding territories (in otariids) or establish dominance hierarchies (in elephant seals). Because these males must compete for access to females, associated with extreme polygyny is the strong SEXUAL DIMORPHISM seen in elephant seals, including large body size (adult males as much as five times as large as females), elongated proboscis, enlarged canine teeth, and thick skin on the neck. Other phocids (e.g., Weddell seal, harp, ringed, ribbon, bearded, hooded) mate in the water or on ice and show a reduced level of polygyny, which is explained in part by the difficulty in gaining access to females in unstable environments such as pack ice.

Pinnipeds are characterized by sexual bimaturity with females reaching sexual maturity before males. In polygynous species, males require several years of physical maturation following sexual maturity before they successfully compete for access to females. Gestation in most species of pinnipeds averages between 10 and 12 months; walruses have the longest gestation period of 16 months. Most species regulate their reproductive cycle by delayed implantation (from 1.5 to 5 months). Delayed implantation prolongs birth until conditions are more favorable for offspring survival. Pinniped females of all species give birth to a single pup. In most species, pupping occurs in spring or summer.

The maternal behaviors and lactation strategies of pinnipeds are influenced by their breeding habitat whether on ice or land. Most phocids exhibit a fasting strategy where females fast completely and remain out of water for the duration of a relatively short lactation, ranging from less than 1 week in hooded seals to almost 8 weeks in the Weddell seal. It has been suggested that the unstable nature of pack ice has selected for the extremely short lactation periods of some ice-breeding phocid seals. To compensate for the brevity of lactation, the milk produced by these species is energy dense, with a fat content up to 60% in some species (i.e., hooded and harp seals). Rapid pup growth is ensured by the richness of the milk. In the foraging cycle strategy of most otariids, mothers fast for only a few days following the birth of pups. Then the mothers begin foraging trips at sea, leaving their pups for a few days at a time. The lactation period of otariids are longer, ranging from several months to more than 1 year, and milk is generally less energy dense than in phocids (e.g., milk fat content averaging between 24 and 40%). Walruses exhibit a variant of the otariid strategy, termed the aquatic nursing strategy, in which walrus pups accompany their mothers on foraging trips into the water. The length of lactation in walruses is the longest among pinnipeds, lasting 2 or 3 years.

Among generalizations that can be made about pinniped longevity is that females, especially those of polygynous species, tend to live longer than males. In many cases, males do not survive even to the delayed age of sexual maturity. Seals have been known to pup successfully at 24–25 years and live as long as 40 years or more. Significant factors implicated in the natural mortality of pinnipeds include disease (especially morbilliviruses), PREDATION (e.g., white sharks, killer whales), starvation, and PARASITES.

Pinniped Ecology

W. DON BOWEN
Department of Fisheries and Oceans, Dartmouth, Nova Scotia, Canada

CARRIE A. BECK AND DEBORAH A. AUSTIN
Dalhousie University, Halifax, Nova Scotia, Canada

Ecology deals with the interactions between individuals and their environment. In this context, environment is taken broadly to include other organisms and the physical environment. These interactions take place at various spatial and temporal scales and influence both the abundance and the distribution of individuals. However, ecology is also a historical science in that the patterns we see today reflect past events and phylogenetic relationships. Thus, processes acting on both evolutionary and ecological time scales have undoubtedly influenced many of the characteristics of pinniped ecology we see today. Pinnipeds are large, long-lived, aquatic mammals exhibiting delayed sexual maturity and reduced litter size; a single precocial offspring is the norm. As such, they share many of the demographic features of other large mammals. Population numbers do not change dramatically from year to year, and numbers are most sensitive to changes in adult survival, followed by juvenile survival and fecundity (Eberhardt and Siniff, 1977). We assume that these characteristics are under selection and that variability in foraging success affects survival probability and reproductive performance of individuals. Nevertheless, uncertainty about historical condition and influences limits the extent

to which present characteristics can be interpreted as evolutionary adaptations. Inevitably, discussions of pinniped ecology and other aspects of pinniped biology will overlap. This article focuses on five aspects of pinniped ecology: abundance, distribution, reproduction, foraging, and the ecological roles of pinnipeds in aquatic ecosystems.

I. Abundance

Despite interest in the ecology of pinnipeds, the abundance of many species is poorly known. The abundance of species of commercial importance (past, northern fur seals, *Callorhinus ursinus;* or present, harp seals, *Pagophilus groenlandicus*) is generally better known than for those species that have not been exploited. The accuracy and precision attached to the estimates of abundance vary greatly due to the difficulty in designing good census procedures or to the lack of effort to obtain good estimates. Good estimates of abundance are important because both abundance and trends in abundance are perhaps the most useful indicators of the status of populations.

Commercial exploitation decimated many pinniped species, in some cases to levels nearing extinction (e.g., northern elephant seals, *Mirounga angustirostris*). Over the past several decades or more, some species have recovered or are continuing to recover. Thus, the present abundance of heavily exploited species may not be a good measure of their preexploitation numbers. Pinniped species range over 4 orders of magnitude in abundance, from the crabeater seals (*Lobodon carcinophaga*) at about 12 million (probably the most abundant marine mammal in the world) to the Mediterranean monk seal (*Monachus monachus*) at probably fewer than several hundred individuals (Reijnders *et al.*, 1993). Phocid species are generally more abundant than otariids, with 15 of 18 phocid species numbering greater than 100,000 individuals compared with only 8 of 14 otariid species (Bowen and Siniff, 1999). The reasons for this difference are not entirely clear. Over the past 100 years, both families have been exploited commercially and subjected to other human factors that might have influenced abundance. More likely, the greater abundance of phocids is the result of their greater use of high-productivity areas in temperate and polar waters than is the case in most otariid species. The three most abundant otariids, the northern fur seal, the Antarctic fur seal (*Arctocephalus gazella*), and the Cape fur seal (*A. pusillus pusillus*), all forage in seasonally productive, high-latitude ecosystems, a characteristic shared with the most abundant phocid species (i.e., the ringed seal *Pusa hispida*, the harp seal, and the crabeater seal).

Abundance is determined by the movement of individuals (in and out of the population), births, and deaths. These processes are influenced by both direct and indirect human activities, as well as by ecological factors such as PREDATION, food supply, breeding habitat, disease, competition with other species, and environmental variability. In the absence of human effects, combinations of these ecological factors are thought to regulate the abundance of a population about a level known as carrying capacity. Although the concept of carrying capacity has a long history in ecology, with the possible exception of the Weddell seal (*Leptonychotes weddellii*), there is little evidence that populations of pinnipeds fluctuate about some long-term average level. This lack of evidence may be an artifact of the effects of previous exploitation on population trends and the fact that few populations have been surveyed over many decades. For example, a number of pinniped populations recovering from human exploitation (e.g., Antarctic fur seal, gray seal *Halichoerus grypus*, harbor seal *Phoca vitulina*) have increased at rates in excess of 12% per year over several decades or more. At Sable Island, Canada, the number of gray seal pups born each year has increased exponentially, with a doubling time of about 6 years, for more than 40 years. It is also clear that pinniped populations may decline rapidly as a result of epizootics, such as the phocine distemper virus that killed large numbers of harbor seals in the North Sea, and during short-term extreme changes in ocean climate, such as El Niño (see later).

Ecosystem structure and function are influenced by both top-down (i.e., consumer driven) and bottom-up (i.e., producer driven) processes. Pinnipeds likely exert top-down control on some ecosystems through predation (see Section IV) and are affected by changes in food available brought about by changes in primary and secondary productivity.

An example of a top-down ecosystem perturbation affecting pinniped abundance occurred in the Southern Ocean in the early 1900s. The overexploitation of some species of seals and whales led to an enormous uncontrolled "experiment" in this cold-water ecosystem. A high biomass of Antarctic KRILL is the cornerstone of the Southern Ocean food web, accounting for half of the total zooplankton biomass. Of the six species of pinniped that inhabit the Southern Ocean, crabeater seals, Antarctic fur seals, and leopard seals (*Hydrurga leptanyx*) feed mainly on krill, whereas southern elephant seals (*Mirounga leonina*) and Ross seals (*Ommatophoca rossii*) consume mainly cephalopods and Weddell seals eat primarily fish. Krill is also the main food resource for the resident large baleen whales [blue (*Balaenoptera musculus*), sei (*B. borealis*), minke (*B. bonaerensis*), humpback (*Megaptera novaeanglioe*), fin (*B. physalus*), and southern right (*Eubalaena australis*)]. As the cetacean biomass declined from exploitation by more than 50% between 1904 and 1973, an estimated 150 million t of krill were released annually to the remaining predators (Laws, 1985). The abundance of krill-eating species of pinniped, such as the crabeater seal and the Antarctic fur seal, increased substantially following the massive cetacean exploitation.

Bottom-up effects on top predators such as pinnipeds also can occur rapidly over the course of months. Perhaps the most dramatic example of this occurs during El Niño. El Niño events occur approximately every 4 years in the eastern tropical Pacific, resulting in reduced upwelling and a decrease in primary and secondary productivity. During a severe El Niño, the effects of reduced food availability on seabirds and marine mammals can be quite pronounced. Galapagos fur seals (*Arctocephalus galapagoensis*) have an unusually long lactation period of approximately 2 years that is thought to have evolved to buffer young against minor El Niño events. However, during the severe El Niño event between August 1982 and July 1983, pup production of Galapagos fur seals was only 11% of previous years, and no pups survived past the first 5 months. Adult females responded by increasing the foraging trip length, while most adult males did not appear on the BREEDING SITE and

were unable to hold territories during the breeding season (Trillmich and Ono, 1991).

Top-down and bottom-up effects at times may work in concert to influence the abundance of pinnipeds. Between the 1950s and early 1970s, intensive harvesting in the Bering Sea and the Gulf of Alaska critically reduced the populations of large whales, flatfishes, herring, and other primary consumers of krill and zooplankton. It is believed that the resulting increase in the availability of krill and other zooplankton, coupled with a regime shift in the ocean climate, favored some species such as walleye pollock and not others. This resulted in a change in the relative abundance of both fish and invertebrate assemblages. There was also a regime shift in ocean climate during the 1970s that likely contributed to changes in the biological productivity of these areas. Although the consequence of these changes on marine mammals remains uncertain, both harbor seal and Steller sea lion (*Eumetopias jubatus*) numbers declined dramatically following these changes, resulting in the Steller sea lion being declared an endangered species. A probable explanation for this cycle of events involves a combination of environmental change affecting producers (bottom-up effect) and human exploitation of predators resulting in changes to the ecosystems that have been detrimental to pinnipeds (Bowen and Siniff, 1999).

II. Distribution

Fundamentally, pinniped distributions reflect the need to give birth on solid substrate (land or ice) and to feed at sea. Within these broad constraints, the distribution of pinnipeds is affected by physical (e.g., ice cover, location of remote islands) and biological (e.g., productivity, abundance of predators) characteristics of habitat, demographic factors (e.g., population size, age, sex, and reproductive status), morphological and physiological constraints, and human effects (e.g., disturbance). Although each of these factors may influence distribution, combinations of factors are generally responsible for the distribution patterns observed. Pinniped distribution is also three dimensional, where the third dimension is water depth and the underlying bathymetry. Although a complete understanding of pinniped distribution must consider this three-dimensional world, this aspect of pinniped behavior is discussed elsewhere.

Pinniped species have a restricted and generally patchy distribution in most aquatic environments: estuaries and continental shelves (e.g., gray seals); tropical seas (e.g., monk seals, Galapagos fur seals); the deep ocean (e.g., elephant seals); both Arctic (e.g., ringed seals) and Antarctic polar seas (e.g., crabeater seals, Antarctic fur seals); and freshwater lakes (e.g., Baikal seals, *Pusa sibirica*) (King 1983). It is important to note, however, that our understanding of the distribution of most species is based primarily on the location of breeding colonies. We know less about where most species forage at sea such that our view of the overall distribution of most species is incomplete. For example, based on the location of breeding colonies, northern elephant seals range from Baja California to central California. However, satellite TELEMETRY studies show that this species forages over broad areas of the North Pacific Ocean for much of the year.

If we examine the distribution of pinniped breeding colonies, it is clear that we see patterns that reflect the evolutionary history of pinnipeds and the distribution of resources. At large scales, both sea lion and fur seal distributions reflect their origins in the Pacific Ocean. Northern fur seals and Steller sea lions are widely distributed along both sides of the North Pacific Ocean. The California sea lion (*Zalophus californianus*) and Japanese sea lion (*Z. japonicus*) are or were endemic to opposite sides of the North Pacific, and the Galapagos sea lion occurs at the equator. The four other species of sea lions occupy colonies along the west coast of South America, southern Australia, and New Zealand. With the exception of the northern fur seal and Guadalupe fur seal, the other six species of fur seals occur in these tropical or subtropical southern water, but also extend into the cool, nutrient-rich waters of the South Atlantic and Indian Oceans. Sea lion and fur seal breeding colonies are usually located on remote islands near areas of high biological productivity (e.g., northern fur seals, Antarctic fur seals), which provide both protection from mainland predators and nearby food sources. These conditions are particularly important for lactating females.

Species of the family Phocidae are widely distributed in biologically productive temperate and polar seas. Although most abundant in the North Atlantic and Antarctic Oceans, a reflection of their evolutionary origins in the Atlantic basin, phocid species have circumpolar distributions in both the Arctic Ocean (e.g., ringed seal, bearded seal, *Erignathus barbatus*) and the Antarctic Ocean (e.g., Weddell seal, crabeater seal) as well as a broad distribution in the North Pacific Ocean [e.g., harbor seal, larga seal (*Phoca largha*), ribbon seal (*Histriophoca fasciata*)]. Several endangered species also occur in tropical waters (Hawaiian and Mediterranean monk seals, *Monachus* spp.).

Pinnipeds must return to a solid substrate (land or ice) to give birth, rear their offspring, and in many species to molt. For most species, these requirements result in seasonal changes in distribution. In the case of species that breed on pack ice, such as harp and hooded (*Cystophora cristata*) seals and the walrus (*Odobenus rosmarus*), seasonal changes in ice cover virtually guarantee some change in the distribution of individuals. This may partly explain why 7 of 13 (54%) species of pinnipeds that give birth on ice (i.e., most phocid seals and the walrus) are migratory compared to only 4 of 20 (20%) species that give birth on land (2 of 6 phocids, 2 of 14 otariids; Bowen and Siniff, 1999). However, this difference also may be partly explained by the variable quality of data on the at-sea distribution of pinnipeds.

Migration appears to be a common feature of the ice-breeding phocid species, but this behavior is perhaps best documented in the northern elephant seal. This land-breeding species shows extreme sexual size dimorphism, with males being about five times heavier than females. Northern elephant seals undertake the longest known migration and some of the deepest dives reported for a mammal (Stewart and DeLong, 1993). Individual elephant seals make two long-distance migrations of 18,000 to 21,000 km between breeding and molting sites in California and pelagic foraging areas in the North Pacific. Using the California current as a corridor to areas further north, northern elephant seals leave the breeding beaches in southern California for northern offshore foraging areas. The

first migration occurs following the breeding season, in which adult male and female elephant seals travel an average of 11,967 and 6289 km, respectively, and remain at sea for an average of 124 and 73 days. After the molt, the seals depart on a second migration. Females are at sea for approximately twice as long as males and cover an average distance of 12,264 km compared to an average of 9608 km by males. males migrate farther north than females, with most males traveling as far as the northern Gulf of Alaska and the eastern Aleutian Islands. These sex differences in foraging distribution, and perhaps diet, may have evolved to reduce competition between females and the much larger males of this species.

III. Reproductive Ecology

The reproductive ecology of pinnipeds varies considerably, reflecting differences in body size, geographic distribution, and habitats used by individual species. Despite this diversity, there are common features that reflect their common ancestry as terrestrial carnivores, and their subsequent adaptation to a predominately aquatic lifestyle.

As noted previously, a conserved trait of their terrestrial ancestry is the requirement for all pinniped species to give birth to their offspring on a solid substrate (land or ice). However, pinnipeds must feed at sea, often some distance from the breeding grounds. This spatial and temporal separation of parturition from aquatic foraging is thought to have played a large role in shaping the mating and lactation strategies of pinnipeds. Three general strategies have evolved to deal with the conflict between at-sea foraging and terrestrial parturition (see later); however, the requirement for terrestrial parturition has likely contributed to some common features of pinniped reproduction, such as birth synchrony.

In most pinniped species, reproduction is seasonal and highly synchronous (e.g., harp seals). The evolution of reproductive synchrony is often associated with seasonal resource availability. In ice-breeding species (e.g., harp and hooded seals), the timing of reproduction is linked to the seasonal availability of sea ice. Seasonal changes in prey abundance and environmental conditions can also influence the timing of parturition and mating. The Hawaiian monk seal (*Monachus schauinslandi*) displays only weak synchrony in reproduction. In this species, births extend over a 6-month period. Given the less variable tropical habitat of this species, reproductive synchrony may not have been under strong selection relative to the species in more variable temperate and polar environments. Subtropical populations of California and Galapagos sea lions and Galapagos fur seals also show slightly less temporal synchrony of reproduction relative to more temperate populations (Boness, 1991).

Other common features of pinniped reproduction include postpartum mating and delayed implantation. These two characteristics of pinniped reproduction also appear to reflect the terrestrial ancestry of the taxa with both features occurring in many modern terrestrial carnivores. However, selection for postpartum mating may have continued as pinnipeds adapted to their aquatic environment. Given the wide-ranging and dispersed distribution of pinniped species during the at-sea foraging season, the aggregation of individuals at pupping colonies may have offered one of the few predictable opportunities for male and females to interact.

Another common feature of pinniped reproduction is the production of a single, precocious offspring; litters of two are rare. Offspring are born with their eyes open and begin to vocalize within minutes of birth. Neonates are also able to move short distances to their mother and to begin suckling shortly after birth. Harbor seal females produce extremely precocial offspring that are capable of swimming and diving with their mothers within an hour of birth (Bowen, 1991).

A. Mating Systems

Within the Pinnipedia, mating systems range from extreme polygyny (e.g., northern fur seals) to sequential defense by males of individual females. The mating system of individual species is closely associated with the dimensionality and stability of the habitat used and the distribution of females at parturition. Broadly speaking, species can be grouped as land-breeding and aquatic-breeding species.

1. Land-Breeding Species Land-breeding pinniped species include all fur seals and sea lions, northern and southern elephant seals, and the gray seal. These species colonize oceanic islands and coastal areas to give birth and mate. The aggregation of individuals during the breeding season has been attributed to the fact that oceanic islands are relatively rare and unevenly dispersed such that the availability of suitable pupping sites may limit the distribution of females (Boness, 1991). Predation may also select for female clustering, with females being less vulnerable to terrestrial predators and/or harassment by conspecific males when in large groups (dilution effect). Aggregation of females within a stable, two-dimensional habitat has led to the evolution of a polygyny in these species, with males defending either resources needed by females (e.g., birth and thermoregulatory sites in otariid species) or the females themselves (e.g., elephant seals and gray seals). By competing with and limiting the access of other males to females, successful males mate with multiple females, thus increasing their reproductive success. The degree of polygyny in land-breeding pinniped species ranges from extreme in the northern fur seal and elephant seals where one male may mate with 16–100 females to moderate (6–15 females) in gray seals, Hooker sea lions (*Phocarctos hookeri*), and the Galapagos fur seal (Le Boeuf, 1991).

As in other polygynous species, land-breeding pinniped species are sexually size dimorphic. Males in these species can be much larger than females and often show other secondary sex characteristics. These dimorphic characteristics are the result of sexual selection for traits that increase an individual's ability to monopolize and defend resources needed by females or females themselves. Large body size, and concomitant large body energy stores in the form of subcutaneous blubber, permits dominant males to fast and thus remain ashore during the period when females become receptive. The most extreme example of sexual size dimorphism in pinnipeds occurs in elephant seals where males are 5–6 times heavier than females in the northern species and up to 10 times heavier than females in the southern species.

2. Aquatic-Breeding Species Walruses and all other phocid seals [Weddell, Ross, crabeater, leopard, bearded (*Erignathus barbatus*), hooded, ringed, Baikal, Caspian (*Pusa caspica*), larga, harp and ribbon] give birth on pack ice or fast ice and mate in the water. Although Hawaiian monk seals and harbor seals give birth to their offspring on land, they too mate in the water. In species where pups are born on ice, females tend to be more widely distributed, although access to breathing holes in the ice may promote clumping in some species (e.g., walrus and Weddell seals). This broader distribution of females, on an unstable habitat, limits the number of females a male can monopolize at any given time and as a result these species typically show reduced levels of polygyny (e.g., harbor seals; Coltman *et al.*, 1999). The fact that mating occurs in the water, a fluid three-dimensional environment, may also limit the ability of males to monopolize females, resulting in reduced levels of polygyny.

Wells *et al.* (1999) suggested that the mating strategies used by ice-breeding species could be classified as scrambling (males search for receptive females and move on to the next); sequential defense (males sequentially defend single females through mating); and lekking (males aggregate and attract females using displays). At present, there is insufficient information on the breeding behavior of most aquatic breeding species to draw firm conclusions about the type of mating system used. Data on the mating behavior of these species are limited to that which can be observed on ice prior to copulation. For example, observational data suggest that hooded seals utilize a sequential defense form of mating system whereby males compete with one another to defend a single mother and her pup on the ice. The male then remains with the pair until the pup is weaned and then enters the water with the female, presumably to mate. The application of new methods, including genetic paternity assessment and animal-borne video, will be needed to clarify the mating strategies used by these species.

In species that mate aquatically, there may be less selective advantage for males to be larger than females because of the limited ability of males to monopolize females in this environment. As a consequence, in most of these species, male and females are of similar size and in some cases females are larger than males. For example, male Weddell seals are slightly smaller than females and it has been suggested that smaller size makes the male more agile during underwater mating activities (Le Boeuf, 1991). Underwater vocalizations also appear to be an important component of the mating behavior in aquatically mating pinniped species. For example, in Pacific walruses, which exhibit a lekking mating system, males perform complex underwater visual and vocal displays in small groups next to female haul-out sites to attract females. Male Weddell, harbor, harp, hooded, and bearded seals also produce a range of underwater vocalizations during the breeding season that may be used to attract females or to establish underwater territories or display areas.

B. Lactation Strategies

Male pinnipeds do not participate in the care of offspring. Thus, parental care is the exclusive responsibility of the female. Female care involves the transfer of energy-rich milk to the pup and protection from conspecifics and terrestrial predators (Bowen, 1991). In some species (e.g., the walrus), females may also teach their young to forage, as young accompany mothers on foraging trips during the lactation period. Female pinnipeds have dealt with the temporal and spatial separation of energy acquisition (aquatic foraging) from high levels of energy expenditure (terrestrial lactation) in different ways, resulting in the three basic lactation strategies: a foraging cycle, fasting, and aquatic nursing. Until recently, each of the pinniped families was thought to use only one of these strategies (otariids, the foraging cycle; phocids, fasting; and odobenids, aquatic nursing) and the evolution of these differing strategies was presumed to reflect phylogeny. However, studies have indicated that this traditional view is an oversimplification (Boness and Bowen, 1996; Boyd, 1998). For example, harbor seal females exhibit a foraging cycle strategy previously thought to occur only in otariid species.

1. Foraging Cycle All otariids and some of the smaller phocid species (e.g., harbor seals) exhibit this lactation strategy. Females come ashore for parturition with a moderate level of stored body energy. After giving birth, females remain onshore and fast while attending and nursing their young for a perinatal period ranging from a few days to a week. After this initial provisioning period, females leave their pups and return to sea to feed. These trips range from less than 1 day in some species to as long as 14 days in others, depending on the distance to the foraging location and prey abundance. Females then return to land to nurse their pup, after which they repeat the cycle until the pup is weaned. The lactation period in otariid species is quite long, ranging from 4 months to 3 years (Bowen, 1991). Females of these species are considered income breeders, relying on current food intake to support both their own metabolic needs and the energetic cost of milk production. The milk produced by female otariids is relatively energy dense (24–40% fat) compared to terrestrial mammalian species. Pup growth rates are rather low, ranging from 0.06 kg/day in Galapagos fur seals to 0.38 kg/day in Steller sea lions (Boness and Bowen, 1996).

Harbor seals, a phocid species, also exhibit this lactation strategy—alternating short foraging trips to sea (7–10 hr) with terrestrial nursing. The harbor seal is a relatively small phocid species, with females weighing approximately 84 kg at parturition. Given the small quantity of body energy that these females are able to store, female harbor seals are forced to make regular foraging trips to acquire sufficient energy to wean their pups successfully. Compared to otariid species, the length of the lactation period in harbor seals is much shorter (24 days) and the milk produced by females has a relatively higher fat content (50%). Consequently, pup growth rate is higher in harbor seals relative to otariid species (0.6 kg/day). Foraging cycles during lactation may also occur in ringed seals and other relatively small phocid species. Evidence shows that the females of two medium size phocids, the Weddell seal and the harp seal, may also forage during the lactation period. However, the intensity of foraging and the degree to which successful weaning of offspring relies on these foraging trips are not clearly understood.

2. *Fasting Strategy* In the larger-bodied phocid species, females fast during lactation. Females arrive at the breeding site with large energy stores in the form of adipose tissue (i.e., blubber). In the western Atlantic, for example, gray seal females arrive at Sable Island weighing an average of 210 kg. Of this body mass, 32% or 67 kg is fat. After parturition, females fast for the entire lactation period (e.g., 16 days in the case of gray seals) using their stored energy to support the ENERGETIC cost of milk production and their own maintenance metabolism. For this reason, female phocids are considered capital breeders—having stored energy often months before it is needed. The lactation period in phocids is much shorter than in otariid species, ranging from 4 days in hooded seals to 60 days in Weddell seals. Maternal body size, metabolic rate, and the fasting ability of females may play an influential role in determining the duration of lactation both within and between species (Boness and Bowen, 1996; Boyd, 1998).

Another characteristic feature of the phocid fasting strategy is the production of extremely high-fat milk, ranging from 47% fat in southern elephant seals to 61% fat in hooded seals. This energy-dense milk results in a high rate of offspring growth, ranging from 1.4 kg/day in the Hawaiian monk seal to 7.1 kg/day in the hooded seal (Bowen, 1991). Weaning occurs abruptly when mothers return to the sea to feed. Pups often fast for weeks following weaning, living off their accumulated fat stores before entering the water and beginning to forage independently.

3. *Aquatic Nursing* The walrus is the only pinniped species that exhibits aquatic nursing. Just prior to parturition, pregnant females separate from the herd and give birth to their offspring alone on pack ice. New mothers remain on the ice fasting for the first few days postpartum, relying on stored body energy accumulated prior to parturition. Subsequently, females and their young return to the herd to forage. Walrus pups suckle in the water for between 2 and 3 years on relatively low-fat milk (24.1%). As with otariids, weaning is gradual. Young walruses begin to feed on benthic organisms as early as 5 months of age and likely gain valuable foraging experience from their mothers over the remainder of lactation. At weaning, female offspring are assimilated into the mother's herd, whereas male offspring join other male groups.

Lactation strategies are often viewed from the female's perspective. This seems reasonable, but in long-lived species such as pinnipeds, females may trade-off investment in current offspring against investment in future offspring. This may lead to conflicts between females and their offspring over the level of investment received. The transition from nursing pup to nutritionally independent juvenile usually occurs without parental supervision in pinnipeds. This transition is arguably the most important period of a pinnipeds' young life. As offspring size affects subsequent survival, we should expect that offspring would attempt to obtain as much milk as they can during lactation. Thus, the nutritional requirements and physiological abilities of individual offspring must also play a role in shaping lactation strategies. For example, the fasting ability of offspring constrains the duration of foraging trips by female fur seals and sea lions.

IV. Foraging

Successful foraging is essential for survival and reproduction and is therefore a critical determinant of fitness. Pinnipeds are among the largest vertebrate carnivores in marine ecosystems and yet the foraging behavior of these apex predators is poorly understood. As noted earlier, pinnipeds inhabit diverse environments, consequently they forage at highly varied spatial and temporal scales and in doing so they exploit a wide range of prey.

A. Methods

As pinnipeds generally feed underwater at remote locations, ecologists rely upon indirect methods to gain insight into their foraging behavior and diets. Very high frequency (VHF) radio tags have been used to study the at-sea locations of coastal species such as harbor seals. Acoustic tags have been used to track the underwater movements of gray seals. More recently, microprocessor-based, time-depth recorders (TDRs) have been used to collect information on dive duration, depth, frequency, and temporal distribution and to calculate the at-sea locations of pinnipeds using solar navigation equations. However, the use of TDRs is limited by the need to recover the instrument to retrieve the stored information and therefore only those species that can be reliably recaptured are used in TDR studies. In contrast, satellite-linked, time-depth recorders transmit collected data on diving parameters and surface positions to polar-orbiting satellites operated by Service ARGOS. This technology has broadened the range of species that have been studied, but the expense of using satellite-linked tags often places limits on the number of individuals studied.

Although we have learned a great deal from the use of location telemetry and dive recorders, these studies have provided little insight into the feeding success rate of pinnipeds. Recent work has demonstrated that estimates of feeding success can be determined using stomach temperature telemetry and animal-borne video. The body temperature of a marine prey is often considerably lower than that of its pinniped predator, thus the stomach temperature of the predator should drop following prey ingestion. This approach has been used successfully on free-living harbor seals and several other species. When combined with information on the diving behavior and movement patterns in the same individual, stomach telemetry can provide new insights into the spatial and temporal patterns of foraging success relative to foraging effort. Animal-borne video technology (Marshall, 1998) has taken our understanding of foraging behavior and diet one step further by providing direct observations of the way in which pinnipeds search and capture prey and how foraging behavior changes as a function of prey type. These video images, coupled with data on swim speed, diving characteristics, environmental conditions (such as sea temperature), and energy expenditure, promise to revolutionize our understanding of pinniped foraging ecology.

Determining the diet of marine mammals also requires the use of indirect methods. The most common methods rely on the recovery and identification of hard prey structures that are resistant to digestion from the stomach, intestine, or feces of individual animals. Sagittal otoliths, cephalopod beaks, bones, scales, invertebrate exoskeletons, and shells can be used to determine the species consumed and, in some cases, to estimate

the size and age of the prey. Fecal samples are increasingly being used for this purpose because they are less expensive to collect, a high proportion of samples contain identifiable prey, and estimates of diet are less affected by differential rates of digestion than estimates from stomach samples (Bowen and Siniff, 1999). Although the use of hard parts to estimate the diet of pinnipeds is common, this method is subject to a number of biases, which may limit the value of results. First, stomach and fecal contents only provide an estimate of the diet near the point of collection, and as a result, offshore diets cannot be sampled easily. This may seriously bias the diet of wide-ranging species such as elephant seals, harp seals, northern fur seals, and Juan Fernandez fur seals (*Arctocephalus philippii*). Second, hard parts are often eroded during digestion or digested completely such that prey size may be seriously underestimated and prey identification may not be possible. Finally, perhaps the most serious disadvantage is that dietary analysis based on hard parts is strongly biased against soft-bodied or small prey with fragile structures.

Inevitably our understanding of the diets of pinnipeds is tied to the development of new methods. Fatty acid signature analysis is a relatively new method, which has been developed to study marine mammal foraging and diet (Iverson, 1993). Lipids in marine ecosystems are diverse and characterized by long-chain polyunsaturated fatty acids that originate in unicellular phytoplankton. In monogastric carnivores, such as pinnipeds, ingested fatty acids with a carbon chain length greater than 14 are deposited in body tissues in a predictable way. As a result, the fatty acid composition or signature of the predator reflects the fatty acid composition of prey species consumed (Iverson, 1993). By comparing the reference signature of various prey species to the fatty acid signature of the predator (obtained from blubber tissue or milk), diet composition can be estimated both qualitatively and quantitatively. The use of fatty acid signature analysis eliminates the dependence on recovery of hard parts and integrates the diet over a period of weeks to months such that the location of sampling becomes less important.

Stable isotope ratios of carbon and nitrogen found in the muscle, skin, vibrissae, or blood of pinnipeds and other predators are also being used to investigate diet. These ratios reflect a composite of prey species eaten over a broad time scale. By examining the levels of $^{15}N/^{14}N$ found in body tissues, scientists can determine the trophic level at which the pinnipeds fed. The carbon isotope ratio ($^{13}C/^{12}C$) has been found to vary geographically and thus the level of carbon isotope in the predator's tissues provides insight into foraging location. Although this technique is useful in determining trophic level and foraging location, it does not permit the specific diet composition of individuals to be assessed.

B. Diet

A large number of prey species have been identified in the diet of various pinniped species, leading to the view that pinnipeds are generalist predators. This is consistent with the expectation that large, wide-ranging predators consume more types of prey, as their environment becomes patchier. However, in most cases a relatively small number of taxa account for the majority of food eaten (Bowen and Siniff, 1999). For example, gray seals on the Scotian Shelf, Canada, consumed 24 different taxa; however, only two to four species accounted for over 80% of the energy consumed depending on the time of year.

Fish and cephalopod species are the main prey types eaten by pinnipeds (Table I). However, crustaceans also appear to account for a substantial portion of prey consumed by some species. Crustaceans are a major prey of harp seals in the North Atlantic and of ringed seals and bearded seals in the Bering Sea. In three Antarctic species, Antarctic fur seals, crabeater seals, and leopard seals, krill accounts for up to 50% of the diet. Unlike most pinnipeds, which generally feed on mobile prey (e.g., fishes, cephalopod molluscs, and crustaceans) in pelagic and benthic habitats, the walrus feeds almost exclusively on sessile benthic invertebrates in soft-bottom sediments.

Several pinniped species are also known to feed on other pinnipeds (Bowen and Siniff, 1999). Male southern fur seals appear to commonly feed on young South American fur seals (*A. australis*). Steller sea lions are known to prey on a variety of pinniped species, including harbor seals, ringed seals, bearded seals, young northern fur seals, and larga seals. Walruses prey on larga seals, ringed seals, and young bearded seals.

The diet composition and foraging behavior of pinnipeds are influenced by a number of factors. The ecology and behavior of prey species clearly play a role in shaping the foraging strategies of pinnipeds. Research on male harbor seal foraging behavior at Sable Island, Canada, using animal-born video found that prey behavior affected both capture technique and profitability of different prey types. Other studies have shown that between-year differences in the diet composition of harbor seals were correlated with differences in the distribution and abundance of herring and sprat, two important prey species.

Intrinsic factors, such as age and sex, may also play a role in the diet composition of individuals within pinniped species. Given that pinnipeds are long-lived predators, their individual foraging tactics and behavior may change over time to reflect increased physiological capabilities and learning. For example, harbor seal pups feed on pelagic prey such as herring and squid, whereas the diet of adults is dominated by benthic species. Similarly, the contribution of benthic prey (e.g., crabs, clams, and sculpins) to the diet of bearded seals increases with age. Age-specific differences in diet composition have also been found in southern elephant seals and harp seals.

Diet composition may also differ between sexes in pinniped species that exhibit sexual size dimorphism (e.g., northern and southern elephant seals, otariid species). Due to the relationship between basal metabolic rate and mass, larger individuals require more total energy per unit time than smaller individuals. Oxygen storage capacity also increases with body mass due to the larger blood pool in which to store oxygen and the larger muscle (myoglobin) mass. In addition, larger animals have a slower mass-specific metabolic rate such that they utilize their larger oxygen stores at a slower rate relative to smaller individuals. Thus, larger individuals are capable of longer, deeper foraging dives. These physiological attributes may allow, or require, males (the larger sex) to pursue different prey types (potentially higher quality prey) than females. Although theory suggests that the diets of males and females may differ, cur-

TABLE I
Major Prey of Selected Pinnipeds

Species	*Location*	*Main prey*
Gray seal	Eastern Canada	Sand lance, flatfishes, Atlantic cod
	United Kingdom	Sand lance
Harbor seal	Eastern Canada	Herring, Atlantic cod, pollock, squid
	Western Canada	Pacific hake, Pacific herring
	Sweden	Atlantic cod, sole, herring, sand lance
Harp seal	Northwest Atlantic	Arctic cod, herring, capelin
	White Sea/East ice	Capelin, sand lance, herring
Hooded seal	Greenland	Greenland halibut, redfish, Gadidae
Ringed seal	Bering Sea	Saffron cod, Arctic cod, shrimp
Ribbon seal	Bering Sea	Pollock, eelpout, Saffron cod
Bearded seal	Bering Sea	Shrimp, crab, clam
Northern elephant seal	California	Cephalopods, Pacific whiting
Southern elephant seal	Heard/Macquarie Island	Squid, pelagic and benthic fishes
	Heard Island	Squid, pelagic fishes
Leopard seal	Southern Ocean	Krill, cephalopods, penguins, seals
Northern fur seal	North Pacific	Anchovy, herring, capelin, sand lance
	Bering Sea	Pollock, capelin, herring, squid
South African fur seal	Benquela Current	Anchovy, hakes, squid
Antarctic fur seal	South Georgia	Krill, cephalopods, fish
Sub-Antarctic fur seal	Gough Island	Squid
Australian fur seal	Tasmania	Squid
South American fur seal	Peru	Sardine, southern anchovy, jack mackerel
Jan Fernandez fur seal	Alejando Selkirk Island	Myctophid fishes, squid
New Zealand fur seal	New Zealand	Octopus, squid, barracuda
Steller sea lion	Gulf of Alaska	Pollock, herring, squid
California sea lion	California	Northern anchovy, Pacific whiting, squid

rently there are few studies to test this hypothesis. However, studies on southern elephant seals do indicate sex differences in diet.

C. Foraging and Diving Behavior

The foraging ecology of pinnipeds and other air-breathing vertebrates is constrained by the need to surface for oxygen. Dive duration is constrained by the interplay between the amount of oxygen that can be stored and the rate at which the diver expends oxygen. Thus, it is inevitable that patch use, and the resulting distribution of foraging in time and space, will be influenced by the physiological constraints. Other factors, such as prey density and depth, may play an important role in how pinnipeds forage within these physiological constraints.

Foraging pinnipeds dive repeatedly with relatively short surface intervals between dives; this cluster of dives is called a dive bout. In general, dive bouts are thought to indicate foraging within a prey patch, particularly in otariid species. Theoretically, divers should organize their behavior for optimal patch use. To organize their behavior in this way, divers should optimize both the time budget of the dive cycle (dive duration and surface interval) and the number of dive cycles to repeat. Both of these factors will influence the amount of prey caught and the energy and time consumed during the dive bout. However, there may be a trade-off between prey depth and profitability such that prey items that might be exploited when closer to the surface are less likely to be exploited as the depth of that prey increases.

Empirical tests of optimal foraging theory and optimal patch use in diving pinnipeds are uncommon, largely due to the difficulty and expense of studying these wide-ranging predators and their prey. However, it appears that some otariids feed near the surface on vertically migrating prey, such as krill, to maximize energetic efficiency.

Phocids are generally better suited for deep diving and for longer periods of time than are their otariid and odobenid counterparts. This is largely because phocids have a larger blood volume and larger myoglobin content in the muscles and thus store more oxygen per unit of body mass. Phocids also dive in continuous bouts and are known to spend up to 90% of

their time in the water submerged. Thus, unlike otariids and odobenids, phocid seals live at depth, returning periodically to the surface to breathe. Although diving behavior is often considered to be synonymous with foraging in otariids, dive shape analysis in phocids demonstrates that diving may also be used for travel, predator avoidance, and sleep (Wells *et al.*, 1999).

The function of different types of dives has been investigated through the analysis of the two-dimensional profile (time vs depth) of individual dives (i.e., dive shape) and swimming speed during diving. Foraging dives are those in which time spent at the bottom of the dives is a significant fraction of the total dive duration. In northern elephant seals and Weddell seals, these dives are often to similar depths over time, suggesting that the seals are exploiting prey patches that remain at a constant depth and are dense enough to maintain high encounter rates. In contrast, dives characterized by a middle segment of slow downward drift are thought to be associated with the digestion of food in female northern elephant seals. Although dive shape undoubtedly contains information about the behavior of individuals, animal-borne video has revealed that different behaviors can be represented by the same dive shape, thus limiting the inferences that can be drawn from shape alone.

D. Factors Affecting Foraging Ecology

Pinnipeds are important consumers of marine resources; however, for most species little is known about how they interact with the biotic and abiotic features of marine ecosystems. Knowledge of the spatial behavior of pinnipeds is important because spatial patterns can fundamentally affect the nature and dynamics of species interactions. These interactions largely determine the distribution of foraging. Within the ocean, food is distributed in patches and this distribution can be strongly influenced by the physical properties, such as water temperature and the availability of nutrients. For example, the distribution and migratory patterns of northern elephant seals correspond with the location of three dominant water masses of the North Pacific. The localized biological productivity in these water masses and associated fronts result in a high abundance of cephalopods, an important food of this species.

Seasonal changes in prey distribution and abundance can also influence pinniped foraging patterns. Reduced prey availability leads to changes in foraging behavior that include increased trip duration, trip distance, and increased foraging effort. For example, Antarctic fur seals increase their times at sea, northern fur seals increase diving effort, and California sea lions use both tactics during periods of limited prey resources.

E. Spatial and Temporal Scales of Foraging

The relative mobility, range, and body size of an animal affects the resolution at which it recognizes environmental heterogeneity. For example, a relatively small-bodied, central place forager, such as a lactating harbor seal, would identify resource patches at a smaller meso-scale than a highly mobile animal, such as a gray seal. To understand the relationship of an organism to its environment, one must understand the interactions between the intrinsic scales of heterogeneity within the environment and the scales at which the organism can respond to this heterogeneity. Scale issues are critical for effective conservation and management of pinnipeds because of shifts in habitat use and dispersal over ontogeny and a relatively long life span.

A large body size and the capacity for storing large amounts of fat in the form of BLUBBER enable some species of pinnipeds to feed irregularly and thus to exploit distant foraging locations and patchy resources. In contrast, smaller pinnipeds, such as Antarctic fur seals, perceive environmental heterogeneity at a more local scale. For example, fur seals forage at two spatial distributions: (1) fine scale, represented by short (<5 min) travel durations between patches and (2) meso-scale, represented by longer periods of travel (>5 min) (Boyd, 1996). Similarly, based on fatty acid signature analysis, harbor seals appear to demonstrate meso-scale partitioning of their foraging habitat in Prince William Sound, Alaska. Fatty acid signatures obtained from harbor seal blubber biopsies differed within the Sound at a spatial scale of about 40–50 km, and at a smaller scale of 9–25 km, reflecting fine-scale differences in diet between haul-out sites (Iverson *et al.*, 1997).

Although the patch structure of an environment is expressed in both space and time, temporal variation in predator behavior is likely to provide an insight into the spatial distribution of a highly dynamic prey source that may be difficult to track in other ways. For example, in the Antarctic Ocean, krill is distributed patchily and is the major prey resource of lactating Antarctic fur seals. By using the diving behavior of females obtained from TDR records, it is possible to track the way in which fur seals respond to within season and interannual variation in prey patchiness and abundance. Over a 5-year period, changes in the distribution of travel durations between diving bouts suggested that the spatial distribution of krill swarms varied between years. Although their foraging behavior did not indicate that there was a reduction in the number of krill patches, reduced pup growth rates suggested that patches were of poorer quality, and thus the females had difficulty meeting lactation needs. To compensate, females spent a greater amount of time at each patch, thereby maximizing their average rate of energy intake (Boyd, 1996).

To maximize fitness during years of reduced prey abundance, pinnipeds must be sufficiently plastic in their foraging strategies to compensate for added foraging costs. To determine the temporal scales at which predators make these behavioral decisions, Boyd and colleagues simulated increased foraging costs in Antarctic fur seals by adding an extra drag to lactating females, thereby increasing energy expenditure. At the scales of individual dives, the treatment group made shorter, shallower dives than the control (no extra drag added) seals. It appeared that diving behavior was adjusted to maximize the proportion of time spent at the bottom of dives. At the scale of diving bouts, there was no variation between the two groups in bout frequency and duration, or the time spent diving. However, at the scale of complete foraging cycles, the time spent at sea was significantly longer in the treatment group, yet there was no difference in pup growth rate between control and treatment groups.

In contrast to otariids, most phocid seals are able to fast throughout much of the breeding season due to their large body size and corresponding energy stores. As a result, behavioral responses of phocids to changes in food availability be-

tween years may be more flexible, resulting in less severe effects on their population dynamics. Still, a change to a less profitable prey or increased foraging effort may still have energetic consequences that result in impacts at the population level. In the Moray Firth, Scotland, clupeid fishes are the dominant prey of harbor seals. In years when clupeids are absent from inshore waters, seals travel further to feed and use alternative prey. As a consequence, the seals showed evidence of reduced body condition, suggesting that there were energetic consequences to this change in diet. Between-year differences in survival rates suggest that temporal variation in prey abundance and resulting diets also have consequences for the dynamics of phocid populations (Thompson *et al.*, 1996).

V. Role of Pinnipeds in Aquatic Ecosystems

Although pinnipeds are one of the more visible components of the marine ecosystems, our understanding of their ecological roles is surprisingly limited. Still, there is some evidence that pinnipeds may have important effects on the structure and function of some ecosystems (Bowen, 1997). Given that pinnipeds are large, long-lived animals that are often present in considerable numbers, we might expect some species to exert top-down control on ecosystems. However, conclusive studies are lacking, largely due to the difficulty of conducting manipulative experiments in the ocean, the fact that interactions occur at quite different spatial and temporal scales, and the inherent indeterminancy in the behavior of complex marine systems.

Despite the long-standing debate over the ecological interactions between pinnipeds and commercial fisheries, there is little understanding of the impact of pinniped predation in these situations. For example, the recent collapse of the Atlantic cod stock on the eastern Scotian Shelf has fueled debate over the impact of gray seal predation, both in causing the decline and in preventing early recovery. Model results indicated that gray seal predation accounted for only 10 to 20% of the estimated mortality caused by the fishery and therefore was unlikely to have played an important role in the decline.

One example of top-down control exerted by a pinniped species comes from a study of lakes in northern Quebec. Lower Seal Lake has a population of land-locked harbor seals and, compared to nine neighboring lakes without seals, supports a different fish community. The relative abundance of lake trout (*Salvelinus fontinalis*) was greater in the nine lakes without seals, whereas brook trout (*S. namaycush*) was the dominant species in Lower Seal lake. Compared to lake trout in neighboring lakes, those in Lower Seal Lake were on average smaller, younger, grew more rapidly, and matured earlier, all of which represent life history characteristics that are associated with heavy exploitation. Although based on strong inference rather than direct empirical evidence, it appears that seal predation was responsible for both the changes in community structure and the life history traits of fish species in Lower Seal Lake (reviewed in Bowen, 1997).

Pinnipeds may also play a role in structuring benthic communities. Walruses disturb bottom sediments during feeding. By selectively feeding on older individuals of a few species of bivalve mollusks, walruses may be responsible for structuring the benthic fauna. Ingestion and defecation by walruses may result in substantial redistribution of bottom sediments, which may favor colonization of some species. In addition, during the process of feeding, walruses produce many pits and furrows in the soft sediments. Thus, walrus feeding appears to affect community structure in three ways: by providing food for scavengers such as sea stars and brittle stars, by providing habitat under discarded bivalve shells, and by reducing the abundance of macroinvertebrates in feeding pits compared to surrounding sediments. Nonetheless, the effects of walrus feeding behavior on macrobenthic assemblages over periods greater than a few months and at larger spatial scales remain greatly unknown.

VI. Conclusions

Our understanding of the ecology of pinnipeds has increased dramatically over the past several decades, but advances have been rather uneven. For example, the lactation strategies of pinnipeds are reasonably well understood, but many aspects of foraging ecology and the ecological role of pinnipeds in aquatic ecosystems remain elusive. As in all areas of science, our ability to measure the system under study influences the rate of progress profoundly. New types of data loggers, telemetry, and methods to estimates the diet of free-ranging pinnipeds will undoubtedly play a prominent role in advancing our understanding. However, we should not underestimate the importance of collaborative research involving ecologists, oceanographers, and population and ecosystem modelers.

Pinniped Evolution

ANNALISA BERTA
San Diego State University, California

The name Pinnipedia was first proposed for fin-footed carnivores more than a century ago. Pinnipeds—fur seals and sea lions, walruses, and seals—are one of three major clades of modern marine mammals, having a fossil record going back at least to the late Oligocene [27 to 25 millions of years before present (Ma)]. The earliest pinnipeds were aquatic carnivores with well-developed paddle-shaped limbs and feet. A North Pacific origin for pinnipeds has been hypothesized; the group subsequently diversified throughout the world's oceans.

I. Pinniped Ancestry: Origin and Affinities

There has long been debate about the relationship of pinnipeds to one another and to other mammals. The traditional view, also referred to as diphyly, proposes that pinnipeds originated from two CARNIVORE lineages, an odobenid (walrus) plus otariids (fur seals and sea lions) grouping affiliated with URSIDS (bears) and phocids (seals) being related to mustelids (weasels, skunks, otters, and kin) (Fig. 1A). The current view supported by cladistic analysis of both morphologic and molecular data supports pinnipeds as monophyletic (having a single origin). Although the hypothesis presented here positions ursids as the closest relatives of pinnipeds, it is acknowledged that there is difficulty separating the various lineages of arctoid carnivores (mustelids, procyonids, and ursids) at their point of divergence (Fig. 1B). Other hypotheses support pinnipeds as either allied with MUSTELIDS or as having an unresolved arctoid ancestry.

There is, however, still disagreement about relationships among pinnipeds. Most of the controversy lies in the debate as to whether odobenids are most closely related to phocids or to otariids. Most morphologic data support a link between phocids and the odobenids, whereas molecular data favor a link between odobenids and otariids.

II. Divergence of Major Lineages

The broad pattern of evolution within pinnipeds shows divergence of five major lineages. These include the three extant lineages—Otariidae, Phocidae, and Odobenidae—and two extinct groups—the Desmatophocidae and a basal lineage *Enaliarctos* (Berta and Sumich, 1999; Fig. 2). At times the Odobenidae have been included in the Otariidae, although cladistic analysis currently supports these as distinct monophyletic groups.

Within Pinnipedimorpha (living pinnipeds plus their fossil allies) are included archaic pinnipeds *Enaliarctos* and *Pteronarctos* + pinnipeds (Fig. 2). Berta and Wyss (1994) established a cladistic diagnosis of the group based on 18 synapomorphies of the skull, teeth, and postcrania. Unequivocal derived features include large infraorbital foramen, anterior palatine foramina anterior of maxillary-palatine suture, upper molars reduced in size, lower first molar metaconid reduced or absent, humerus short and robust, deltopectoral crest on the humerus strongly developed, and digit I on the manus and digit I and V on the pes emphasized. The basal taxon *Enaliarctos* from the late Oligocene and early Miocene (27–18 Ma; Fig. 3) of California is known by five species, one represented by a nearly complete skeleton (Fig. 4). *Enaliarctos* was a small, fully aquatic pinnipedimorph with shearing teeth (as is typical of most terrestrial carnivorans), flexible spine, and fore- and hindlimbs modified as flippers. Several features of the hindlimb suggest that *Enaliarctos* was capable of maneuvering on land, although it probably spent more time near the shore than extant pinnipeds. Ecologically, the earliest pinnipedimorphs were coastal dwellers that likely fed on fish and other aquatic prey. A later diverging lineage allied more closely with pinnipeds than with *Enaliarctos* is *Pteronarctos* from the late Miocene (19–15 Ma) of coastal Oregon. *Pteronarctos* is recognized as the earliest pinniped to have evolved the unique maxilla diagnostic of modern pinnipeds. The maxilla of pinnipeds makes a significant contribution to the orbital wall. This differs from the condition in terrestrial carnivores in which the maxilla is limited in its posterior extent by contact of several facial bones (jugal, palatine, and/or lacrimal).

Fur seals and sea lions (EARED SEALS), the Otariidae, are diagnosed by frontals that extend anteriorly between the nasals,

large and shelf-like supraorbital process of the frontal, secondary spine dividing the supraspinous fossa of the scapula, uniformly spaced pelage units, and the presence of a trachea with an anterior bifurcation of the bronchi (Berta and Sumich, 1999; Fig. 5). Although otariids are often divided into two subfamilies, Otariinae (sea lions) and Arctocephalinae (fur seals), only the sea lions are believed to have descended from an exclusive common ancestor, at least according to morphologic data. The otariids are the earliest diverged pinniped lineage, originating approximately 11–12 Ma (Fig. 3) and including the poorly known *Pithanotaria* from the late Miocene of California and three species of *Thalassoleon* described from the late Miocene of California, Mexico, and Japan. *Thalassoleon* is distinguished from *Pithanotaria* in its larger size and lack of a thickened ridge of tooth enamel at the base of the third upper incisor (Fig. 6). An extinct species of the Northern fur seal genus, *Callorhinus*, has been described from the late Pliocene of southern California, Mexico, and Japan. One fossil fur seal from the Pleistocene of Peru of the southern fur seal genus *Arctocephalus* has been referred to a new subgenus, *Arctocephalus* (*Hydrarctos*). Cladistic analysis of otariids by Berta and Deméré (1986) recommended that *Hydrarctos* be elevated to generic status. Several extant species of *Arctocephalus* have a FOSSIL RECORD extending to the Pleistocene in South Africa and North America (California). The fossil record of modern sea lions is poorly known. The following taxa are reported from the Pleistocene: *Neophoca* (New Zealand), *Eumetopias* and *Zalophus* (Japan), and *Otaria* (Brazil).

Otariids appear to have originated in the North Pacific (Fig. 7). Sea lions diverged as a distinct lineage between 3 and 5 Ma. Both fur seals and sea lions dispersed to the Southern Hemisphere within the past 3 Ma. The diversification of otariids in the Southern Hemisphere has been attributed to several factors, including increased levels of primary productivity in colder waters, which at this time reached to the equator, and island hopping assisted by favorable currents. Sea lion diversification proceeded subsequent to the isolation of populations in the Northern and Southern Hemispheres of the Pacific basin, leading to divergence of the California, Japanese, and Galapagos sea lions (*Zalophus*) and Steller's sea lion (*Eumetopias*) in the

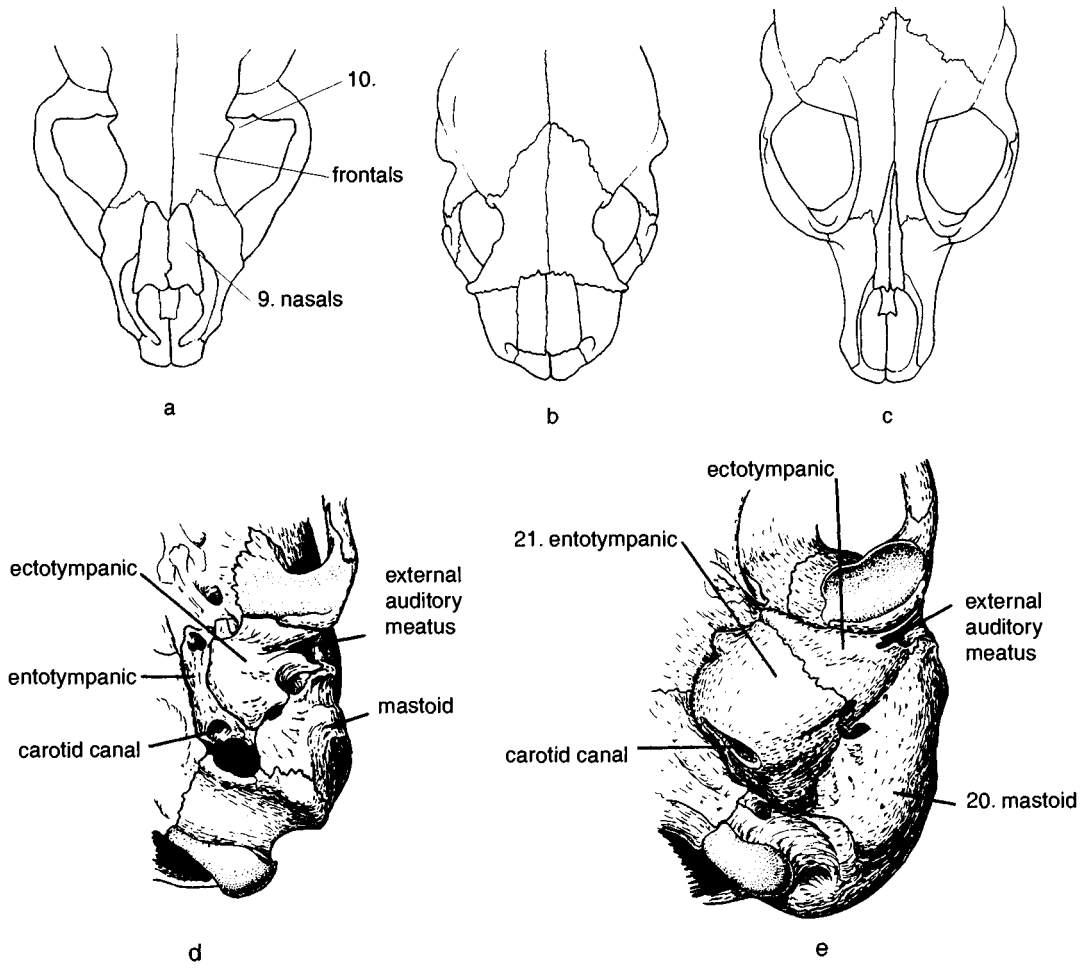

Figure 5 *Skulls/ventral view of ear regions of (a, d) otariid, (b) walrus, and (c, e) phocid illustrating otariid synapomorphies: frontals extend anteriorly between nasals (contact between these bones is transverse in walruses or V-shaped in phocids) and phocid synapomorphies: pachyostotic mastoid bone (not seen in other pinnipeds) and greatly inflated ectotympanic bone. From Berta and Sumich (1999).*

north and the Australian sea lion (*Neophoca*) and southern sea lion (*Otaria*) and the New Zealand sea lion (*Phocarctos*) in the south.

Walruses or Odobenidae are diagnosed as a monophyletic group by the presence of a broad, thick pterygoid strut, fourth upper premolar with a strong posterolingually placed protocone shelf, lower first molar with the talonid heel absent, and a calcaneum with a prominent medial tuberosity (Fig. 6). Another purported odobenid synapomorphy (i.e., construction of the antorbital process by the maxilla and frontal bones) is now known to be primitive (Deméré and Berta, 2001). Morphologic study of the evolutionary relationships among walruses has identified the following taxa: *Prototaria*, *Proneotherium*, *Neotherium*, *Imagotaria*, dusignathines, and odobenines; the latter includes the modern walrus.

Fossil walruses first appear in the early Miocene (16–18 Ma; Fig. 3) fossil record with *Prototaria* in Japan and *Proneotherium* in North America (Oregon). These archaic walruses are characterized by unenlarged canines and narrow, multiple rooted premolars with a trend toward molarization (Fig. 8), adaptations suggesting retention of the fish diet hypothesized for archaic pinnipeds rather than evolution of the specialized mollusc diet for the modern walrus. Portions of the axial and hindlimb skeleton of *Proneotherium* preserve evidence of a number of aquatic adaptations, including a laterally flexible spine, a broad, shortened femur, and a paddle-shaped foot (Deméré and Berta, 2001). In addition to *Proneotherium* and *Prototaria*, two monophyletic clades of walruses are recognized that diversified in the late Miocene (Fig. 3). Dusignathine walruses, which include *Dusignathus*, *Pontolis*, and *Gomphotaria*, developed enlarged upper and lower canines. *Gomphotaria pugnax*, the most completely known dusignathine, is distinct cranially and dentally in its possession of large, procumbent upper lateral incisors and canines; the latter with deeply fluted roots and a small orbit. Odobenines, which include *Aivukus*, *Alachtherium*, *Valenictus*, and *Odobenus*, evolved the enlarged upper tusks seen in the modern walrus. Unique among pinnipeds is the toothlessness of *Valenictus chulavistensis* from the

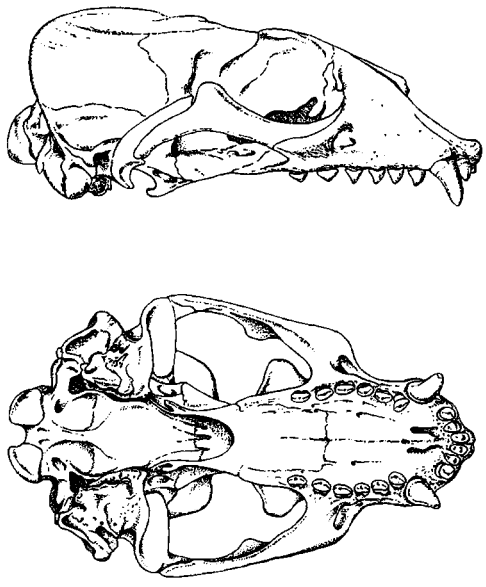

Figure 6 *Skull of an early otariid,* Thalassoleon mexicanus, *from the late Miocene of western North America in lateral (top) and ventral (bottom) views. Original 25 cm long. From Repenning and Tedford (1977).*

late Pliocene of California, presumably an adaptation for suction feeding (Deméré, 1994).

It has been proposed that the modern walrus lineage (odobenine walruses) entered the Caribbean from the Pacific via the Central American Seaway (between 5 and 8 Ma) and dispersed northward into the North Atlantic (Fig. 7). Less than 1 Ma the living genus *Odobenus* returned to the North Pacific through the Arctic Ocean. Alternatively, on the basis of a new, earlier record of the modern walrus lineage form Japan, it has been suggested that this lineage may have evolved in the North Pacific and dispersed instead to the North Atlantic through the Arctic during the Pleistocene.

The earless seals, the Phocidae, are diagnosed as a monophyletic group by pachyostotic mastoid region, greatly inflated entotympanic bone, complete absence of the supraorbital process of the frontal, strongly everted ilia, and lack of an ability to draw the hindlimbs forward under the body due to a massively developed astragalar process and greatly reduced calcaneal tuber (Wyss, 1988; Fig. 5). Phocids have traditionally been divided into two or four major subgroupings, there is considerable disagreement regarding which are monophyletic. Most molecular and morphologic evidence supports "monachines" (or Monachinae) as early diverging phocids. The Phocinae are universally accepted as monophyletic, although relationships among taxa within this group differ among workers.

Although an earlier, less well-documented record of phocids from the late Oligocene of South Carolina exists (Koretsky and Sanders, in press), there is undisputed evidence for both the "monachine" and phocine seal lineages from the middle Miocene (approximately 15 Ma) on both sides of the North Atlantic. The phocine lineage is represented by *Leptophoca,* and the "monachine" lineage is represented by *Monotherium* (Fig. 3). Despite the fact that a number of fossil "monachines" have been described, not all are known by comparable elements. In addition to *Monotherium* among the better known taxa from eastern Europe are *Pontophoca* from the middle Miocene and *Callophoca* from the early Pliocene; both taxa are under study by Koretsky. Several archaic lobodontine (?phocine) seals (i.e., *Arcophoca* and *Piscophoca*) represented by complete skeletons are known from the late Miocene and/or early Pliocene of South America (Peru) and *Homiphoca* from South Africa (Fig. 3). *Acrophoca* is unique among phocids with its long, slender skull, flexible neck, and elongated body (Fig. 9). Although these fossil taxa have been referred to the lobodontines, a subgrouping of "monachines," new discoveries, as well as restudy of material previously referred to these taxa, suggest that they may in fact be more closely related to phocines. The fossil record of extant "monachines" is poorly known and includes only *Monachus* and *Mirounga* from the late Pleistocene and the lobodontine *Ommatophoca* from the late Pliocene (Fig. 3). With regard to fossil phocines among the best known taxa are *Prophoca* (middle Miocene) in the eastern North Atlantic, *Cryptophoca* (late Miocene) in the Black Sea region, and *Phocanella* (early Pliocene) in both the eastern and the western North Atlantic (Fig. 3). Extant phocine genera with a fossil record include *Phoca* from the late Pliocene and *Erignathus* and *Histriophoca* from the late Pleistocene (Fig. 3).

The purported first appearance of phocids in the North Atlantic suggests that the common ancestor of phocids had migrated to the North Atlantic, either northward through the Arctic Basin or southward through the Central American Seaway (Fig. 7). Support for a southern route is based on the hypothesized close relationship of phocids and the extinct desmatophocids, the latter occurring as far south as Mexico, and the fact that the Bering land bridge blocked access to the Arctic through much of the late Oligocene and early Miocene. The BIOGEOGRAPHIC history of monk seals (*Monachus* spp.) is conflicting, as there are differing hypotheses for their phylogenetic position relative to other phocids. Alternative routes show dispersal in both directions through the Central American seaway followed by diversification in the colder waters of the Southern Hemisphere to produce the lobodontine seal fauna of the Antarctic today.

The biogeographic pattern for phocine seals is no less complicated given the different phylogenetic hypotheses proposed. Although it was suggested earlier that phocines were a Northern Hemisphere radiation, a considerable diversity of phocine seals is known from the Southern Hemisphere during the late Miocene and/or early Pliocene (assuming that *Acrophoca, Homiphoca,* and *Piscophoca* are phocines rather than lobodontine "monachines"). In addition, other phocine lineages appear to have been isolated in the Paratethys Sea (northern arm of the Tethys Sea stretching across the area now occupied by the Black, Caspian, and Aral Seas of Eurasia) and the North Atlantic during the late Miocene and Pliocene. Several dispersal routes for phocines seem likely. One hypothesized dispersal involved an initial migration from the Paratethys Sea into the

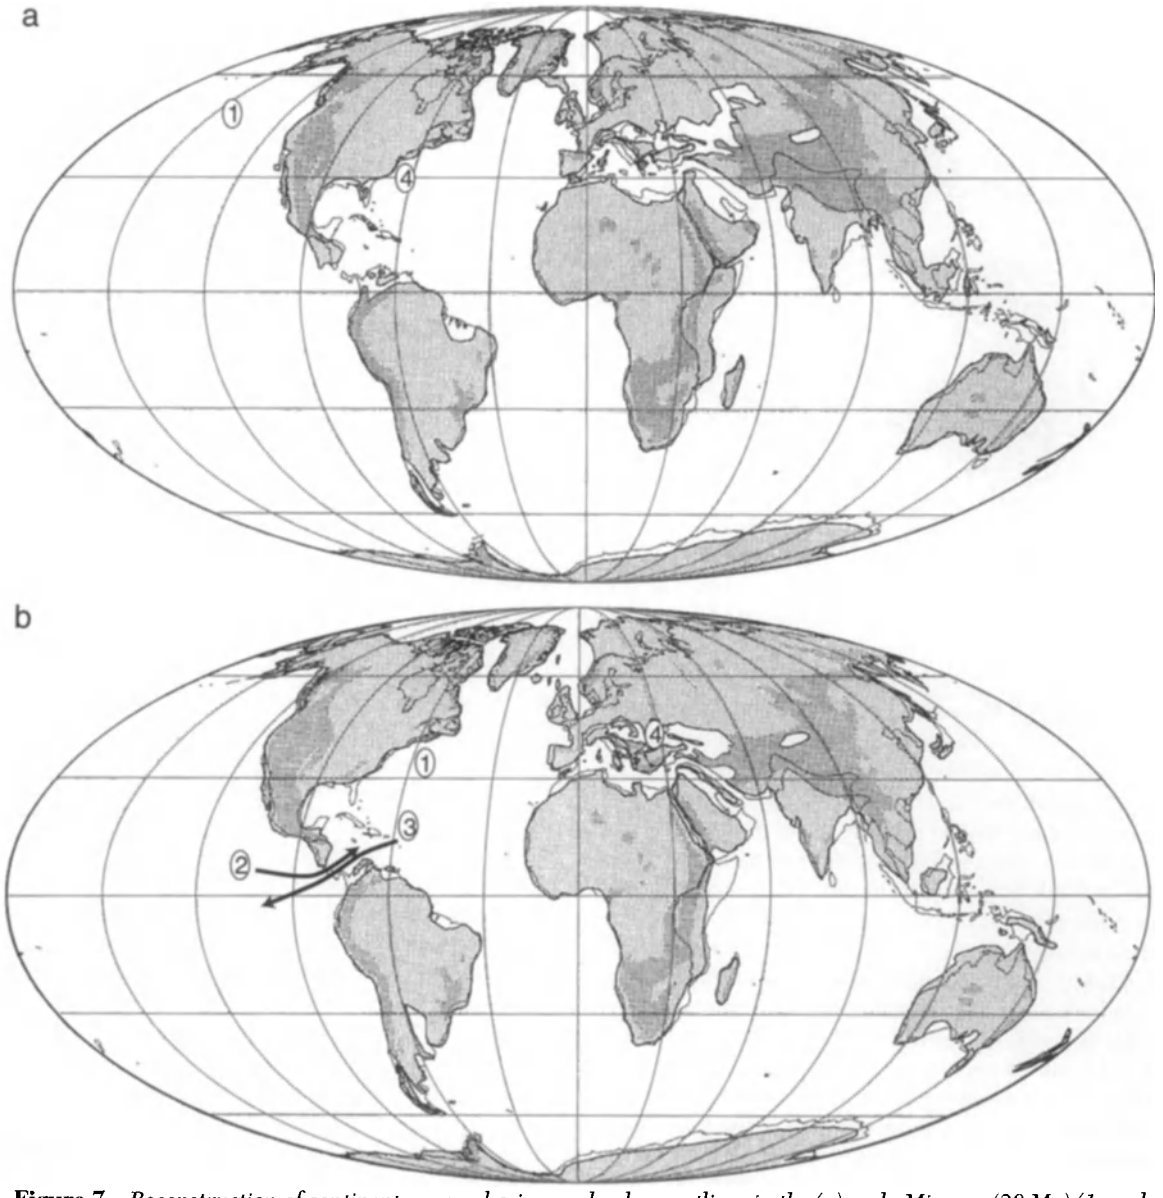

Figure 7 *Reconstruction of continents, ocean basins, and paleocoastlines in the (a) early Miocene (20 Ma) (1, early records of archaic pinnipeds, odobenids, and desmatophocids) and (b) middle Miocene (12 Ma) (1, early well-documented phocids; 2, dispersal of "monachines" and odobenids to Atlantic; 3, dispersal of phocines to South Pacific; and 4, isolation of phocines in remnants of Paratethys Sea and in North Atlantic). From Berta and Sumich (1999); base map from Smith* et al. *(1994).*

Arctic Basin, followed by an eastward migration to give rise to modern *Phoca/Pusa*. In this scenario the land-locked Baikal seal (*Pusa sibirica*) gained access to Lake Baikal from the Arctic via large lakes at the southern margin of the Siberian ice sheet. A second land-locked species, the Caspian seal (*Pusa caspica*) remained in the Caspian Sea as an isolated remnant of Paratethys as judged by the presence of fossils similar to living Caspian seals in this location. A second dispersal involved a westward migration of the remaining phocines from the North Atlantic to their current ranges. The hooded seal (*Cystophora cristata*) occurs at high latitudes of the Atlantic basin and apparently never dispersed successfully to the Pacific. The bearded seal (*Erignathus barbatus*) is presently confined to the Arctic and sub-Arctic around the North Atlantic, but Pleistocene records extend as far south as Portugal. Another hypothesis argues for a North Atlantic origin for all phocines with glacial events causing speciation. For example, cyclical fluctuations in glacial maxima (with concomitant variations in

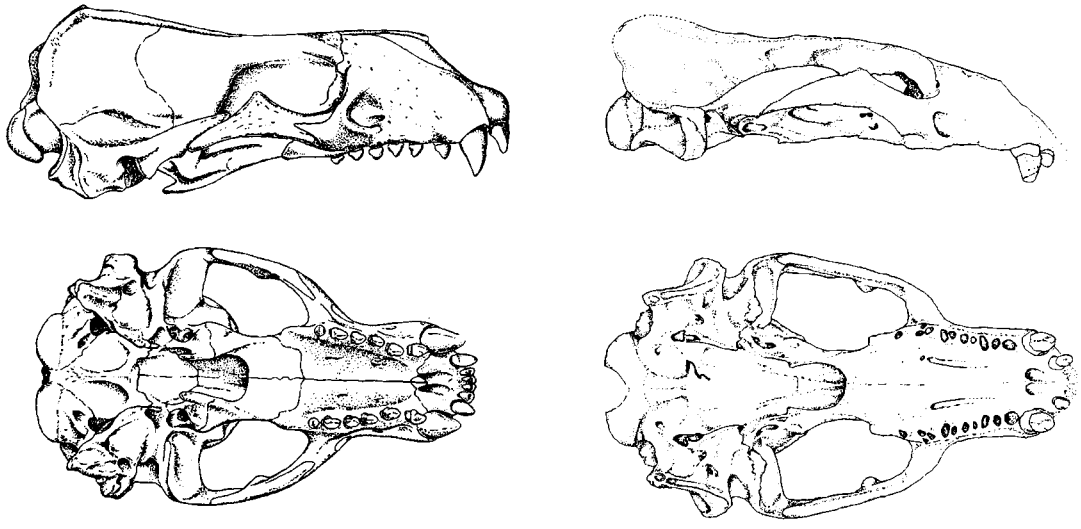

Figure 8 *Lateral and ventral views of skulls of fossil odobenids. (Left)* Imagotaria downsii *from the Miocene of western North America. Original 30 cm long. From Repenning and Tedford (1977). (Right)* Prototaria planicephala *from the Miocene of Japan. Original 27 cm. From Kohno* et al. *(1995).*

sea level) through the Pleistocene mediated range expansions of *Phoca* spp., ultimately leading to the isolation of populations in refugial centers (i.e., Arctic, Okhotsk, Aleutian) and the divergence of populations (e.g., ribbon seal, *Histriophoca fasciata*, ringed seal, *Pusa hispida*, larga seal, *Phoca larga*, harbor seal, *Phoca vitulina*, harp seal, *Pagophilus groenlandicus*).

An extinct family of archaic pinnipeds, the desmatophocids, are characterized by elongate skulls, relatively large eyes, mortised contact between two cheekbones, and bulbous cheek teeth (Fig. 10). Cladistic analysis has identified the Desmatophocidae, which includes two genera, *Desmatophoca* and *Allodesmus*, as the common ancestors of phocid pinnipeds. This clade, phocids + *Allodesmus* and *Desmotophoca*, termed the Phocoidea, is supported by four synapomorphies, including premaxilla–nasal contact reduced, squamosal–jugal contact mortised and marginal process below ascending ramus well developed (Deméré and Berta, in press; Fig. 2). This interpretation differs from previous work that recognized desmatophocids as otarioid pinnipeds (a paraphyletic group that includes walruses but excludes phocids). Desmatophocids are known from the early and middle Miocene (23–10 Ma) of the western United States and Japan (Fig. 3). Newly reported occurrences of *Desmatophoca* confirm the presence of sexual dimorphism and large body size in these pinnipeds (Deméré and Berta, in press). *Allodesmus* is a diverse taxon (as many as six species have been named) with taxa informally divided into "broad headed" and "long headed" subgroups. The previous suggestion that *Allodesmus* retained a mobile proboscis, much like the modern elephant seal, seems unlikely on anatomical grounds. *Allodemus*, known by several complete skeletons, retains several features consistent with forelimb propulsion but also displays adaptations for hindlimb SWIMMING (Adam and Berta, 1998).

Acknowledgments

I thank Thomas Deméré for helpful discussions of pinniped biostratigraphy and Irina Koretsky for providing unpublished information on phocid seals.

Pinniped Life History

IAN L. BOYD
University of St. Andrews, Scotland, United Kingdom

The life history of an individual is the pattern of allocation of resources to maintenance, growth, and reproduction throughout its lifetime. Life history analysis attempts to explain the scheduling of the allocation process throughout an organism's life. It assumes implicitly that it is appropriate to classify individuals by age because this is a major component of the independent variable representing time that is used to examine variation in resource allocation. However, we know that other properties of an individual, such as its body condition or foraging skill, are also important variables that affect reproduction and, ultimately, fitness.

Most life history studies involving pinnipeds have assumed that age is the main force in pinniped life histories when, in fact, age per se may have relatively little to do with influencing fitness. It is a paradox of life history studies that they are, by definition, time-based approaches to examining variation in the fitness between individuals when time itself probably has less biological importance than other factors. One such factor in pinnipeds is body size, long recognized as a determinant of sexual maturity in pinnipeds. Age at sexual maturity in pinnipeds can be expressed as a decreasing function of growth rate. Expressed at the level of populations, this is interpreted to mean that individuals within pinniped populations that are at a level well below the environmental carrying capacity would experience higher growth rates and would, therefore, become sexually mature at an earlier age (Bengtson and Laws, 1985). This was an implicit acknowledgment that age was not the operant factor in pinniped life histories and was at best secondary to the size of the energy reserves of an individual. Nevertheless, despite the considerably greater difficulties that exist with measuring age in pinnipeds than there are with measuring body size (e.g., mass or some other suite of morphometrics), age has continued to be used as the primary independent variable in life history studies.

I. Characteristics of Pinniped Life Histories

Pinniped life histories are characterized by three main features: (1) by mammalian standards, pinnipeds have high annual survival rates, giving potential longevities in the order of 2–4 decades; (2) the average age at sexual maturity is delayed by 2–6 years depending on the species (Table I); and (3) each adult female normally produces a maximum of one offspring per reproductive cycle. Variations on this theme at the level of individuals and species can provide insight into the evolution of life histories in pinnipeds.

Pinniped life histories are assumed to have evolved to maximize the genetic fitness of individuals. This occurs in pin-

[a]Rates are expressed per year. Data for fur seals are summaries from tables in Wickens and York (1997); otherwise the original sources are given. Data for male mass were not included if no demographic data were available.
[b]Sexually and socially mature individuals.
[c]Pregnancy and birth rate are assumed to be equivalent.
[d]Juvenile survival rates fall within the same range.
[e]Juvenile survival >1 year old ~0.70.
[f]Survival in first year.
[g]Values for juvenile males aged 4 months–2 years are 0.20–0.50; those for males aged 2–5 years are 0.75–0.90.
[h]Probably negatively biased because of the inclusion of juveniles.

nipeds within the constraints of a semiaquatic existence and has most probably led to the relatively narrow range of life histories we observe within the taxon. All pinnipeds rely to some degree on ice or land for reproduction, particularly the processes of birth and lactation. Many interacting variables have led to the evolution of pinniped life histories, including the joint and sometimes conflicting needs to avoid predation, to forage with maximum efficiency, and to choose a mate of high quality.

By mammalian standards, pinnipeds are animals with a large body size. However, in terms of their demography and their investment in reproduction, pinnipeds do not appear to differ greatly from other mammals after body size has been taken into consideration. There are also no obvious relationships between body size and life history variables at the species level within the pinnipeds (Table I), although, as we shall see, this is not the case for variation between individuals within species.

Large body size has a cost in that relatively large amounts of resources are invested in tissue growth and maintenance and it takes a relatively long time to reach a body size capable of supporting reproduction. There is also a need to produce precocial young that can defend themselves against predation from an early age or that can forage independently of their mothers within days to weeks of birth. This necessitates greater investment in individual offspring and limits the number of young that can be produced at a single reproductive attempt. It also means that the rate of reproduction (number of young born per unit time) is relatively low. The combination of high investment in growth, causing a delay in sexual maturity, and low reproductive rates, even when sexually mature, means that pinnipeds must have relatively high longevities (low rates of mortality). Without this combination of demographic variables individuals could not, on average, replace themselves during their lifetimes.

II. Methods for Examining Life Histories

Life histories are represented most concisely by demographic models based on empirical measurements of survival and fecundity rates. Demographic variables for pinnipeds are summarized in Table I. Amongst the 36 species of pinnipeds, some form of demographic information is available for most species, but as seen from Table I, there are very few for which there could be said to be complete information, and, in almost all of these, information is mainly available for females. Very little is known about the life histories of male pinnipeds. It is also perhaps a little misleading to represent these demographic variables in terms of species, as many vary as much between different populations of the same species as they do between the species themselves. Averaging across populations also has the disadvantage that it obscures the variation in life histories between individuals. Therefore, while life histories may, in practice, often be examined at the level of populations using demographic parameters, it is an important tenet of life history analysis that it is based on the demography of individuals. This distinguishes life history analysis from the study of population dynamics, which normally deals with individuals as if they are all identical.

The most complete information about life histories for any population of pinnipeds comes from Weddell seals (*Leptonychotes weddellii*) at McMurdo Sound, Antarctic (Hastings *et al.*, 1998), and northern elephant seals (*Mirounga angustirostris*) from Año Neuvo or the Farallon Islands, California (Reiter and Le Boeuf, 1981; Sydeman *et al.*, 1991). These studies were based on the long-term mark-recapture of individuals. Similar studies have been carried out on Antarctic fur seals (*Arctocephalus gazella*) (Boyd *et al.*, 1995) and gray seals (*Halichoerus grypus*) (Pomeroy *et al.*, 1999). Mark-recapture is probably the only way to examine life histories in pinnipeds to provide the quality of data necessary to understand the complex interactions between factors that influence fitness. However, such studies can only be undertaken in special circumstances where there is particularly easy access to the study population. In most cases, information about population life histories has been derived from cross-sectional samples of populations based on one-off or sequential culls that were often part of a commercial harvest (Fowler, 1990; Bowen *et al.*, 1981). Although some of the disadvantages of this method may be offset by the advantages of a large sample size, it has the potential to lead to misinterpretation of the pattern of life history. Some of these problems are discussed.

III. Constraints on Life Histories

Pinniped life histories have evolved under a combination of factors that are broadly based around the need for animals to balance their energy budgets. These include the constraints involved with (1) being homeothermic in water that is 25 times more conductive than air and (2) the high temporal and spatial variability in the distribution of resources within the marine environment. Phylogeny may also be seen as a constraint in that the ancestors of pinnipeds may not have possessed an ideal range of characteristics (physiological, anatomical, social, or distributional) for exploiting the marine environment. Therefore, current pinniped life histories may be constrained by difficulties with inherent mechanisms.

An example of such a constraint is the apparent necessity for a terrestrial (or pagophilic) phase during the reproductive cycle. This may be a consequence of the occupancy by ancestral pinnipeds mainly of temperate and polar marine habitats in which small neotates may have difficulty with thermoregulating in cold water, thereby necessitating terrestrial living for young neonates. Pinnipeds may have been locked into this form of reproductive cycle from an early stage in their evolution.

The constraint of the terrestrial phase in reproduction has brought with it other social and life history consequences. The necessity for mothers to find suitable terrestrial habitat (including ice) for parturition has more or less isolated, both spatially and temporally, the reproductive process from the feeding grounds. Species that exploit distant, unpredictable food sources require larger body mass than those that exploit food that is present at relatively close range to the pupping location. This is because there will be a critical duration over which a pup can be left without feeding and with low risk of starvation. If mothers cannot forage profitably during lactation within this critical duration, it is necessary for mothers to carry with them at parturition most of the food reserves required to raise their pup to independence (Boyd, 1998).

The extreme seasonality of food availability in higher latitudes has also led to extreme seasonality of reproduction, resulting in spatially and temporally synchronized reproduction. It is possible that both sexes have used this to affect greater mate choice, which has produced polygynous, highly competitive mating systems. These combined factors have led, in most species, to an annual cycle of reproduction.

IV. Costs vs Benefits of Reproduction

Even though individuals may have the option to reproduce annually, longitudinal studies show that they do not always exercise this option. Even when individuals do reproduce, they may adjust the amount of resources they supply to their offspring. The reasons for this are centered on the decisions that individuals must make during their life times in order to maximize their fitness, often measured in terms of number of

offspring produced across their whole lifetime and not just one reproductive cycle.

There are obvious fitness gains from reproduction, but there are also costs involved. For example, in Antarctic fur seals (*Arctocephalus gazella*), reproduction in any year carries with it a 40% greater chance of dying in the following year. It also carries a similar cost in terms of reduced probability of breeding in the following year (Boyd *et al.*, 1995). In northern elephant seals (*Mirounga angustirostris*), mothers that reproduce for the first time at age 3 incur greater costs, in terms of reduced survival, than those that breed first at age 4 (Reiter and Le Boeuf, 1991). Female gray seals (*Halichoerus grypus*) that expend more on their offspring in 1 year also have reduced reproductive success in the following year (Pomeroy *et al.*, 1999). Thus, female pinnipeds must find a solution of how best to allocate energy between growth/maintenance and reproduction that optimizes the balance between fitness costs and benefits of reproduction. Those individuals that achieve the optimum balance will have greatest lifetime fitness. How pinnipeds make investment decisions in order to optimize this balance is unknown. In reality, few individuals may actually achieve the optimum, especially in variable environments, but natural selection favors those individuals that make investment decisions that approach the optimum most closely.

V. Age at First Reproduction

All pinnipeds experience a delay of several years in the time taken to reach sexual maturity (Table I). Several studies have shown that the age at first reproduction is not constant. In harp seals (*Pagophilus groenlandicus*) it is negatively related to population size (Bowen *et al.*, 1981), implying that the age at which individuals mature is density dependent [although see Trites and York (1993)]. Further evidence for a shift in age at sexual maturity with population size exists for crabeater seals (*Lobodon carcinophaga*) (Bengtson and Laws, 1985). The speed with which the change occurs shows that this is not an effect mediated by natural selection for individuals with different life history patterns, rather it is almost certainly driven by changes in the growth rates of individuals as population density and, by implication, per capita food availability changes. Consequently, the mean age at sexual maturity in a population may simply be a reflection of the mean growth rate.

Among northern elephant seals, females tend to begin breeding at age 3 or 4. The fitness of individuals that begin to breed at age 4 is greater than those that begin at age 3 because there is a cost, in terms of reduced survivorship, for those that began breeding at age 3 (Reiter and Le Boeuf, 1991). In Antarctic fur seals there is a similar disadvantage to breeding at an earlier age (Lunn *et al.*, 1994), although, for those individuals that survive, there is no subsequent effect on reproduction through the remainder of life.

These results suggest how age at sexual maturity can be determined by natural selection. In northern elephant seals and Antarctic fur seals there appears to be a trade-off between the fitness costs of breeding early in life and the fitness gains from early reproduction. Although, on average, individuals that begin breeding at age 3 have lower survival, it is possible that those that breed at age 3 and survive have increased fitness mainly because they have, on average, one more reproductive attempt than those that begin breeding at age 4. Animals may opt to take a greater risk by breeding first at age 3 but with the prospect of greater ultimate lifetime fitness. For the trade-off between breeding first at age 3 or age 4 to operate and be evolutionarily stable, both strategies must have equal median lifetime fitness.

VI. Variations in Measures of Fitness

Strictly speaking, fitness should be measured in terms of the number of grandchildren that are produced by an individual. However, no study of pinnipeds has been able to do this, so a variety of fitness indices are used. The simplest and least informative of these is fertility rate, followed by weaning rate, proportion of offspring surviving their first year, and proportion of offspring surviving to reproductive age. There are specific examples of each of these measures from studies of pinnipeds.

Fertility rates in pinnipeds are normally in excess of 0.8 (Table I) and, given other vital rates in pinniped demography, they normally have to be of this order for populations to have the potential to grow. Longitudinal studies of individual pinnipeds show that most females experience fallow reproductive cycles in their lifetimes (Lunn *et al.*, 1994). It remains unclear if the observation of declining fertility with increasing age in cross-sectional samples of pinniped populations reflects senescence of individuals. The observation could equally be caused by greater survival rate, and therefore greater representation in older age classes, of individuals with intrinsically low reproductive rates.

Like age at sexual maturity, fertility is probably linked to the attainment of a critical minimum body condition at a specific stage of the reproductive cycle. In fact, physiologically, there may be virtually no difference between the process of puberty and the seasonal recrudescence of the reproductive system, so the two processes could be considered to be controlled by a common mechanism.

Fertility rates are influenced by previous experience of reproduction. In northern elephant seals, it appears that most females that miss a breeding attempt compensate for this by having a higher probability of weaning a pup in the following year, although, early in the reproductive life span, the opposite effect has been observed, i.e., individuals that miss a reproductive cycle have low success in the following year. Therefore, offspring quality may be affected by previous reproductive experience. Antarctic fur seals are significantly less likely to reproduce in a year following a reproductive attempt.

Weaning rates are affected by both age and previous experience of reproduction in northern elephant seals. It appears that although weaning rates increase initially with experience, these begin to decline later in life. This may represent a cumulative cost of reproduction that is manifest as senescence. However, it is still uncertain if this effect is an artifact of sampling caused by greater longevity in individuals that tend to skip reproduction more frequently or invest a smaller proportion of their energy reserves in their offspring.

In Weddell seals (*Leptonychotes weddellii*) offspring survival to age 1 and reproductive age both increase with mater-

nal age and experience and, for male offspring, in relation to maternal body length (Hastings and Testa, 1998). Again, this suggests that those individuals that were able to invest more resources in their offspring, by virtue of their larger size and greater experience (perhaps reflecting the occupancy of better habitat), had enhanced fitness.

VII. Comparing Males and Females

Because females are the limiting sex and because it is much more difficult to study reproductive success in males, more attention has been focused on female than on male pinnipeds. Nevertheless, males may invest large amounts of their energy reserves in reproduction. In general, males have shorter life expectancies than females (shown by lower annual survival rates in Table I), but it is not clear how this is influenced by the investment in reproductive effort. Investment theory would suggest that the shorter life expectancy of males is because of their preparedness to take greater risks with their survival. The potential gains from reproduction, in terms of offspring, in males that are successful competitors because they make a large investment are greater than for females that are restricted to producing a single offspring per season.

There is also confusion in the literature about when males become sexually mature. The age at physiological maturity in males is probably similar to that of females, but many authors make a distinction between physiological and social maturity, which is defined by the age at which individuals are capable of competing for matings. Recent genetic evidence (e.g., Amos *et al.*, 1993) is casting doubt on some of the former interpretations of what social maturity actually means because the pattern of mating success in males often does not follow the pattern suggested by the observed social structure. In the near future, we may have to revise our views of the life history patterns of male pinnipeds.

VIII. Optimal Life Histories: Modeling the Way Forward

Life history analysis in pinnipeds is fraught with difficulties. Longitudinal studies in which individuals are studied throughout their lifetimes can only be carried out on a narrow range of accessible populations and they are expensive and logistically complex to maintain over the time periods (usually decades) required to achieve useful results. Cross-sectional studies are extremely limited in what they can tell us about the dynamics of life histories, and commercial harvests, the usual source of these data, are a thing of the past. We have to find a new way forward.

To date, almost all studies of pinniped life histories have been empirically based and, as pointed out in this description, they have highlighted the interactive nature of parameters such as longevity and reproductive rate. A modeling framework is required in order to allow these interactions to be investigated, to make better use of the data sets that already exist, and to identify critical gaps in the empirical data.

If a pinniped is to maximize its lifetime fitness F, then it must choose the optimal allocation of resources to reproduction through its lifetime. Thus, $F = f_1 + f_2 + f_3 \ldots f_n$ where f_a is the fitness contribution from year a in the life of the pinniped, which lasts n years. We know that there are certain functional relationships between maternal size or condition and the probability that she will reproduce or survive. If we assume that the relationship between offspring condition and its ultimate fitness is asymptotic, then, up to a certain level, the more energy that a female delivers to her offspring the greater will be her fitness. If the energy delivered to an offspring (e_a) is a proportion p of the energy available to the mother, then from what we know of the growth patterns and the energetic efficiencies of pinnipeds, it is possible to estimate the energy available for reproduction throughout the life span of an average individual. By setting rules that an individual will only reproduce if it has a sufficient excess of energy above that required for maintenance, we may be able to investigate the life history patterns in different environments as well as the effects of stochastic variability in food availability on life histories.

Many of the dynamic relationships described here should become explicit in the results of such an energy-based life history model. Similarly, such a model could help the interpretation of some of the cross-sectional population data in the context of dynamic life history processes. This type of approach seems to be essential if progress is to be made in pinniped life history analysis and for the full implications of life history analysis to be realized. Because the mechanism underlying population trajectories is the sum of individual life histories, understanding the environmental factors that affect life histories is fundamental to understanding population and species viabilities.

Pinniped Physiology

DANIEL E. CROCKER
Sonoma State University, Rohnert Park, California

DANIEL P. COSTA
University of California, Santa Cruz

Pinnipeds are unique among mammals because they feed in the marine environment and reproduce on land or ice, requiring a spatial and temporal separation of feeding from lactation. Seals stay at sea for weeks and often months at a time, yet they must spend considerable amounts of time on land. The amphibious nature of pinniped life has necessitated a wide range of physiological adaptations to life in water and on land. Pinnipeds must meet the physiological challenges of marine existence using specialized adaptations that still facilitates existence on land. This life history requires a remarkable plasticity of physiology. Broad categories of physiological adaptation include (1) aquatic locomotion, (2) apnea and diving physiology, (3) sensory physiology, (4) osmoregulation, (5) thermoregulation, (6) fasting physiology, and (7) lactation physiology.

Pinnipeds have had to overcome numerous problems associated with moving efficiently in the dense aquatic medium, and this adaptation has reduced their ability to move about on land. Otariids have hindflippers that can be turned under the body for terrestrial LOCOMOTION, whereas phocid seals cannot turn their hindflippers under the body and instead use lunging movements to get around on land.

Perhaps the most complex suite of adaptations required for making a living in the ocean is the physiology associated with breath-hold diving to foraging depths. In addition to adaptations for dealing with great pressures, pinnipeds exhibit physiological adaptation for apnea, increased oxygen storage, bradychardia, hypoperfusion, hypometabolism, and neuronal and hormonal control of cardiac and spleen function.

The sensory systems of pinnipeds enable them to successfully navigate, forage, and communicate in a variety of environments. Seals hear and see relatively well both in the air and underwater. Because the behavior of sound and light in water is markedly different than that in air, this again requires plasticity in their sensory physiology. Ultimately, sensory physiology must provide the appropriate visual and auditory information to facilitate social interactions on land, while allowing detection and capture of prey and detection and avoidance of predators at sea. Adaptations include well-developed underwater directional hearing and visual sensitivity at low light levels.

Living in salt water poses osmoregulatory problems for pinnipeds. In addition, pinnipeds must stay in water balance during periods on shore during which they may fast completely from food or water. Because animals also lose water for evaporate cooling, osmoregulatory strategies are linked to thermoregulation.

Pinnipeds are exposed to a remarkably variable range of environmental temperatures. They are able to tolerate frigid ocean temperatures at depth as well as high amounts of thermal radi-

ation encountered when hauled out on land. Adaptations that help pinnipeds retain heat in the ocean environment, such as thick blubber or dense fur, may also promote overheating on land. Adaptations that may play a role in thermoregulation include large body size, blubber or dense fur, countercurrent heat exchange systems, and possibly high metabolic rates.

I. Fasting Physiology

A. Lipid Utilization and Protein Sparing

Many pinnipeds fast for extended periods during their breeding season or during molting (Table I). Mating, giving birth, nursing pups, and, for some species, molting all require long periods of time on land. This is particularly true of phocid seals, which undergo voluntary periods of prolonged fasting twice a year. Adult male pinnipeds may abstain from food or water for as long as 3 months while maintaining a territory or competing for dominance rank on the breeding ROOKERY. In many phocid species, females fast completely from food and water for over a month while delivering tremendous amounts of energy to their pups as milk. Offspring are weaned abruptly and, in many species, the pup then undergoes an extended postweaning fast before departing to sea and initiating foraging. This postweaning fast may be an important developmental time relative to the diving physiology of the offspring. In most cases, these extended fasts are associated with behaviors or processes resulting in considerable energy expenditure (e.g., combat, mating, lactation, molting). Adult animals may lose as much as 35–57% of stored body reserves during these periods (Fig. 1).

The lengths of these voluntary fasts may vary considerably. Fasts can last as long as 3 months in breeding males of both otariids and phocids. Otariid females alternate short onshore periods with foraging trips. These fasts can last from several days to 1–2 weeks postpartum. In phocid seals that fast throughout lactation, the fasting duration can be as short as 3–5 days in hooded seals (*Cystophora cristata*), whereas northern elephant seals (*Mirounga angustirostris*) nurse a pup for 23–30 days after an additional 1–2 weeks fasting before parturition. Unlike most other groups of animals that undergo natural fasts, activity levels remain high. Males expend energy in territorial interaction, dominance interactions, and MATING BEHAVIORS. Females expend energy in agonistic encounters for breeding space, interaction with males, and for milk synthesis. Pups are also active during their fasts, making daily movements into the water and often exhibiting high movement rates.

Despite this high level of energy expenditure, seals are able to minimize the depletion of lean body mass, with the bulk of energy reserves coming from adipose tissue. Within the first weeks of the fast, rates of mass loss in nonlactating animals decrease markedly and then remain relatively stable and low for the remainder of the fast. This is accomplished primarily through a reduction in metabolic rate during the fast. This decline is evident in some species on a whole body basis as well as when corrected for changing body size and composition. The key adaptation for extended fasting appears to be the ability to spare protein while fasting, thereby reducing vital organ damage. This stage of fasting, called stage II fasting, is characterized by substantial decreases in blood urea nitrogen levels and urinary excretion of nitrogenous wastes. These characteristics are evident throughout the fasts of phocid seals (Fig. 2). This decreased protein degradation is reflected in reduced absolute and proportional declines in the use of protein reserves. Protein contributes as little as 1–6% of total energy utilization by the end of the fast. For example, at the beginning of the postweaning fast, northern elephant seals meet around 4% of their energy needs through protein catabolism. By the end of the postweaning fast this value has declined to around 1%.

Nonesterified fatty acids (NEFA) provide the majority of the animal's energy needs during long-term fasts. Increases in both turnover and plasma concentrations of NEFA have been demonstrated in several species. Reported NEFA values are greater than those reported for any other animal (as high as 3.1

TABLE I
Duration of Natural Fasts for Pinnipeds Exhibiting Extended Fasts during Breeding

Females		*Males*	
Crabeater seal	~4 weeks	Crabeater seal	~4 weeks
Gray seal	2.5–3 weeks	Gray seal	3–8 weeks
Hawaiian monk seal	5–6 weeks	Hooded seal	~4 weeks
Hooded seal	1.5–2 weeks	Leopard seal	Unknown
Leopard seal	Unknown	Northern elephant seal	2–3 months
Northern elephant seal	5 weeks	Ross seal	Unknown
Ross seal	Unknown	Southern elephant seal	2–3 months
Southern elephant seal	4 weeks	All fur seals	~2.5 months
Weddell seal[a]	6–7 weeks	All sea lions[b]	~2.5 months

[a]Females enter the water frequently and some may feed.
[b]California sea lion males enter the water periodically to feed. Fasting duration in the species is ~2 weeks.

Figure 1 *An adult female northern elephant seal early (right) and late (left) in the lactation period. Northern elephant seal females lose between 35 and 45% of body mass during breeding.*

m*M*) and increase over the fast in some species. Plasma glycerol levels show similar increases and probably are an important substrate for gluconeogenesis. There is some evidence that seals can selectively utilize reserves from different parts of the body (i.e., blubber reserves vs core tissues) during different phases of the fast. Ketone bodies (HBA) accumulate somewhat during the fast in weaned elephant seals and gray seals, *Halichoerus grypus*, and Weddell seals, *Leptonychotes weddellii*, and subsequently decline rapidly as the end of the fast is approached. This suggests that ketone bodies may contribute to energy metabolism during long-term fasting, although levels are significantly lower than nonfasting adapted species and never reach levels affecting acid–base balance or causing ketosis. Particularly striking in this regard are data from lactating northern elephant seals, who despite the aforementioned high and increasing NEFA levels over the fast, exhibit consistently low HBA values across lactation (0.03 to 0.13 m*M*). It is also important to note that increasing HBA levels were only demonstrated in juvenile animals of relatively small body size.

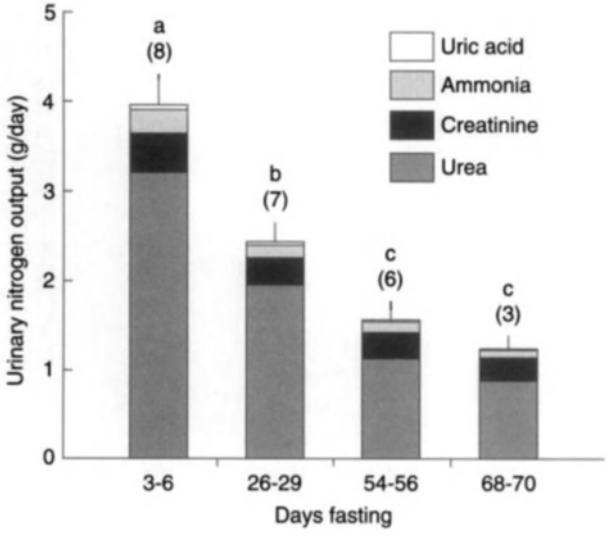

Figure 2 *Changes in daily urinary nitrogen excretion in fasting elephant seal pups. Letters denote significant differences between periods ($P < 0.05$). Samples sizes are in parentheses. From Adams and Costa,* J. Comp. Physiol. B *165, Water conservation and protein catabolism in northern elephant seal pups during the post weaning fast. Copyright 1993 Springer-Verlag.*

Stage III fasting or terminal starvation occurs when 30–50% of total body protein has been used. In nonfasting adapted species, this is associated with a decrease in lipid utilization and a decline in circulating ketone bodies. Evidence for entrance into stage III fasting in seals has been equivocal. The increase and subsequent decline in ketone bodies at the end of the fast in some fasting pups would suggest entry into stage III. However, only two studies have demonstrated increases in protein catabolism following the period of effective protein sparing. When considering the protein utilization by lactating females, it is important to include the loss of body protein for milk synthesis. One study on northern elephant seals demonstrated reductions in protein sparing with the depletion of lipid reserves that, together with the nutrient demands of milk synthesis, moved females close to the 30% value of body protein loss considered extreme in humans (Fig. 3). It may be that in normal, voluntary fasts, stage III fasting is never reached, with seals departing to sea before this point. Blubber reserves also play an important role in thermoregulation, and blubber depletion for energy needs is limited by the need to thermoregulate.

B. Hormonal and Fuel Regulation

Studies on hormonal and fuel regulation during fasting have suggested that seals may exhibit the protein conservation and high lipid utilization of stage II fasting throughout their lives. Fat is an important energy source throughout development and life,

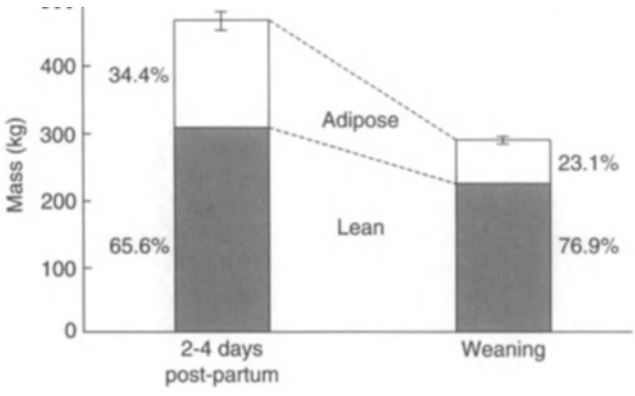

Figure 3 *Changes in maternal mass and body composition over the lactation period in female northern elephant seals. On average, females lose 27% of total body protein stores during lactation.*

including high-fat milk, high-fat fish, and body fat stores. Studies of the role of insulin in glucose regulation in suckling pups have suggested that seals may be preadapted for fasting. Low insulin concentrations, impaired glucose clearance, and low insulin to glucagon ratios exhibited in both feeding and fasting pups contribute to the mobilization of lipids from body stores. In general, fasting pups are hyperglycemic and hypoinsulemic. Slow recovery of baseline blood glucose levels after insulin injection suggests that blood glucose concentrations are not closely regulated in a typical fashion by the release of the hormones insulin and glucagon. In elephant seals, insulin to glucagon ratios were less than one, which is correlated with high rates of hepatic gluconeogenesis in other mammals. The direct contribution of glucose to the total metabolic rate is less than 1% in seals during extended fasts. Fatty acid oxidation studies confirmed that lipid is the main energy source and suggest that glycerol liberated by lipolysis may provide substrate to meet the animal's glucose needs. Studies on elephant seals, harbor seals (*Phoca vitulina*), and gray seals suggest that glucose turnover rates are typical of mammals, although glucose carbon is predominantly recycled and oxidation rates are low. Recycling protein and glucose carbon may serve as an important shuttle mechanism for carbon (e.g., synthesis of nonessential amino acids).

Currently, our understanding of the fasting physiology of pinnipeds is biased toward studies on juvenile animals, especially the postweaning fast. Investigations have demonstrated dramatic differences in fasting physiology between lactating and molting females as well as fasting pups. The pressures of nutrient delivery for milk synthesis may have significant impacts on the metabolic strategies used by females during extended fasts. Very little is known about fasting in adult males, who potentially have some of the highest metabolic rates while fasting. Future studies can benefit from interspecific comparisons of fasting physiology relative to natural fasting durations. Even more instructive may be intraspecific comparisons among sexes and age classes during development, lactation, molting, and breeding. These comparisons will help demonstrate how the fasting biochemistry of animals responds to the varying energy and nutrient demands of breeding and lactation.

C. Renal Physiology during Fasting

Water balance during fasting is maintained by the input of metabolic-derived water from lipid catabolism. Significant reductions in urinary water loss contribute to the maintenance of water balance (Fig. 4). The low rate of protein oxidation and an efficient urinary-concentrating mechanism in pinnipeds reduce urinary water loss during fasting. Early work on harbor seals demonstrated reductions in glomerular filtration rates (GFR) associated with fasting and hyperfiltration after feeding. Subsequent investigations have been equivocal, leaving it unclear whether the mechanism underlying reduced urine flow is decreased glomerular filtration or increased tubular resorption. Investigations on weaned northern elephant seal pups have revealed no correlation between plasma levels of vasopressin and urinary concentrating ability. Similar investigations have demonstrated a fivefold increase in plasma aldosterone concentration during the first 5 weeks of fasting that then began to decrease. This pattern mirrors reported changes in urine osmolarity, which increases through the eighth week of the fast and then declines. This suggests an important role for aldosterone in regulating urine concentration by its action on sodium resorption in the collecting duct.

Investigations on lactating adult northern elephant seals have demonstrated dramatic increases in GFR across the fast and suggest that these elevated rates could be an adaptation to increasing the efficiency of urea excretion during reduced urine flow. This mechanism reduces residency time and passive resorption of urea in the collecting tubules. The efficiency of urea excretion in lactating females declined from 49 to 38% over lactation, suggesting that with a declining urine flow and stable plasma urea concentration, increased GFR is necessary to increase urea excretion as protein catabolism increases.

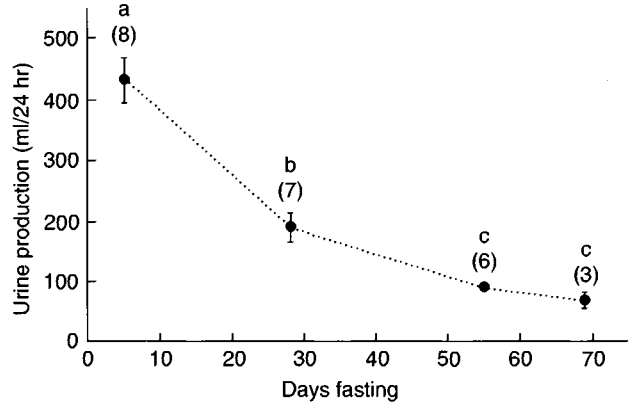

Figure 4 *The decline in daily urine production of elephant seal pups progressing through the postweaning fast. Letters denote significant differences between periods ($P < 0.05$). Samples sizes are in parentheses. From Adams and Costa,* J. Comp. Physiol. B *165, Water conservation and protein catabolism in northern elephant seal pups during the post weaning fast. Copyright 1993 Springer-Verlag.*

II. Immune System

One aspect of pinniped physiology that warrants further investigation is the immune system. For the polygynous species that breed on land, BREEDING SITES are potentially pathogenic environments. Many animals with open wounds (as high as 90% of adult males in some species) are packed closely together on a substrate soiled with excrement and rotting corpses. Neonates with poorly developed immune systems are born directly onto this substrate. Investigations have suggested depressed humoral immunity in neonates and that rapid postpartum increases in humoral immunity are the result of *de novo* synthesis, with a reduced role for passive maternal transfer. Interestingly, some studies have suggested increases in humoral immune response in adult females during breeding.

III. Lactation Physiology

The physiology of lactation in pinnipeds is significantly impacted by constraints resulting from the temporal separation of foraging and parental investment. Pinnipeds have evolved two general lactation strategies to manage pup provisioning within these constraints. After a short perinatal fast, otariids alternate foraging trips with suckling bouts. Initial milk production is synthesized from maternal reserves, whereas subsequent milk nutrients are derived from resources acquired while foraging. Phocids, particularly the larger species, fast during a brief but energy-intensive lactation during which nutrients for milk synthesis are derived exclusively from maternal tissues. Some smaller phocid seals, such as harbor seals or ring seals, *Pusa hispida*, forage during lactation. Pinnipeds consistently produce lipid-rich milk, independent of lipid content of the diet. Even more amazing is that lactation, an energetically expensive period, occurs while the female is fasting. Long-term fasting is characterized by protein sparing, reductions in metabolic rate, and reductions in water loss for urea nitrogen excretion. Studies on nonlactating fasting phocids have shown that protein stores are spared with the bulk of energy demands being supplied by the oxidation of fatty acids. In contrast, lactation is characterized by dramatic increases in metabolism and significant transfer of nutrients and water to the mammary gland for the synthesis and secretion of milk. The general metabolism of the lactating female is reorganized in a way that ensures the appropriate nutrients are partitioned to the mammary gland. In nonfasting animals, lactation is accompanied by increased levels of food consumption and digestion, with accompanying increases in the absorptive capacity of the gastrointestinal tract. In fasting phocids, regulatory mechanisms override protein and energy-sparing mechanisms to make the nutrients necessary for milk synthesis available at the expense of body nutrient reserves. The high demands of lactation coupled with complete abstinence from food and water present a complex regulatory problem. An investigation in northern elephant seals suggested that changes in the energy demands of milk synthesis across lactation may impact fasting physiology and ultimately limit the period of parental investment. From this perspective, lactating phocid females may be one of the best examples of homeorhesis "orchestrated changes for the priorities of a physiological state," found in nature.

Studies have suggested changes in milk composition and the nutrient requirements of milk synthesis across lactation in pinnipeds. These patterns are controlled by hormonal and biochemical changes. Of these changes, those that impact mobilization of adipose tissue stores, metabolism of lipids, and utilization of lipids by the mammary gland are the most significant. These changes are also important as pinnipeds transition from periods of nutrient deposition and mobilization for milk synthesis. Decreased insulin levels remove the strong antilipolytic effects of this hor-

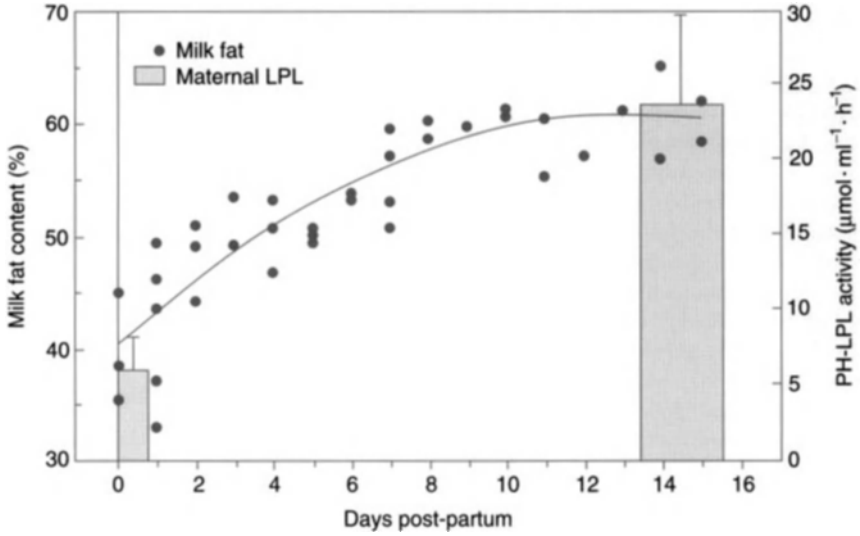

Figure 5 *Changes in maternal postheparin LPL activity in relation to changes in milk fat over lactation in gray seals. From Iverson et al.,* J. Comp. Physiol. *165, Lipoprotein lipase activity and its relationship to high milkfat transfer during lactation in grey seals. Copyright 1995 Springer-Verlag.*

mone. Cortisol and other glucocorticoids influence lipid metabolism directly and indirectly. Cortisol stimulates hormone-sensitive lipase in adipose tissue and antagonizes the actions of insulin. Hormone-sensitive lipase activity increases lipid mobilization from adipose tissue. Lipoprotein lipase (LPL) is the primary enzyme involved in directing triglycerides mobilized from tissue stores to tissues for utilization. LPL is bound to tissues and facilitates the hydrolyzation of triglycerides, allowing uptake of fatty acids by the tissue. Under normal conditions of insulin release, LPL activity in tissues increases and triglyceride is cleared from the blood. During fasting, LPL activity in adipose tissue decreases, while hormone-sensitive lipase activity in adipocytes increases. The general pattern found in lactation is a decrease in adipocyte LPL activity before parturition and an increase in mammary gland LPL activity. The hormone prolactin is believed to be primarily responsible for LPL regulation in lactation. Investigations on harbor seals and gray seals have suggested a similar pattern. General activity levels of LPL increased 10-fold over lactation in these species and were significantly higher than levels found in humans (Fig. 5). The dramatic increase in milk lipid content early in lactation in some phocids seals may in part be explained by a significant increase in mammary gland LPL activity.

Very little work has been done on the physiology underlying milk secretion in pinnipeds. The release of milk fat globules occurs by apocrine secretion, in which the apical portion of the cell membrane is sloughed off. The high fat contents of pinniped milk suggest significant increases in the amount of membrane and its turnover. Pinnipeds may partially reduce this requirement by utilizing larger fat globules that require smaller amounts of membrane loss per unit lipid secreted. Data on mammary gland size in phocids have been equivocal, suggesting increased size relative to body mass in some species but not others. In any case, phocid seals appear to be particularly efficient at mobilizing and transporting nutrients to the mammary gland, perhaps by reducing the levels of *de novo* synthesis of milk lipids occurring at the mammary gland. This efficiency must in turn be matched by rapid and efficient digestion and assimilation of milk lipids by the offspring.

Plankton

AKITO KAWAMURA
Kyoto, Japan

Plankton is the collective name given to the assemblage of free-swimming or suspended microscopic organisms considered too small to move independently of ocean currents. Large animals that are able to disperse under their own power are called nekton. The distinction between plankton and nekton, however, is sometimes blurred. For example, larger animals that are capable of limited self-propulsion, such as jellies and salps, are often included in the plankton. Large euphausiids, such as Antarctic krill, whose ability to actively determine and maintain their position is poorly understood, have been referred to as either macroplankton or micronekton. Phytoplankters are plants, and zooplankters are animals.

I. Phytoplankton

Phytoplankton consists of microscopic unicellular plants and forms the basis of marine ecosystems; nearly all life in the sea derives from the solar energy fixed in photosynthesis by these plants. Two factors control phytoplankton growth: light irradiance and nutrients. Light is only available in the top layers of the oceans, variably down to about 200 m or less, whereas nutrients are more abundant in deeper layers. Evolution of small size has enabled phytoplankton to absorb scarce nutrients through maximizing the ratio of surface area to volume. Small size, down to 2 μm, also confers high buoyancy and a low sinking rate, keeping the cells near the surface. Grazers on the phytoplankton must also be extremely small in order to be able to feed on them. As well as being the "grass of the sea," phytoplankton comes into cetology in one of the common names of the blue whale (*Balaenoptera musculus*), "sulphurbottom," which refers to a yellowish-brown layer of diatoms (single-celled epiparasitic algae) accumulating on the whale while it feeds in cold polar waters.

II. Zooplankton

Zooplankton consists of animals from several taxonomic groups from Protozoa to Vertebrata and is a main source of food for many marine mammals. Carnivorous, omnivorous, and herbivorous zooplankters have been found in the stomach of baleen

whales; three groups of crustaceans are the most important: copepods, euphausiids, and amphipods. These and other planktonic animals have developed a wide variety of specialized mechanisms and techniques for feeding on phytoplankton and suspended particulate matter, including appendicular nets and guiding whorls in copepods, finely structured appendages in euphausiids, and ciliary movements in pteropods such as *Limacina* and *Cavolinia*. "Basket feeding" in the Antarctic krill, *Euphausia superba*, is a kind of mass raptorial feeding. Nektonic animals have also developed filters by modifying gill rakers into functional sieves, e.g., as in the basking shark (*Cetorhinus maximus*) and whale shark (*Rhincodon typus*). Buccal teeth with well-developed accessory cusps also function as sieves in crabeater seals (*Lobodon carcinophaga*) and leopard seals (*Hydrurga leptonyx*), which feed on krill. The most highly derived filtering system among the vertebrates is that of baleen in whales, which enables them to utilize varying sizes of minute particles suspended in the viscose water medium.

III. Plankton and Whales

Whales can feed efficiently on zooplankters because they occur in dense swarms. Their patchy distribution and aggregation may be partially passive and due to oceanographic features such as Langmuir circulation but may also involve active processes on their part. When Antarctic krill swarm densely at the surface, the water is discolored with brick-red patches due to their carotenoid pigmentation. A swarm is usually a species-specific phenomenon, as in birds or fishes. In a particular feeding ground in the subantarctic area, sei whales (*Balaenoptera borealis*) and southern right whales (*Eubalaena australis*) feed on copepods (*Calanus tonsus*) that swarm at a density of 21,000–23,000 individuals/m^3, or 29–35 g/m^3. The background density in the same region is fewer than 1/m^3 (Kawamura, 1974). Based on acoustic data, Antarctic krill has been found to swarm at a density of some 60,000 individuals/m^3 or more or $\geq$33 kg/m^3 (Miller and Hampton, 1989). The baleen whales exploit these swarms, harvesting immense amounts of biomass in a process that could be compared to seining pelagic fish schools. The concentration of biomass by swarming zooplankton is incredible; it has been estimated that the energy represented by the phytoplankton in 5 million gallons of seawater is equal to that in only 1 pound of black beans (Fraser, 1969), yet baleen whales may efficiently collect some 4% of body weight daily by exploiting swarms of zooplankton that feed on the phytoplankton (Fig. 1).

The stomach contents of a whale usually consist of zooplankton of a single species, one of only a limited number of major species (Table I), depending on location and species of whale. This is due to the swarming habit, which does not occur in all planktonic crustaceans (Kawamura, 1980a). Sometime, however, two or more species may be found in a single stomach due to accidental engulfment or to feeding on swarms of different species. The dominant copepods in the North Pacific are *Eucalanus bungii* and *Metridia pacifica* and in the Southern Ocean *Calanus propinquus*, *Calanoides acutus*, and *M. gerlachei*, but these are not fed on by whales because they do not swarm. In temperate and tropical waters, the Bryde's whale (*Balaenoptera edeni*) feeds on the swarming euphausiids *Pseudeuphausia latifrons*, *Thysanoessa gregaria*, *Euphausia recurva*, and *E. diomedeae*. No swarming copepods have been found in the Indian Ocean, despite high species diversity in that region. Balaenopterid and balaenid whales each show similar food habits in different oceans and seas but exhibit different food preferences (Bowen and Siniff, 1999); the former feed by "swallowing" (engulfing) large

[b]Five pteropod species could be added.
[c]Doubtful because no scientific name is known, but "squid."

amounts of water, which allows them to also feed on squid and fish of suitable size as well as euphausiids, whereas balaenids feed largely by "skimming" for copepods (Mitchell, 1974). However, the bowhead whale (*Balaena mysticetus*) is also known to feed near the bottom on planktonic amphipods in the Arctic. Gray whales (Eschrichtiidae: *Eschrichtius robustus*) feed mainly on benthic amphipods in the Bering and Chukchi Seas but also consume planktonic crustaceans and fish eggs and larvae in the southern parts of their range (Darling *et al.*, 1998).

IV. Plankton and Seals

Seals also feed on plankton, but to a lesser extent than baleen whales, with the degree depending on species, age, breeding condition, and season. Some Antarctic seals eat euphausiids. Two species (*Euphausia superba* and *E. crystallorophias*) were found in 1 of 48 Weddell seals (*Leptonychotes weddellii*), 94 of 100 crabeater seals, 37 of 159 leopard seals, and 9 of 21 Ross seals (*Ommatophoca rossii*) (Laws, 1984). The high proportions for crabeater and leopard seals reflect the specialization of their dentition for straining. In addition, Ross and Weddell seals feed on benthic and near-bottom planktonic amphipods, isopods, and mysids. In leopard seals (*Hydrurga leptonyx*), the proportion of krill in the diet decreases with age; krill were found in the stomachs of 87% of juveniles (vs 23% overall). Larga seals (*Phoca largha*) and ice-breeding harbor seals (*P. vitulina*) in the Okhotsk Sea feed largely on fish, but pups of harbor seals, ribbon seals (*Histriophoca fasciata*), and ringed seals (*Pusa hispida*) feed on swarming euphausiids, such as *Thysanoessa inermis* and *T. raschii*, which appear in association with the pack ice of their habitat (Kato, 1982). This planktonic food is important after weaning until the seals become able to catch fish or squid.

V. An Efficient (but Vulnerable?) Ecology

The marine ecosystem is a world of size-dependent structures, based at the bottom on suspended organic particles of phytoplankton and zooplankton. Annual global marine primary production of about 2×10^{10} tons of carbon has been estimated to produce some 2.4×10^{8} tons of fish after passing through up to five trophic levels (Ryther, 1969). The baleen whales shorten this chain, as do other top krill-eating predators in the Antarctic such as seals and penguins. Solar energy is transferred to large animal production with greater efficiency than in any other ecosystem. A 30-m blue whale can consume vast numbers of 4–5-cm krill. Similarly, a 0.3-cm copepod is available to a 13- to 16-m sei whale. The ratio of predator length to prey length is as great as 8300:1. These are the most extreme cases of size disparity between predator and prey in marine ecosystems (Berta and Sumich, 1999). Relatively few species of prey are involved (Table II), e.g., only 17–20 of the 85 or so known species of euphausiids and only 7–10 of the approximately 1800 known species of copepods (Mauchline, 1998). This may indicate ecological vulnerability of the baleen whales, as they have few options for substitution of food species. The distribution and abundance of the largest baleen whale stocks are/were determined by the distribution of their favored densely swarming planktonic prey (Nemoto and Kawamura, 1977). The most marked case is that of the highly stenophagous Southern Ocean blue whale, which feeds exclusively on *E. superba* (Clapham *et al.*, 1999).

Playful Behavior

BERND WÜRSIG
Texas A&M University, Galveston

Play consists of actions performed for no other apparent purpose than their own enjoyment. However, it is recognized that play occurs in young animals to learn motor and social skills needed to survive. Play as "enjoyment" may have evolved simply because something enjoyable will be sought after, and if

needed actions of learning are enjoyable, they will be done. Tussling sibling brown bears, rolling and cuffing each other, are obviously playing. But it has long been a truism that such play in the proximal sense is vital in learning self-defense and in establishing rules of association. Play tends to decrease in frequency as mammals become older and does not often occur in adults. Obvious exceptions are some primates and cetaceans, although as behavioral studies gather details, researchers are learning that play in adults of other species is actually more common than described previously. Play may also be an attempt to relieve boredom, and we would expect play to be especially well developed in the larger brained, behaviorally flexible mammals (Goodall, 1990).

I. Motor Imitation

Many marine mammals seem to be especially good at imitating the actions of their conspecifics or of individuals of other species. Thus, untrained dolphins in oceanaria have been described as performing a colleagues' trained repertoire essentially flawlessly when called upon to do so. Apparently, the dolphins learned the motor actions simply by observation (Pryor, 1995). While this by itself is not play, the capability of imitation is often expressed as play: dolphins have imitated a diver's movements of cleaning the pool; as well as the grooming and swimming movements of seals and other pool inhabitants. The dolphins would generally approach the object of imitation, slow their own travel to approximate that of the slower coinhabitant, and then move their body in exaggerated imitation of movements of the other individual. The human diver, alternately bending and straightening at the waist as he cleaned the aquarium tank with a rubber scraper, was imitated by the dolphin bobbing its head and neck up and down in rapid and jerky fashion. At the same time, the dolphin released clouds of bubbles from its blowhole in synchrony with the bubbles of the diver's air regulator and made a squeaking sound in an apparent attempt to reproduce the squeaks of the rubber on glass. The author has seen similar behavior in nature, with a bottlenose dolphin (*Tursiops truncatus*) adult in the Bahamas imitating a particularly clumsy tourist who had difficulty in descending below the water as she propelled herself with her skin dive flippers and by rotating her arms. The dolphin matched her speed, alternately bobbed at the surface and descended in unison with the woman, jerked its peduncle and tail back and forth in unnatural fashion, while at the same time rotating its short front flippers as if they were flailing arms. The effect looked highly hilarious, and it would be difficult to rationalize the behavior as anything but a bit of malicious fun, or play.

II. Vocal Imitation

While motor or physical imitation seems to be mainly in the purview of TOOTHED WHALES, other marine mammals also practice vocal imitation. This imitation may be an outgrowth of learning one's own species-specific (and perhaps group or pod-specific, as in killer whales, *Orcinus orca*) vocalizations, but the capability can then become a method of play. In the 1970s, a captive male harbor seal (*Phoca vitulina*), named Hoover by his caretakers, was capable of imitating the voice of a human worker who frequented his area, complete with a New England accent and a bit of a drunk-sounding slur (Ralls *et al.*, 1985). Beluga whales (*Delphinapterus leucas*) can also imitate human sound and will at times use these imitations in apparent mischievous play. While dolphins cannot imitate human sounds very precisely (they seem to lack the vocal capability, not the intelligence, to do so), they will easily imitate clicks, whistles, barks, scrapes, and squeaks (as the fore-mentioned window-washing sounds) that can occur in an aquarium with other animals. A particularly readable account of imitation, innovation, intelligence, and cognition can be found in Tyack (1999).

III. Examples of Play

When we meet marine mammals underwater, we are apt to be subjects of intense curiosity. Sea lions, fur seals, and harbor seals will dash around us, pirouette in front of us, and gaze at us. Interestingly, these same animals ignore us or become wary if we approach too close to them when they are hauled out on shore. When in their watery milieu, however, fear is gone. Manatees and dugongs are similarly attracted to humans underwater, except in those places where they are hunted. This curiosity can turn to play. Just about every researcher who dives with marine mammals has tales of sea lions tugging on his or her flippers; manatees and dugongs mouthing an arm or leg in apparent playfulness; and dolphins playing "the leaf game," where they present the human with a bit of flotsam and wait or return until it is given back to them (Johnson and Norris, 1994).

However, although many people prefer to think that dolphins and humans have an especially play-prone bond, dolphins (and pinnipeds) are known to interact in playful fashion with many other animate and inanimate objects in their environment. Thus, they may "tease" a sea turtle by mouthing and pulling on its tail or legs or they may swim beside a like-sized shark, imitating every movement that the shark makes. Some species of dolphins are also known for adroitly balancing pieces of flotsam on their jaws, flippers, dorsal fin, or tail or carrying a piece of algae, plastic, or other pliable object in a manner to keep it balanced on an appendage simply by force of the forward movement of the body. This activity tends to take place when the group of animals is being highly social, usually with much sexual activity as well. The dolphin playing with the inanimate object, however, tends to be alone, apparently transferring its sense of socializing to playing with the object (Fig. 1).

While apparent play is often clouded by the possibilities of curiosity or learning, the author has witnessed several clear-cut examples of play in nature, detailed in the next three sections.

A. The Mischievous Dusky Dolphin

When dusky dolphins (*Lagenorhynchus obscurus*) have fed and socialized, they are in a very playful mood. They race toward a boat from kilometers away, attempting to ride the bow wave of the vessel. They leap in acrobatic somersaults and flips that appear to show sheer exuberance and orient toward, bite at gently, and otherwise manipulate objects in their environment. There is much social/sexual interaction and apparent play, often in twos and threes, but lone animals carry pieces of kelp on their rostrum or melon and anterior edges of flippers, dorsal fin, or fluke. Most of these behaviors could be interpreted as being a part of learning or honing skills, but the author has repeatedly seen nonequivocal play, as follows.

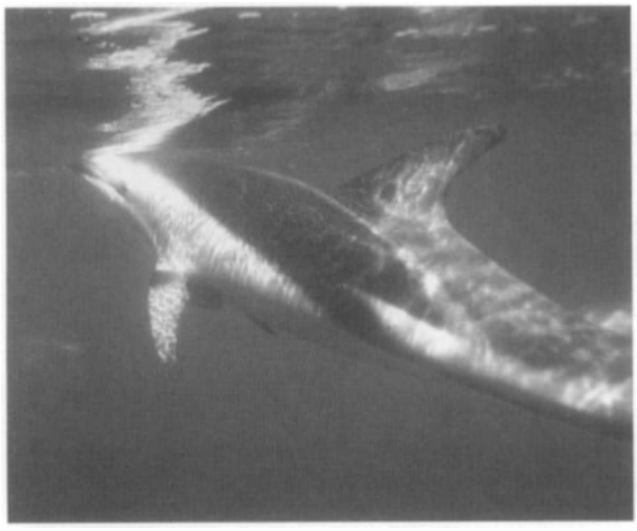

Figure 1 *A dusky dolphin* (Lagenorhynchus obscurus) *playing with kelp in Patagonia, Argentina.*

After dolphins have fed on schooling anchovy near the surface, marine birds who took advantage of the aggregated fish ball sit on the water, digesting. These are of a variety of species, but almost always include kelp gulls (*Larus dominicanus*) and brown-hooded gulls (*L. maculipennis*), yellow or red legs, respectively, dangling below a round white rump. The sight seems almost irresistable for some dolphins, who slowly circle one of these birds, approach it at an angle and from the rear, very gently open their jaws around one or both dangling appendages, and then rapidly but not totally close the mouth and surge forward and down. This action drags the bird below water by about 30 to 60 cm before the mouth is reopened and the bird literally pops back to the surface. The bird frantically flutters and preens before it flies off. The dolphin meanwhile slowly swims off, at times to attempt the same "trick" with another hapless gull. At all times (this has been seen about one dozen times to date), the bird is unharmed, suggesting particular finesse as the dolphin closes its pointy-toothed jaws and surges forward. The intent appears to be to surprise, certainly not to harm, perhaps like a child sneaking up behind a person to pop a balloon. The same attempts have been seen with dolphins orienting toward the dark feet of Magellanic penguins (*Spheniscus magellanicus*) bobbing at the surface, but the penguins, ever aware of their environment below, simply paddle rapidly ahead or dive before the dolphin can complete its action.

B. Creating a Bow Wave

Dolphins ride or surf on oceanic waves and those created by ships. They also ride on the fleeting bow waves created by rapidly surging large whales, and the dolphins appear to "work" particularly hard to get the whales to surge forward. A (generally small) group of dolphins will swim rapidly to the sides and front of the head of a baleen or sperm whale, close to the eyes. When the whale surges forward abruptly in an apparent attempt to evade the dolphins, the dolphins surf the one steep white-water wave so created during that surge. It is believed that the activity is not pleasing to the whale, as the whale exhales forcefully during the surge, with a sonorous "snort" that indicates aggression or anger in other contexts. In right whales (*Eubalaena* spp.), the loud in-air "dolphin blow" of a snorting, surging, whale alerts researchers that *Lagenorhynchus* sp. or bottlenose dolphins are playing with the leviathans. The snort is so loud that on a calm sea it can be heard for a distance of several kilometers. One whale is "good for" anywhere from 5 to 10 surges. It then tires or decides to give up evading the dolphins, and the sport is over for the time or needs to be reinitiated with another whale nearby.

C. Balancing Bowhead Whales

Baleen whales engage in the surface activities of BREACHING, tail lobbing, flipper slapping, and holding the tail above the surface of the water. While much of this is certainly play, at least at times, the percussive nature of these activities possibly aids in communication and may also represent outgrowths of anger or frustration. Holding the tail out of the water for many minutes at a time, a habit of some right and bowhead whales (*Balaena mysticetus*), may feel good as a stiff breeze touches the skin and may even be a form of recreational "sailing" with the tail (as suggested by Payne, 1995).

Bowhead whale adults (approximately 18 m long) have been seen interacting with large logs (up to 10 m long) on summer–fall feeding grounds in the Beaufort Sea. They nudge and propel the log, handle it with their flippers and tail, and attempt to push it under water. Several of these activities seem similar to surface social interactions during sexual activity, and it could be argued that log handling is play useful to developing physical social skills. However, the most dramatic part of log handling is balancing the object, quite adroitly, on the back or belly. The author has seen log balancing (by an adult female) wherein the whale rolled gently sideways to compensate for the action of large oceanic swells rolling past the whale's body. The whale was so adept at this balancing that she could briefly keep both ends of the huge log suspended in air, a feat perhaps not unlike a trained sea lion balancing a ball on its snout. It is difficult to imagine how this activity could be anything but play or an "artistic" attempt at perfecting a difficult task (Würsig *et al.*, 1989; Wells *et al.*, 1999) (Fig. 2).

D. The Darker Side of Play

While apparent mischievous behavior of pulling on gull or turtle legs or of inciting whales to become aggravated could be potentially AGGRESSIVE or harmful play, it probably is not. However, some interspecies behaviors are definitely harmful and it is unclear whether they represent play or merely aggression. Short-finned pilot whales (*Globicephala macrorhynchus*) have been described aggressively and for almost 2 hr swimming around and into a pod of obviously frightened sperm whales (*Physeter macrocephalus*) (Weller *et al.*, 1996). Because pilot whales are not known to feed on the much larger sperm whales, it is possible that this action occurred only "for the fun of it," although other explanations, such as perhaps attempting to get whales to regurgitate squid gathered at depth, cannot be ruled out. A large male pilot whale in Hawaii carried a human diver into depth and held onto her with his mouth for tens of seconds. While he could easily have bit into her and killed her, his hold-

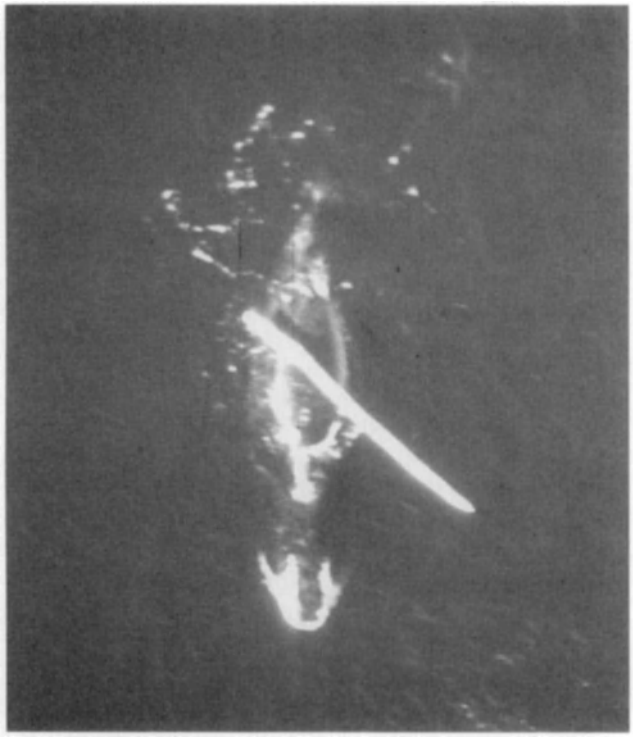

Figure 2 *A bowhead whale playing with a log.*

ing her was relatively gentle (but firm), and play appears to have been the reason (Shane *et al.*, 1993). The woman survived only because she was an expert swimmer and diver and did not panic.

Bottlenose dolphins, the staple of show dolphins in over 100 aquaria worldwide, are known for at times aggressive play. In Scotland, a group of bottlenose dolphins is known to attack and fling about harbor porpoises (*Phocoena phocoena*), not for food and possibly simply for the sport of it. Bottlenose dolphins and harbor porpoises of the area also do not appear to compete with each other for space or food, but it is unknown whether more than a few ("rogue") dolphins are involved in this particularly gruesome sport that has killed at least one dozen harbor porpoises at this writing.

Polar Bear

Ursus maritimus

IAN STIRLING

Canadian Wildlife Service, Edmonton, Alberta, Canada

The polar bear, *Ursus maritimus* (Phipps, 1774), is, on average, the largest of the eight species of bears found worldwide and is completely white. Typically, the body is stocky, lacks a shoulder hump, and has a longer neck in relation to the rest of the body than other ursids. Other English common names for the species are white bear, ice bear, and Nanuk. The taxonomy is order Carnivora, family Ursidae, genus *Ursus*, and species *U. maritimus*. There are no subspecies.

Adult males typically measure 200 to 250 cm in length from the tip of the nose to the tip of the tail and weigh 400–600 kg, although some individuals may reach about 800 kg. The total length of adult females is 180–200 cm and they normally weigh 200–350 kg while pregnant females may occasionally exceed 500 kg. There is some GEOGRAPHIC VARIATION in size and growth rates of bears in different populations. Polar bears are plantigrade and have five toes on each foot, with nonretractable claws. The forepaws are large and oar-like, as an adaptation for SWIMMING. The hind legs are not used while swimming. Females normally have four functional mammae, although supernumary nipples have also been reported. The dental formula is i 3/3, c 1/1, p 2-4/2-4, and m 2/3. The vitamin A content of the liver ranges is about 15,000 unit per gram and is toxic to humans.

I. Distribution

Polar bears are distributed in ice-covered waters throughout the circumpolar Arctic. About 20 individual populations are currently recognized, varying in size from a few hundred to a few thousand bears in each, with a world population estimate (in 1997) of 22,000–27,000. Although small numbers of animals may be found in the permanent multiyear pack ice of the central arctic basin, their preferred habitat is the annual ice over continental

shelves of the continents and islands around the coastline of the Arctic Ocean where overall biological productivity and densities of ringed seals [Pusa hispida (= *Phoca hispida*)], their primary prey, are greatest (Fig. 1). The southern limit of their distribution in winter varies with the extent of seasonal pack ice in the Bering, Labrador, and Barents seas. In areas where the ice melts completely in summer, such as Hudson Bay or southeastern Baffin Island in Canada, polar bears spend several months on shore fasting on their stored fat reserves until freeze-up in the fall.

II. Ecology

Regional concentrations and seasonal movement patterns of polar bears are influenced primarily by the type and distribution of sea ice and by the density and distribution of seals. From freeze-up in the fall until breakup in the spring, polar bears prefer coastal areas and inter-island channels lying over the continental shelf, especially active ice areas associated with shore leads or the floe edge. The size of home ranges of bears living within the Canadian Arctic Archipelago is generally smaller than those of polar bears dispersed in open ocean areas such as the Chukchi Sea. In general, polar bears are less abundant in areas of extensive multiyear ice and in the immediate vicinity of polynyas with overwintering walrus (*Odobenus rosmarus*) populations, probably because the density of ringed seals is lower there.

Polar bears that have continuous access to sea ice hunt throughout the year. Their hunting techniques and rates of success change with the seasons and vary in different areas. The most common method of hunting is to lie beside a breathing hole waiting for a seal to surface and breathe. Contrary to popular myth, they do not cover their noses with a paw when stalking a seal, although when stalking, they do keep their heads low while walking slowly and steadily toward potential prey. The largest proportion of a polar bear's annual caloric intake for the year occurs in spring and early summer, at which time newly weaned ringed seal pups are 50% fat by wet weight. The specific sea ice habitats most hunted by polar bears in spring are stable shore-fast ice with deep snowdrifts along pressure ridges, which are suitable for ringed seal birth lairs and breathing holes; the floe edge where leads are wide (>1 km); and areas of moving ice with seven-eighths or more of ice cover. After breakup of the annual ice in late spring to early summer, hunting success is reduced and, in areas where open water prevails from late summer through autumn, polar bears seek onshore retreats where they simply fast on their stored fat reserves until freeze-up.

Figure 1 Ursus maritimus, *the polar bear, is aptly named, as the species is often observed miles from the nearest land on polar pack ice and swimming between ice floes where they hunt ringed seals and sometimes bearded seals. Photo by François Gohier.*

The principal prey species of polar bears are ringed seals and, to a lesser degree, bearded seals (*Erignathus barbatus*). Ringed seals maintain their breathing holes from freeze-up in the fall to breakup in the spring by abrading the ice with the heavy claws on their foreflippers. Many winter breathing holes are located on the last cracks to close over in the fall and bears are able to locate them by smell, even under a meter or more of compacted wind-blown snow. In areas where wind, water currents, or tidal action causes the ice to continually crack and subsequently refreeze, seals are apparently more accessible to polar bears and the bears are able to hunt them there more successfully. In places where the snow cover in the fiords is deep in spring, large numbers of ringed seals give birth to their pups in subnivean liars where they are hunted by polar bears of all ages and sex classes, but especially females with newborn cubs. Bearded seals concentrate where natural cracks and polynyas form through the winter because it is easier to breathe there. Polar bears are also known to occasionally prey on walruses, belugas (*Dephinapterus leucas*), narwhals (*Monodon monceros*), waterfowl, and seabirds.

Most maternity denning takes place in snowdrifts on land in coastal areas. In western Hudson and James bays, however, pregnant females must enter maternity dens prior to when suitable snowdrifts form in most years so they dig dens in frozen peat in small banks along the edges of lakes or streams. Individual females show fidelity to denning areas, although not to individual den sites. In the western Beaufort Sea north of Alaska, a large proportion of the adult females den 200 km or more offshore in the multiyear ice of the Beaufort Sea.

III. Behavior and Physiology

Polar bears breed in April and May. Males are twice the size of females, which probably reflects the intense competition between them for mating with available females. Because females keep their cubs for 2.5 years in most areas, they are normally available for mating no more often than once every 3 years. Thus the functional sex ratio of breeding age animals is a minimum of 3 males:1 female. Polar bears have induced ovulation, which means a female must mate many times before she will ovulate and can be fertilized. Polar bears also have delayed implantation so the fertilized egg ceases developing after the first few divisions and remains dormant in the uterus until implantation in mid-September to mid-October, depending on latitude. The young are born in a snow den about 2 months after implantation and weigh about 0.6 kg at birth. The eyes of newborn cubs are closed and their body hairs are so fine they have mistakenly been reported to be hairless at birth. Cubs are

nursed by the female until they are large enough to leave the maternity den in late March or early April, by which time they weigh 10–12 kg. In most areas, cubs are weaned at 2.5 years of age, after which the female mates again. Females breed for the first time at 4–5 years of age and continue to have cubs to the end of their lives. About two-thirds of the litters are twins, while single cub litters are the next most common, and triplets are infrequent, although not rare. The largest litters and heaviest cubs are born to adult females in their prime, about 8–18 years of age, whereas younger and older females tend to have single cub litters more often. In populations that are not overharvested, females live into their mid-20s, although some reach their early 30s. Males generally reach their early 20s with occasional animals reaching the late 20s. In general, bears living in areas that are more biologically productive are larger and reproduce earlier than bears in areas that are less productive.

Polar bears have a remarkable ability to store large amounts of fat during periods when prey (mainly seals) are available and then fast for protracted periods when food is not available. In Hudson Bay, where the annual ice melts completely by mid-July and does not reform until mid-November, all bears in the population must fast for at least 4 months on their stored fat, whereas pregnant females do not feed for 8 months, during which period they must support themselves as well as nurse their young so the cubs can grow large enough to withstand the rigors of the arctic environment. Only pregnant females go into dens for the winter; bears of all other age and sex classes remain on the ice and hunt throughout the winter except briefly during the coldest or most inclement periods when they may occupy temporary dens in the snow. Whenever food is unavailable, the metabolism of a polar bear automatically slows to a hibernation-like physiological state, in which energy is consumed at a lower rate. This change occurs after about 7–10 days of not eating and can occur at any season of the year, rather than only in the autumn prior to winter denning, like other species of bears. Thus, because the digestibility of fat by a polar bear is about 98%, it has the ability to store large amounts of fat quickly when food is available and then switch to a more efficient metabolic state for as long as necessary when food is unavailable.

IV. Fossil Record

Polar bears are thought to have originated from brown bears (*Ursus arctos*), possibly in the vicinity of Siberia during the glacialogical advances of the late Pleistocene a million or so years ago. Polar bears and brown bears are capable of interbreeding in zoos and the young are fertile. However, in the wild, there is little overlap in the habitats during the breeding season. The molars and premolars of polar bears are more jagged and sharper than those of other bears, reflecting their rapid evolutionary shift toward carnivory from the flatter grinding teeth of their more omnivorous relatives. The oldest known fossil is from London, England, and is less than 100,000 years old.

V. Interactions with Humans

Polar bears are important to the culture and economy of aboriginal people in Alaska, Canada, Greenland, and Siberia, who harvest 8–900 bears annually. Population research is ongoing in most areas to try to ensure that harvests are undertaken at sustainable levels. Thus, the survival of polar bears is not currently threatened by hunting, but this must still be regulated carefully because they have a low reproductive capability and would require 20 or more years to recover from an overharvest. Many contaminants in the Arctic marine ecosystem are lipophilic and bioaccumulate as they move up in the food chain. Because polar bears are at the top of the ecological pyramid, and live predominantly on fat, they are capable of achieving high levels of contaminant loading in some areas. It is not yet known whether these contaminants are high enough to interfere with reproductive functions or the immune system. In some areas, such as western Hudson Bay, long-term studies have demonstrated that climatic warming is causing the ice to break up earlier, which is correlated with decreasing condition and reproductive rates of polar bears there. In more recent years, ecotourism to view polar bears, especially at Churchill, Manitoba, has increased markedly with positive local economic benefits and a significant increase in the worldwide appreciation of the bears themselves.

Pollution and Marine Mammals

PETER J. H. REIJNDERS
Alterra, Marine and Coastal Zone Research, Den Burg, The Netherlands

ALEX AGUILAR
University of Barcelona, Spain

Awareness of the threat of environmental contaminants to marine mammals is widespread. High concentrations of certain compounds in the tissues of these animals have been associated with organ anomalies and impaired reproduction and immune function, as shown by large die-offs among seal and cetacean species. This has prompted alertness about the impact of pollution and stimulated research into the relationship between observed effects and pollutants. However, a clean cause and effect relationship between the residue levels of contaminants and the observed effects has been demonstrated in only a few studies. In the absence of evidence, this might elicit a serious backlash because concerns expressed are easily interpreted as fear mongering. This could lead to inertia in taking appropriate management measures, which is undesirable from a conservation as well as an environmental management perspective.

The main reasons for the lack of proof of the impact of pollution on marine mammals are the difficulty or impossibility of experimenting in laboratory conditions with these animals and the frequent occurrence of confounding factors that hamper the establishment of cause–effect relationships. Examples of these factors are the fact that pollution always occurs as a mixture of a large number of chemical compounds, the lack of data on biological variables influencing tissue levels, quality of samples usually analyzed, the limited information on pathology and occurrence of disease in the specimens studied, the absence of reliable population data, and the lack of information on the influence of other detrimental factors, such as the impact of fisheries and of other human-related sources of disturbance.

I. Substances of Concern

In general, the concept of pollution incorporates many different substances to which marine mammals are exposed and might affect their health adversely. These include chemical compounds, oil pollution-derived substances, marine debris, sewage-related pathogens, excessive amounts of nutrients causing environmental changes, and radionuclides. The influence of oil and petroleum-derived compounds, such as polycyclic aromatic compounds, of marine debris, of sewage-related pathogens, and of nutrients-related changes, such as the occurrence of biotoxins, has not been the subject of focused research in marine mammalogy. As a consequence, data on these pollutants, either as concentrations in tissue of the affected marine mammals or as effects on them, are extremely limited. This article therefore only addresses pollution caused by chemical substances.

Traditionally, most laboratories tended to routinely analyze organohalogenated compounds such as DDT, DDE, DDD, polychlorinated biphenyls (PCBs), lindane, dieldrin, endrin, hexachlorobenzene (HCB), heptachloro-epoxide (HEPOX), and mirex, and trace elements such as mercury, lead, selenium, and cadmium. Some laboratories, able to use more sophisticated equipment, have also analyzed polychlorinated dibenzodioxins (PCDDs) and polychlorinated dibenzofuranes (PCDFs). Such a narrow approach brings the risk of overlooking the impact of other, poorly known compounds. However, the monitoring of all known synthetic organic chemicals and their metabolites currently in use would require analysis of about 300,000 compounds. Therefore, criteria have to be developed to identify priority compounds on which to focus monitoring. Criteria for the identification of these compounds should include the level of production and release into the environment, bioaccumulation potential, and toxicity. Examples of "novel" compounds that fall into the category of priority compounds are organotins, polybrominated biphenyls (PBBs), and polybrominated diphenyl ethers (PBDEs).

Because research funds are limited, another issue to be addressed is the choice between monitoring pollutant concentrations or investigating their effects. The latter option is in our view clearly preferable. If an effect is observed, more focused research for the responsible compounds can follow.

Taking into account the two elements discussed earlier and without ignoring the potential impact of other compounds, it is currently accepted that a list of compounds of highest priority should include all organohalogens usually referred to as persistent organic pollutants (POPs), particularly including PCBs, DDTs, PCDDs, HCB, dieldrin, endrin, mirex, PCDFs, PBBs, PBDEs, polycyclic aromatic hydrocarbons (PAHs) and phenols, and metals, particularly including their organic forms such as methyl-mercury and organotins.

II. Pollution from an Environmental Perspective

Pollution is only one of the many environmental factors that influence the health status of marine mammals. The assessment of the impact of pollution on marine mammals has therefore to be undertaken in a holistic perspective, considering also

the potential of pollutants to interfere with their ability to recuperate from stress caused by other environmental forces. As an example, PCBs could cause immune suppression in a given seal population without directly leading to an increased mortality. However, if such a population is exposed to an introduced virus, the extent of a resulting epidemic is likely to be much aggravated.

Marine ecosystems are complex, and environmental forces operating on populations are often multifactorial and produce synergistic or cumulative effects. Therefore, it will be complicated to attribute a given effect to a single factor. To illustrate the complexity of unraveling the impact of pollution, we discuss here some of the environmental factors, natural or anthropogenic, that influence the resilience of marine mammals to pollution.

A. Prey Depletion

Natural environmental variations such as redistribution of planktonic organisms may bring changes in distribution, abundance, or recruitment of the species that constitute the food of marine mammals. However, depletion of prey may often also be caused by overfishing by commercial fisheries. Depending on the extent of the depletion, marine mammals may respond to the reduced supply of prey either by switching to other species, or by temporarily moving to another area. Frequently, however, they undergo an impoverishment of their body condition and their recruitment rates become lower. The resilience of animals in such populations/stocks is affected negatively, potentially increasing the detrimental impact of pollutants.

B. Habitat Disturbance

Habitat may be disturbed by a wide range of human activities, including recreation, construction works, and many others. For pinnipeds, sea otters (*Enhydra lutris*), and some coastal cetaceans, the physical alteration of the litoral, including the mere presence of humans and their associated infrastructure, may be a significant detrimental factor. Noise pollution is a particular source of concern because many marine mammals rely on sound emission and detection for finding their prey, communicating, and navigating. Activities producing noise-related disturbance include shipping, boating, military maneuvers, seismic testing, and oil and gas drilling.

C. Disease

Natural factors influence the incidence of disease. For example, a shift in distribution of prey species may lead to an increased parasite infestation rate likely to affect the resilience of populations to pollutants. Although the incidence of infectious disease in marine mammals is poorly known in general terms, morbillivirus epizootics that have recently affected pinnipeds as well as cetaceans have elicited extensive research on the effects of viral diseases on marine mammal populations.

Deadly bacterial diseases are generally considered to be secondary to other conditions such as viral disease, parasitic infection, or trauma. However, like some pollutants, bacteria can also interfere with reproduction, as was demonstrated by the finding of *Brucella* organisms in porpoises and dolphins.

In marine mammals, similarly to other better studied groups of vertebrates, disease and the toxic effect of pollutants are often interrelated. This relationship is discussed in more detail in the next section, although it should be mentioned here that diseases can affect metabolic systems and, consequently, alter physiological functions. Chronically diseased females, for example, usually have a poor reproductive performance, as do females affected by some pollutants.

D. Overall Environmental Changes: Global Warming, Ozone Depletion

Albeit the potential effect of global changes on marine mammals has been little investigated and its consequences are considered less imminent than those caused by other factors, this matter certainly deserves concern. It is predicted that the global rise in temperature will alter marine communities and their productivity, cause a sea level rise, reduce ice cover, and modify rainfall and water current systems. The consequences for marine mammals are unclear, but undoubtedly those alterations will affect their behavior and distribution. An increased incidence of epizootics among pinnipeds is also postulated, as higher densities as a result of increased haul-out behavior will result in a higher transmission rate of infectious agents.

Despite the longer term character of these threats, changes in the distribution and behavior of marine mammals caused by climate variation should be monitored to detect potential relationships at an early stage.

The examples just mentioned show clearly that studying the impact of pollution on marine mammals requires a multidisciplinary approach. Therefore, we advocate assessing pollution impact not in an isolated way, but always in relation to other environmental factors.

III. Factors in Assessing Pollution Impact

Two sources of information may warn that pollution might affect a given population: high tissue pollutant concentrations in the members of that population and changes in the biological parameters of the population such as physiological condition and changes in reproductive or mortality rates. The latter are often derived from population monitoring and/or pathological investigations. However, a number of biological factors and inconsistencies in the sampling and analytical procedures seriously hamper the establishment of such relationships, sometimes even leading to spurious interpretations of environmental data.

A. Biological Factors Affecting Variability in Pollutant Levels

Some persistent chemicals are bioaccumulative and their concentrations in living organisms undergo a progressive amplification through food chains, a process called biomagnification. However, the increase at each trophic level is usually considerably higher than the 10-fold increase predicted by ecological models. Biomagnification, defined as the ratio of concentrations of a compound in the predator to its prey, can be altered significantly, and often much increased, by a number of variables, such as the route of exposure, the physical and chemical properties of the compound, the metabolic capacity of the predator, and its physiological constitution.

B. Diet

Diet composition is a key factor determining resultant tissue concentrations. Because baleen whales feed on planktonic crustaceans and are thus situated lower in the food web, their tissue organochlorine (OC) concentrations are almost invariably lower than those in the top-predator toothed whales living in the same ecosystem.

Within a population of the same species, OC levels can also differ because of variation in diet. For example, juvenile pinnipeds often exploit different food resources than adults, and in many species of cetaceans and pinnipeds, adult males prey on different species than adult females. In some marine mammals, differences may even be associated with reproductive status: the diet of lactating females of some dolphin species is different from pregnant or resting females. Also, the geographical region where food is consumed is critical: during most of the year, male sperm whales (*Physeter macrocephalus*) occupy different geographical regions than females and, as a consequence, their pollutant profiles are quite dissimilar. Differences in diet are also assumed to have an influence on the tissue concentrations of PAHs in marine mammals. Levels of these compounds in marine mammals are generally low, although they tend to be higher in cephalopod-eating marine mammals than in those relying on fish. The explanation appears to be that the ability of fish to metabolize PAHs is better than that of cephalopods.

Tissue levels of metals also appear to be related to the feeding habits and region of exposure. Cadmium, copper, and zinc levels are higher in cetaceans that feed primarily on squid than in those feeding on fish. This is attributed to the ability of squid to retain these elements selectively. Intraspecific differences in tissue metal concentrations have also been linked to segregation in feeding areas; the levels of lead in kidney and muscle tissue of long-finned pilot whales (*Globicephala melas*) and white beaked dolphins (*Lagenorhynchus albirostris*) occurring during summer in the same areas are much different because they segregate geographically—and feed—during the winter.

C. Age and Sex

The tissue concentration of a pollutant in a marine mammal is a function of the difference between the intake rate and the metabolization and excretion rates. OCs have been found to correlate positively with age; levels are relative low in young animals, increase until a certain age, and then either continue to increase or reach a plateau level or decrease. The leveling off or decreasing phase is different for males and females, as is addressed later on. Factors that influence the age-related pattern of accumulation of organochlorines are detoxification ability and the feeding rate. The capacity for detoxification is low in young animals and improves with age; thus the initial increase during the juvenile stage is slowed down by improved metabolization and excretion rates. The resulting leveling off of tissue concentrations is enhanced further by reduced feeding rates in adults.

Superimposed on these is the effect of reproduction in females. OCs, as most lipophilic compounds, cross the placenta and reach the fetus, although not all chemicals do it at equal rates. For example, the lower chlorine-substituted (lower weight) congeners of PCBs are transported more easily than higher chlorinated ones. In addition to placental transport, OCs are also transferred from mother to offspring through milk. Higher chlorinated OCs are transferred less efficiently from the lipid tissue of the mother to her milk and hence to the suckling calf or pup. This process obviously does not start until the females reach sexual maturity and become pregnant for the first time. Therefore, the first pregnancy marks the start of the leveling off or decrease phase in females. There are differences among species and compounds. Moreover, this reproductive discharge in females is not uniform and depends on the characteristics of the reproductive cycle of the species and the physicochemical properties of the compound. The transfer during lactation is much higher than that occurring through deposition in the tissues of the calf or pup during pregnancy. In cetaceans, the discharge of PCBs, expressed as percentage transferred in relation to maternal tissue load, ranges from 5 to 96% during lactation and from 4 to 6% during pregnancy. In pinnipeds, the ranges are 23–81 and 1–10%, respectively. Not surprisingly, the length of the lactation period significantly influences the proportion of the OCs' load transferred to the offspring. It has been estimated that this proportion ranged from 3 to 27% in fin whales (*Balaenoptera physalus*), with a lactation period of around 7–8 months, whereas it was around 80% in bottlenose dolphins (*Tursiops truncatus*) and 72–91% in striped dolphins (*Stenella coeruleoalba*), two species in which lactation lasts about 14 months. Irrespective of the amount transferred, the reproductive discharge results in lower levels of lipophilic pollutants in reproductively active females as compared to males of the same age. However, there are some exceptions to the general rule. In Antarctic minke whales (*Balaenoptera bonaerensis*), levels of PCBs and DDT were found to be higher in immature males than in mature males as a result of a shift in diet caused by adult migration to less polluted areas. In the North Atlantic, adult female sperm whales are more polluted than males of comparable age because they feed on more polluted species and are distributed year-round in regions where pollutant loads are higher.

Age-related variation in tissue concentrations of trace elements is less homogeneous. Mercury, cadmium, selenium, and lead increase with age, somewhat more steeply in females compared to males. There is no clear leveling off for any element except for lead, in which a slower increase has been observed at an older age. Because these elements are not lipophilic, reproductive transfer does not affect their loads in females. It has been suggested that the higher levels of those elements found in females compared to males may be related to differences in metabolic pathways linked to hormone cycles.

Information on other trace elements is scarce. Copper and zinc show no increase with age. In fact, concentrations in newborns are higher than in adults, which is attributed to an age-related decrease in absorption and retention of these essential elements.

D. Nutritive Condition

Nutritive condition affects the volume of fat in the body and its lipid composition. In some cetaceans and pinnipeds, blubber lipid richness may decrease from 90% in a female near term to 30–35% in females just having weaned their offspring.

Although less impressive, males also show changes in blubber layer thickness during the reproductive season. Apart from this reproduction-related change, seasonal variation may also be significant. Variation in blubber layer thickness is lower in toothed whales compared to baleen whales. In some pinnipeds, independently of the reproduction-related changes, blubber layer thickness can vary by as much as 50% (taking the maximum thickness as a reference). This variation has implications for the dynamics of lipophilic contaminants. Because lipids are mobilized more readily from the blubber than lipophilic pollutants, lipid metabolization typically results in an increase in the residue levels. However, it has been found that the increase is less than a kinetic concentrative model would predict. It has been suggested that the more polar fraction of the pollutants is mobilized more readily through the enhanced metabolization and excretory capacity stimulated by a rise in tissue pollutant concentrations subsequent to lipid metabolization.

It is unclear to what extent changes in nutritive condition affect tissue concentrations of nonlipophilic compounds. Changes in mass and composition of tissues where chemicals (e.g., heavy metals in liver and kidney) are likely to accumulate influence the dynamics of these pollutants, but data on these processes in marine mammals are lacking.

Body growth in young animals also influences tissue level of pollutants. In both pinnipeds and cetaceans it has been found that dilution of contaminants occurs in the early stages of growth due to the rapid deposition of blubber and the amassing of liver and kidney tissue. Calculations of tissue concentrations on a lipid basis instead of a fresh weight basis can partially account for such variation, but it does not account for variation in the qualitative composition of the lipid fraction, which is also likely to affect the retention ability of the tissue.

E. Body Size

The influence of body size on variation in the accumulation pattern of pollutants is somewhat complex. Generally, elimination rates of xenobiotic compounds per unit of bodyweight are related inversely to body weight, a trend that also holds for the activity of detoxifying enzymes. Both would tend to favor accumulation of higher pollutant levels in larger animals. Contrary to that effect, the metabolic rate is inversely correlated to body size. Because metabolic rate is correlated with pollutant intake, a higher pollutant accumulation can be expected in smaller species. The influence of metabolic rate has been found to outweigh the countereffect of elimination and detoxifying activities. The concentration factor in a marine mammal is largely dependent of its daily rate of food consumption—inversely related to body size—and the mean concentration of pollutant in its prey. Small animals therefore carry generally higher loads of pollutants relative to their body weight than larger animals.

Variation in body size is more dramatic in cetaceans than in pinnipeds. Some dolphin and porpoise species weigh, when adult, about 30–40 kg, whereas the larger whales can weigh more than 150,000 kg. The range in adult pinnipeds varies from 50 to 4000 kg. An example of variation in pollutant levels between two species of different size is that of two krill-eating Atlantic baleen whale species, in which differences in tissue pollutant levels were explained by differences in body mass. It has been proposed that in species sharing the same waters, the effect of body mass on tissue concentration outweighs that of the small differences in diet or other biological traits.

F. Body Composition

The distribution pattern of pollutants in the body of an animal depends largely on the physical and chemical properties of the substances involved. For example, much work has been carried out to investigate the influence of the position of H atoms on the biphenyl ring in all PCBs, which largely determines the possibilities for their metabolization by marine mammals.

Because lipophilic pollutants accumulate in fatty tissue, about 70–95% of lipophilic pollutants end up in the blubber, which in marine mammals is the largest fat compartment. The chemical composition of the blubber also influences pollutant concentrations. In species with thick blubber, pollutants are stratified in the different layers and significant differences may be found between inner and outer strata. Therefore, the whole blubber layer must be sampled to obtain a representative picture of the individual's load. Mercury, cadmium, zinc, and other heavy metals accumulate mostly in the liver and kidney, and lead accumulates predominantly in bone tissue.

G. Analysis and Sampling

One of the major handicaps in assessing temporal and spatial trends of contaminants in marine mammals is the poor comparability of data. This holds partly for heavy metals, but it is definitely critical for analyses of OCs. The analytical techniques used, and their accuracy, have changed considerably over time and also vary between different laboratories. This greatly hinders comparison between studies undertaken by different laboratories or time periods. Significant improvement in standardizing procedures has been achieved in the last decade through intercalibration exercises. Quality assurance and quality control are of utmost importance, but this also holds for the sampling procedures. To avoid contamination by the packaging material, clean glass or aluminium foil should be used to preserve samples for OCs analyses, and plastic bags should be used to preserve samples for heavy metal analyses. Each sample should be accompanied by the appropriate biological data and, if possible, also with a detailed pathological examination to reveal the incidence of alterations in reproductive biology, early development, and occurrence of diseases. Detailed field and laboratory protocols taking these considerations into account have to be developed before embarking on any ecotoxicological study.

IV. Impacts of Pollution on Marine Mammals

Numerous studies have suggested that exposure to pollutants has an impact on marine mammal populations, mainly on reproduction and mortality. However, in most of these studies, the existence of confounding factors prevents reaching conclusive results and only a few have actually succeeded in demonstrating such a relationship.

The effects of pollution, either observed or suggested, can be grouped conveniently under three categories: impaired reproduction, indirect mortality, and direct mortality.

A. Impaired Reproduction

OCs, particularly PCBs, have been demonstrated to be responsible for impaired reproduction in the harbor seal (*Phoca vitulina*). This conclusion was reached by means of a feeding experiment in which 12 female harbor seals were fed DIETS low in OCs and 12 females received a diet high in OCs, particularly PCBs and DDE. The conclusion was that reproductive success was significantly lower in the more polluted diet group: 4 pups were born instead of 10 born in the control group. The latter figure is similar to what is normally found in free-ranging harbor seals. In addition, the analysis for estradiol-17β and progesterone in blood samples from these seals revealed that reproductive failure occurred at the implantation stage, as such failure was accompanied by low levels of oestradiol-17β. A plausible explanation of this effect is that PCBs impaired the enzymatic metabolism, lowering the circulating levels of estradiol, which in turn led to imperfect endometrial receptivity and prevented successful implementation of the blastocyst.

Elevated OC concentrations have been associated with reproductive impairment in gray seals (*Halichoerus grypus*) and ringed seals (*Pusa hispida*) in the Baltic Sea and in California sea lions (*Zalophus californianus*). Female Baltic gray and ringed seals exhibited uterine occlusions and stenosis, leading to partial or complete sterility; concentrations of OCs were higher in affected animals than in normally reproducing females. It has been proposed that pregnancy was interrupted by PCBs (or PCB-metabolites), followed by the development of pathological disorders. Epidemiological studies on the involved populations strongly support the hypothesis that PCBs or their metabolites, i.e., methyl sulfones, are responsible for the observed reproductive impairment. This has been apparently confirmed by the fact that the incidence of pathological conditions in younger but mature age classes decreased. OC levels in seals as well as other Baltic biota declined sharply between 1970 and 1980. However, unequivocal evidence for a cause–effect relationship has not been provided, although this stage of proof is probably as far as one can get with the constraints of this type of field research.

The case of the California sea lion is even more complex. Initially, still births and premature pupping were attributed to high OC (PCBs and DDE) concentrations. Later studies demonstrated that pathogenic disease agents could also have been responsible. These confounding factors prevented reaching a clear-cut conclusion on the causative role of pollution.

The proof for reproductive disorders in cetaceans caused by specific pollutants is even weaker than for pinnipeds. Impaired reproductive performance caused by PCBs has been suggested in beluga whales (*Delphinapterus leucas*) in the St. Lawrence River. In 2 out of 120 examined belugas, hermaphroditism was observed. However, the pathological studies were not conclusive, and the lack of sound population data which with to compare the observed findings made it impossible to reach a conclusion on the actual role of pollutants on such abnormalities.

Low levels of testosterone were associated with high levels of PCBs and DDE in Dall's porpoises (*Phocoenoides dalli*). However, the biological significance and underlying mechanism are unclear because both variables are age related; further studies are needed to clarify the potential involvement of pollutants.

Abnormal testes, i.e., transformed epididymal and testicular tissue, were observed in North Pacific minke whales (*Balaenoptera acutorostrata*). A possible relation with high levels of OCs has been suggested, but not proved.

B. Disease

Numerous pathological disorders, including skull lesions (paradentitis, osteoporosis, exostosis), cortical adenomas, hyperkeratosis, nail malformations, uterine stenosis and occlusions, uterine tumors (leiomyomas), and colonic ulcers, have been observed in Baltic gray and ringed seals and, to a lesser extent, in harbor seals. Pathological and epidemiological investigations revealed that the observed symptoms were part of a disease complex called hyperadrenocorticism, a disease syndrome associated with high levels of PCBs and DDT and their metabolites. Contrary to reproductive impairment, it is not possible to evaluate conclusively which of these substances elicit a response in seals because of crossed or synergistic effects. As in the case of reproductive disorders, the prevalence of uterine lesions, adrenocortical hyperplasia, and skull bone lesions was found to decrease following a decline of DDT and PCBs in Baltic biota. Conversely, however, the incidence of uterine leiomyoma in Baltic seals has not changed to date. Of even more concern is the increasing incidence during recent years of colonic ulcers in young Baltic gray seals, indicating an increasingly compromised immune system in these animals. DDT tissue levels in these animals decreased strongly between 1969 and 1997, annually by 11–12%, but PCB levels decreased during the same period at a much lower pace, only 2–4% annually. This may suggest a role of PCBs and/or their metabolites in the observed pathologies, although the potential effect of novel, unknown compounds cannot be excluded.

Some studies have shown direct evidence of the immunotoxicity of OCs. Reduced immune responses were correlated with high levels of PCBs and DDT in *in vitro* immune function assays with peripheral blood lymphocytes from free-ranging bottlenose dolphins. In an experiment with captive harbor seals, *in vitro* and *in vivo* immune function tests showed lower immune function related to higher dietary concentrations of OCs. While these two studies show that OCs adversely interfere with immune function, the toxicological and biological significance unfortunately remains unclear.

It has been suggested that lowered immunocompetence induced by contaminants aggravated the die-offs of bottlenose dolphins in the Gulf of Mexico (1990, 1991, 1993) and on the east coast of the United States (1987–1988), striped dolphins in the Mediterranean Sea (1990–1992), harbor seals in the North Sea (1988), Baikal seals (*Pusa sibirica*) in Lake Baikal (1987–1988), and Caspian seals (*P. caspica*) in the Caspian Sea (2000). In most cases the mortalities were ultimately caused by a morbillivirus infection, but exposure to high levels of OCs was proposed to have played a key role by facilitating viral transmission and increasing the susceptibility of individuals to the disease. However, it has been difficult to conclude on the etiology of these mortalities. Different studies have tried to establish links between die-offs and pollution. In the case of the striped dolphin morbillivirus epizootic, animals killed by the disease carried significantly higher PCB concentrations than

survivors. This finding could be explained by (1) immune suppression caused by PCBs, leading to higher mortality of the more polluted individuals; (2) mobilization of pollutants stored in depot tissues thinned by the disease; or (3) changes in physiological functions of the affected individuals, leading to increased PCB concentrations.

In two other studies, levels of organochlorines were related to mortality. In one study, OC levels in seals that died during the morbillivirus outbreak were compared with those in surviving seals. In the other study, OC concentrations in harbor porpoises (*Phocoena phocoena*) that died from physical trauma were compared with animals known to have succumbed to an infectious disease. Both studies were inconclusive in establishing a direct cause–effect relationship between pollutants and susceptibility to disease because of the existence of confounding factors such as heterogeneous body condition between the groups compared. A follow-up study on harbor porpoises from England and Wales has been more conclusive. In this study, PCB concentrations in blubber from animals that died due to physical trauma (e.g., bycatch) were compared with those from animals that died because of an infectious disease. A significant association was demonstrated between blubber PCB concentrations and mortality due to infectious disease, suggesting a causal relationship with chronic PCB exposure. Here, again, the possibility of additive or synergistic effects of other contaminants must be considered.

Other ecotoxicological studies point toward other effects of pollutants on marine mammals. It has been proposed that OCs produced thyroid hormone and vitamin A deficiency in at least harbor seals. Thyroid hormones are important in the structural and functional development of sex organs and the brain, both intra-uterine and postnatal. A vitamin A deficiency may lead to increased susceptibility to microbial infections and retarded growth, as appeared to be indicated by the significant lower birth weights of pups born in the more contaminated dietary group of the captive harbor seal study discussed earlier.

Another noteworthy example of impaired health status possibly caused by pollution is the case of the St. Lawrence beluga population. A range of pathological conditions have been documented in this population, particularly a high prevalence of tumors and digestive tract and mammary gland lesions. High tissue levels of OCs, lead, and mercury have been found in these animals. The establishment of a cause–effect relationship between contaminants and the observed effects in this population is hampered by the possible adverse role of other environmental factors, such as previous overhunting, high levels of noise pollution, and overall habitat destruction. Any of these factors has the potential for causing most of the observed conditions and the population's small size and slow recovery.

C. Direct Mortality

There is no record of any acute chemical poisoning event affecting marine mammals, apart from one case that affected harbor seals: a small colony had been acutely poisoned by an accidental discharge of mercury-contaminated agricultural disinfectant and several deaths occurred.

D. Endocrine-Disrupting Chemicals

Concern has been expressed about xenobiotic-induced endocrine disruption in wildlife and humans. Adverse effects of contaminants on mammalian wildlife through the modulation of endocrine systems are documented predominantly in fish-eating (aquatic) mammals. Indeed, a large number of xenobiotics with endocrine-disrupting properties, such as OCs, have been detected in marine mammal tissue. In previous sections, reproductive and nonreproductive effects, including possible links with the functioning of the immune system, have been discussed in relation to these pollutants. Except for the reproductive toxicity in harbor seals and Baltic seals, evidence of a causal link between endocrine disruption and observed effects is weak or nonexisting. Most often neither a positive proof nor a dismissal, simply a negative endocrine-like effect, could be provided. The reasons for lack of proof are the unavailability of reliable population data, the potential interaction between the many pollutants present, the role of disease agents and other environmental factors, the lack of biomarkers to assess endocrine effects, and the little research on early development in marine mammals.

V. Species Vulnerability

The impact of pollution on marine mammals can occur throughout the entire chain from exposure, uptake, metabolism, and excretion. Concentration in prey is a determining factor. Generally, coastal species are exposed to higher environmental levels than more pelagic species, and species occurring in industrialized (including intensive agricultural) areas usually have higher pollutant levels compared to animals in less developed regions. Among marine mammals, coastal seals and dolphins usually carry the highest tissue residue levels. Superimposed on that is the preferred trophic level of feeding. In the same water mass, species feeding at lower trophic levels are exposed to lower levels of pollutants compared to species feeding higher in the food chain. This is why pollutant levels are almost always lower in baleen whales than in toothed whales. Exceptions to this pattern have been discussed earlier, e.g., for metals in species feeding on squid rather than on fish.

As mentioned earlier, females get rid of pollutants through reproduction. Species that reach sexual maturity at a younger age are at an advantage compared to those that start reproducing at an older age. Early reproduction is also positive for the offspring. The amount of pollutants descendants receive is lower if mothers initiate reproduction activities early because they have not yet built up high tissue concentrations. Similarly, an earlier onset of sexual senescence is a disadvantage in this respect because it halts the discharging process. A protracted lactation period is clearly beneficial for reproductive females because the amount of lipophilic pollutants that they transfer is high. This obviously depends on the time they start to feed again because then the pollutant uptake will counterbalance the discharge. However, the protracted lactation period may have adverse effects on the offspring because the milk is often more polluted than the food that decendants will consume once weaned. It is unclear how this resolves at the population level, i.e., whether the benefit for the reproductive female is higher or lower than the costs for the offspring.

A factor likely to lead to differential vulnerability between species is body size. Small species generally have higher levels

of pollutants relative to their body weight than those of larger body mass.

Metabolization is another operative factor in this context. The P450 enzyme system is the main physiological tool for metabolizing OCs. For example, this system can be induced by PCBs, mediated by the aryllhydrocarbon (Ah) receptor, which is found in mammals and birds. The metabolic ability, however, is not uniform among marine mammals. Overall, cetaceans have a lower metabolization capacity, as measured by phenobarbital (PB) and methylcholantrene (MC) types of activity. Initially, all cetaceans were thought to lack the (PB) type of enzyme. However, research has shown that several dolphin species possess at least some microsomal PB type of enzyme. Still, their PB and MC type of metabolic activity is usually lower than that of pinnipeds and terrestrial species. At a more specific level, ringed seals and harbor porpoises seem to have metabolic capacities intermediate between those of other seals and cetaceans. In conclusion, apart from the more apparent cetacean–pinniped difference in metabolic capacity, sharp differences also exist among species within any given taxa.

The critical question in this respect is, however, whether a low activity of PB-type and/or MC-type enzymes renders cetaceans more vulnerable to pollution, as has been suggested repeatedly. This may not automatically be the case. For example, PCBs can potentially elicit toxicity in at least two ways: as parent compounds (persistent congeners) and as metabolized congeners. The persistent compounds show a PB and mixed PB and MC type of toxicity associated with liver hyperproliferation, lowered levels of thyroxin and vitamin A, and a dioxin type of toxicity (MC) resulting in thymic atrophy, dermal disorders, and liver necrosis. Metabolization of parent compounds can result in at least two contrasting effects: a decreased level of dioxin type of toxicity and an increased metabolic-specific toxicity such as immunotoxicity. The resultant effect of a lower metabolization capacity therefore depends on the relative contribution of the mitigating influence of a decreased dioxin type of toxicity vs a continued PB and mixed PB/MC induction and the effect of reactive intermediates.

In this respect, attention should be drawn to the often misused concept of toxic equivalency. This concept is based on structure–activity relationships of contaminants with receptors. Tetrachlorodibenzo-dioxins (TCDD) and PCBs have a structure that fits the Ah receptor. The degree of induction by TCDD has been correlated with their toxic effects observed in laboratory animals. Given the similarity in structure of PCB congeners, the ability of these latter compounds to induce the Ah receptor-mediated response is expressed as a ratio to the induction by TCDD. This is called the toxic equivalency factor (TEF), which has been used extensively to assess the toxicity of PCB congeners and their mixtures with DDT and PCDD. That toxicity is calculated by multiplying the TEF of each compound by its concentration, and the sum of the resulting values is considered to be the total toxic equivalent (TEQ) for the mixture of compounds found in the sample.

However, it needs to be stressed that TEFs are based on laboratory animal models. Therefore, the TEQ for a given marine mammal sample only means the effect that the mixture of compounds found in that sample would have on a laboratory animal. Because (1) large differences between species exist in the induction of P450-based enzymes, (2) the toxicities of PCB metabolites are not incorporated into the calculations, and (3) the toxicity of modes other than that of a dioxin type are disregarded, the application of TEQ to assess the toxicological risk to which a particular species is subject to is not necessarily reliable. The same holds for extrapolating TEQ between species. We would therefore emphasize that the frequently used practice of assessing whether the toxic significance of a certain value of TEQ found in a marine mammal is lower/higher than a TEQ value found in a species where effects were observed is unfounded and scientifically unsound.

Another issue that remains to be clarified is the apparent ability of marine mammals, particularly observed in species in the northern arctic regions, to tolerate high levels of some heavy metals, such as mercury, lead, and cadmium. It is known that marine mammals are able to detoxify these metallic compounds by, for example, demethylating the highly toxic form of organic mercury into the less dangerous inorganic mercury, by the binding of metals to metallothioneins, or by the binding of selenium to mercury where inactive salts are produced. It is tempting to speculate whether the animals in those areas have evolved responses to mitigate the effects caused by the naturally occurring contaminants.

VI. Developments in Spatial and Temporal Trends of Pollutants

Data on levels of pollutants in marine mammals are more numerous for western Europe, North America, Canada, and Japan. Limited data are available for many other countries and regions (e.g., Africa, New Zealand, India), and very little information is available for the Southern Hemisphere. As mentioned in an earlier section, the fish-eating marine mammals from the midlatitudes (industrialized and intense agricultural use) of Europe, North America, and Japan have the highest loads (see Fig. 1). Residue tissue concentrations are lowest in the upper north polar region and the Antarctic. Nearly all of the OC contamination in marine mammals in the Arctic and Antarctic has reached these areas via atmospheric transport. Levels of the more volatile OCs are higher compared to PCBs and DDT and are distributed more homogeneously. This pattern of distribution of residue concentrations in marine mammals, however, is gradually changing. Levels of OCs are declining in the midlatitude areas, whereas they are increasing in regions distant from pollution sources. The transfer of OCs released in (sub)tropical countries to the atmosphere causes global redistribution. It is predicted that in the near to midterm future the Arctic and, to some extent, the Antarctic will become the major sinks for OCs.

Temporal trends of contaminants in marine mammals have been relatively little investigated because of the lack of long time series of samples and lack of comparability of the analytical results.

For PCBs, DDT, mercury, lead, and cadmium, some data on tissue concentrations in marine mammals from certain areas are available. In most heavily industrialized and agricultural regions, the production and use of DDT and PCBs was halted in the early 1970s. From the mid-1970s onward, levels of DDT

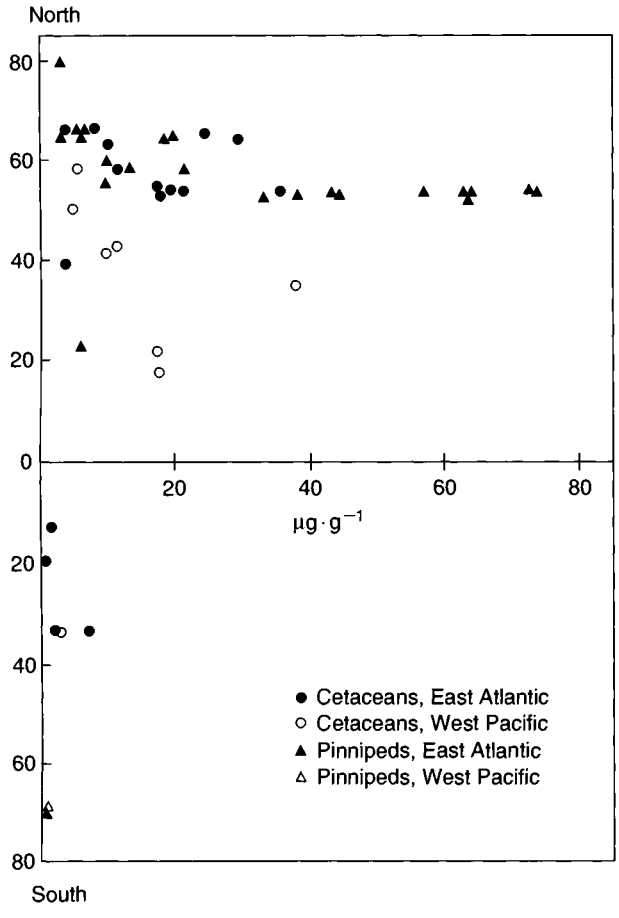

Figure 1 *Latitudinal ΣPCB concentrations (μg·g^{-1} wet weight) in blubber tissue of various marine mammals from the western Pacific and the eastern Atlantic.*

and PCBs in marine mammal tissues decreased. The decline in DDT levels was stronger than that of PCBs. In pinnipeds the decline was 80–90% for DDTs and 60% for PCBs. The difference is most likely due to less stringent control measures for PCBs; large quantities of these compounds have remained in use in many applications. The overall time trend for PCB and DDT levels in marine mammals is that concentrations have decreased since the mid-1970s. The decrease in DDT levels has continued thereafter. However, PCB levels in some areas leveled off at the end of the 1970s/early 1980s. Figure 2 shows the compartmentation of the global budget of all produced PCBs by industry. Given the fact that only 1% of all the PCBs produced has reached the oceans, that 35% are still in use, 30% are accumulated in dump sites, and that the fate of the other 34% is unknown, it is expected that the observed leveling off of the decrease in marine mammals will not be followed by a strong reduction in the near future. Trends for heavy metal pollution are less apparent. In general, it is accepted that between the mid-1970s and mid-1990s there was no clear trend for mercury and cadmium in pinnipeds from the Canadian Arctic and Greenland. On the contrary, levels of mercury and lead in pinnipeds from the Wadden Sea have decreased considerably.

VII. A Fundamental Approach to Address Pollution Impact on Marine Mammals

It is clear that a considerable amount of fundamental research is needed before it will be possible to adequately address the impact of pollutants on marine mammals. Realizing this situation, the International Whaling Commission (IWC), through its scientific committee, has developed a comprehensive program to investigate pollutant cause–effect relationships in cetaceans: "Pollution 2000+." At a later stage, the International Council for the Exploration of the Sea, through its

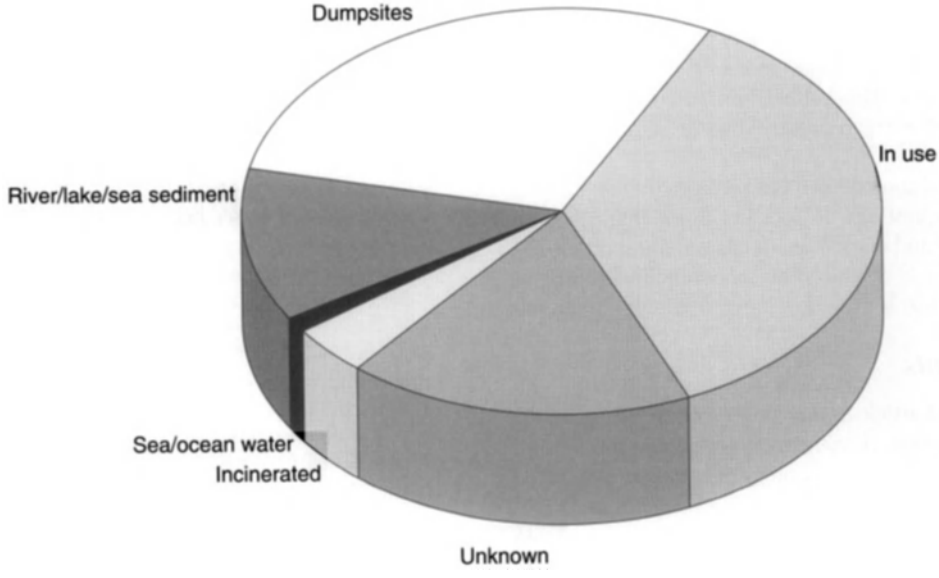

Figure 2 *Compartmentation of global budget of produced PCBs (kilotons).*

Marine Mammal Habitat Working Group, developed a similar research program, this time focusing on pinnipeds.

The ultimate objective of pollution studies as related to marine mammal management is to determine a predictive model to link tissue pollutant levels with effects at the population level. This is obviously a longer term goal. It is realized that if any progress is to be made within a reasonable time frame, a multidisciplinary, multinational focused program of research is required that concentrates on species and areas where there is most chance of success.

The mentioned programs earlier focused on PCBs because these chemicals can be used as model compounds of OC pollution. Moreover, PCBs are found at extremely high tissue levels in cetaceans, their effect on mammals are well known, and substantial information is available on their patterns of variation, geographical distribution, and tissue kinetics. The focal species in the IWC program are common bottlenose dolphin and harbor porpoise because both species occur in waters extending over a gradient of pollution and are likely to provide reasonable sample sizes.

In this program, two short-term objectives were established: (1) to select and examine a number of biomarkers of exposure to and/or effects of PCBs and try to determine whether a predictive and quantitative relationship with PCB levels in certain tissues exists and (2) to validate/calibrate sampling and analytical techniques to address such questions for cetaceans, specifically: determine changes in concentrations of variables with postmortem times and examine relationships between concentrations of variables obtained from biopsy sampling with those of concentrations in other tissues that can only be obtained from fresh carcasses.

Because the ultimate aim of the program is to look at potential effects of pollutants at the population level, it was considered necessary to test and develop techniques to feasibly collect data from large numbers of free-living animals. Because biopsy techniques allow such a type of sampling, an initial step in the project has been to calibrate information obtained from biopsy sampling with that collected from dead animals. It was also considered similarly important to ascertain the influence of postmortem time on levels of contaminants and on indicators of exposure and effect. This calibration is needed to ensure that collected samples are representative of actual pollutant loads.

It is clear that Pollution 2000+ is a core program to address some fundamental questions. It does not imply that other research on pollutants and marine mammals is not important. On the contrary, its value is enhanced by cooperation with existing studies and as a context for the development of new programs.

Acknowledgments

The nature of this article in the context of this encyclopedia implies the use at length of work of colleagues in the field of marine mammalogy and ecotoxicology. The views presented here have been shaped partly by our own research, but definitely also by the discussions held with many colleagues within and outside this field of expertise, as well as the reading of published references. We acknowledge these colleagues and sources for their contribution and have tried to stay as close as possible to their original findings and cited directly from their work where relevant.

Popular Culture and Literature

PAUL H. FORESTELL
Southampton College of Long Island University, New York

A general survey of current human behavior provides a rather paradoxical view of our modern cultural perception of marine mammals. On the one hand, it would seem by almost any indicator that human interest in marine mammals is at a fever pitch. Excursions to view marine mammals in the wild draw countless participants from many cultures and age groups (Fig. 1). Attendance at marine parks and display facilities is at an all time high. The past decade has seen an explosion in books and videos about marine mammals. The sale of marine mammal "themed" merchandise includes thousands of products worldwide. Campaigns to protect marine mammals and their habitat exist on every continent, and the number of local and national governments involved in legislative agendas related to marine mammals is staggering. There has been an exponential increase in the number of marine mammal research projects, many involving direct public participation, and the population of marine mammal researchers is growing steadily.

On the other hand, there are at least five species of marine mammal [Chinese river dolphin (*Lipotes vexillifer*), Gulf of California harbor porpoise (*Phocoena sinus*), North Atlantic right whale (*Eubalaena glacialis*), North Pacific right whale (*E. japonica*), and Mediterranean monk seal (*Monachus monachus*)] in danger of becoming extinct because of human activities. Attempts to interact with dolphins in the wild are claimed to be disturbing the dolphins and endangering humans. Efforts to eliminate the killing of marine mammals in fisheries-related by catch are not succeeding. Sealing continues, and efforts to cull seal populations to protect fisheries are on the rise. Commercial whaling has increased over that of a decade ago. The oceans are being poisoned: 3 million pounds of trash were cleaned from beaches in the United States in 1999, and that amount must be assumed to represent only a fraction of material floating in the world's oceans.

In a recent in-depth analysis, David Lavigne, Victor Scheffer, and Stephen Kellert (1999) concluded that there has been a significant evolution in North American attitudes toward marine mammals since the early 1960s. These authors reviewed a diverse range of indicators, including patterns of consumptive exploitation, tourism, media attention, legislation, nongovernmental organization initiatives, and scientific research. They summarized their findings by noting that "With few exceptions . . . North American attitudes toward marine mammals have shifted from a focus on their killing and material utilization to a more aesthetic interest in observing these creatures in the wild, in captivity, and in various media forms." (Lavigne *et al.*, 1999). The most notable exception to the shift in focus is a general willingness to grant special status to aboriginal groups to hunt marine mammals. The authors further concluded that the change in attitudes has resulted primarily from a rapid urbanization of the human population, increased knowledge of marine mammals through new research and extensive media exposure, and a shift in ethical values.

It seems unarguable that North American attitudes (and those of many nations referred to as "industrialized") have changed from a focus on material utilization. However, a qualitative analysis of available behavioral evidence (i.e., what people actually do, rather than what they express as a value or attitude in surveys) suggests that humans (including North Americans) still basically regard marine mammals as a commodity. A consideration of how marine mammals are represented in current literature and the popular media; the types of marine mammal issues that win public attention; the types of activities that humans engage in around marine mammals; and the role that government plays in managing such activities suggest that rather than a shift from material utilization to aesthetic interest, the shift has simply been from one sort of utilization (or exploitation) to another. In brief, while the general trend has been to an

increasing effort to protect and conserve, the motivational basis for the change remains highly anthropocentric.

I. Background: Shaping Cultural Perceptions of the 1950s

To understand current perspectives on marine mammals we need not only review current evidence, but also provide a summary characterization of the past. Although more completely detailed elsewhere, a brief history of human interactions with marine mammals is presented here in order to provide an appropriate context for considering current perspectives. A review of patterns in the literature and behavior of humans since 1950s is then undertaken to consider the hypothesis that present attitudes of humans toward marine mammals are, as they have been since the dawn of time, based primarily on an anthropocentric worldview.

The recorded history of human interaction with marine mammals begins with a perspective based on small-scale, direct exploitation in pursuit of vital resources. From opportunistic scavenging of stranded animals to organized HUNTING of locally available species, subsistence efforts were focused on obtaining food and by-products needed by the hunters themselves for survival. By its very nature, subsistence hunting depends on an extended knowledge of the ecosystem in which the hunter and the hunted live. Both predator and prey occupy the same setting and require the same kinds of knowledge to survive. Successful subsistence hunting presupposes a body of knowledge, a set of skills, a motivational focus, and sensitivity to the psyche of the hunted that form little or no part of a strictly "utilitarian" exploitation of natural resources. The Japanese novelist Natsuki Ikezawa described subsistence whale hunting as requiring "a compassion with Nature, a harmony with surroundings. To eat and to be eaten are the two sides of the same deed." It is common within subsistence cultures to promote rituals of compassion and respect for that which provides sustenance, even while it is being killed. This is reflected in Polynesian chants, Inuit ceremonies, and the myths of aboriginal peoples throughout North America, Australia, and Asia.

Subsistence hunting extended, relatively unchanged, over a considerable period of time in human history (Fig. 2). Norwegian petroglyphs (rock drawings) believed to be nearly 4000 years old show men in boats, along with seals, dolphins, and whales. Harpoons with poison tips, nets, and stranding drives were employed by indigenous hunters in many parts of the world, including Japan, North America, the South Pacific, and Europe. Small-scale trading of products frequently occurred within localized networks of nearby communities (e.g., among the Arctic Inuit). However, subsistence hunting of marine mammals up until the 12th century primarily involved hunting for the immediate use of the community; for food, clothing, and other products of domestic utility. In almost all cases, the traditions of these subsistence hunters incorporate myths, chants, and rituals honoring the quarry and the skills needed to overcome it. This is an important consideration in understanding current cultural perspectives on marine mammals: a representation of the development of current attitudes as a linear evolution from utilitarian to aesthetic (as presented by Lavigne *et al.*, 1999) is incomplete on two counts. Ancient subsistence attitudes were far more complex than the utilitarian characterization would imply, and current perspectives are far less aesthetic than use of that term would prescribe. In fact, current perspectives on marine mammals probably represent a relatively recent reoccurrence of the same devolution of attitudes from holistic to exploitative that occurred during the transition from subsistence whaling, to commercial whaling, to industrialized whaling. In the present day, we have been witnessing a transition from "subsistence whale watching," to "commercial whale watching," to "industrialized whale watching," as detailed below.

Figure 2 *Tongan whaler c. 1970. Subsistence hunting has been conducted for centuries with essentially unchanged techniques. Photograph by Bill Dawbin.*

The change from subsistence to commercial whaling was accompanied by a significant change in human perspective on marine mammals during the 11th and 12th centuries. It was during that period that the Basques of Spain apparently developed and implemented the first truly "commercial" hunt and initiated a fundamental change in attitude that would sow the seeds of "industrialized" whaling some 600 years later. The Basques probably learned whaling techniques from the Normans, Norwegian settlers who populated the Bay of Biscay during the 9th century. The Basques, tenacious settlers on a critical access route to the Iberian Peninsula (and onward to Africa), were not subsistence whalers. Originally pastoralists who tended flocks in the mountains, they eventually founded the kingdom of Navarre, which included a number of tiny fishing villages along the Biscayan coast. There they found the North Atlantic right whale, which migrated into the Bay of Biscay each year from autumn through spring. The Basques were poised between a vast, untapped resource on the ocean side and a steady flow of traders to the world's centers of commerce on the other. They found a ready market for almost the entire carcass of the whales they brought ashore. Oil for lamps, lubricants, and soap; BALEEN for corsets, buggy whips, fishing rods, and brushes; bones for fence posts and portals; skin for footwear; and meat, blubber, and tongue for food. For 300 years Basque whalers pursued the right whale: first across the

Bay of Biscay and then to the far side of the Atlantic. So good were they at their craft that, as the need for whale oil grew in Europe, they became teachers of those who would take commercial whaling to the furthest reaches of the world's oceans.

In its earliest form, and as practiced by the Basques, commercial whaling involved the application of subsistence techniques, but for the realization of profit rather than direct consumables. As the theater of endeavor moved from the Biscayan coast to North America, Spitsbergen, and the open seas of the Atlantic and Pacific, the method of catching and killing whales changed little, although the processing of whales was carried out variously either on shore or onboard the whaling ship itself. The perseverance of hunting techniques may be verified by a survey of first-hand accounts of whaling operations. Examples include Guillame Rondelet's rendition of Basque whaling in Europe in 1568; Francis Olmstead's description of American sperm whaling in the Pacific in 1841; and Robert Cushman Murphy's documentation of a 1913 sperm whaling voyage to the South Atlantic. Without benefit of modern machinery, commercial whalers using sailing ships, whale boats, and handheld harpoons successfully pursued right whales, bowhead whales (*Balaena mysticetus*), and gray whales (*Eschrichtius robustus*) to near extinction and decimated known sperm whale (*Physeter macrocephalus*) populations. A similar fate was visited upon elephant seals (*Mirounga* spp.), walruses (*Odobenus rosmarus*), and sea otters (*Enhydra lutris*), while Steller's sea cow (*Hydrodamalis gigas*) was completely extirpated.

An important change that accompanied the transition from subsistence to commercial hunting was that animals were hunted and killed by humans who were not otherwise connected to the ecosystem or the animals targeted by the enterprise. Strangers came from faraway places for the sole purpose of obtaining as much of the resource as could be most quickly taken away for sale in distant markets (Fig. 3).

By the middle of the 19th century the cost of whale oil climbed as stocks of whales declined. Alternative products were derived from turpentine, cottonseed, and linseed and replaced whale oil in a number of uses. The distillation of petroleum was the single greatest factor in the decline of commercial whaling as practiced by the sailing ships of the American whaling fleets at the end of the 19th century.

Figure 3 *As commercial hunting replaced subsistence hunting, the public came to view whales as circus curiosities rather than honored quarry. The head of a dead right whale forms the backdrop for a family snapshot. (Painting by Larry Foster, 1974).*

The transition from commercial whaling to industrialized whaling began in 1863 when Svend Føyn, a Norwegian sealer, made his first successful kill of a blue whale (*Balaenoptera musculus*) using a cannon mounted on the bow of a 90-foot steamship that fired a 100-lb. harpoon with an exploding tip. The combination of cannon, exploding harpoon, and steamship meant that large fast whales could be dispatched with relative speed and efficiency. Readily accessible populations of blue, fin (*B. physalus*), and humpback whales (*Megaptera novaeangliae*), unprofitable targets for sailing ships, gave new life to commercial whaling. For 40 years Norwegian-style whaling spread around the world. At the turn of the 20th century, a German chemist discovered a way to convert animal oil into solid fat. Soon after, additional processing was developed to rid whale oil of its inherently strong taste and odor. The result was that whale oil once again became a commodity of worldwide importance, particularly for making margarine and soap, and whaling once more became a profitable enterprise.

Rapid developments in technology soon made it possible to hunt and kill whales more efficiently and in greater numbers. In addition, changes in the economic policies of industrialized nations widened the gulf between consumer and consumed. As both demand and competition grew the philosophies and practices of the industrial revolution were incorporated into whaling enterprises, significantly altering the way whalers did business. The goal was no longer the realization of profit, but maximization of profit. This led, during the first half of this century, to a phenomenal arms race against whales. As the handheld harpoon was replaced with Svend Føyn's cannon, the try-pots gave way to huge pressure cookers; and gigantic hydraulic tail-grabbers dragged entire blue whales out of the ocean, through stern slipways, and onto the flensing decks of pelagic factory ships. By the 1950s a 65-foot whale, weighing 80 tons, could be hauled up the slipway and turned into processed oil, frozen meat, and ground-up fertilizer in just over an hour. By the 1960s nearly every major nation of the world had participated in the decimation of whale stocks—some 30,000 to 50,000 whales per year were taken in the Antarctic alone between 1930 and 1960 (Fig. 4).

By the 1950s it could well be said that the human attitude toward marine mammals had become a strictly utilitarian one. Although the industrialization of slaughter occurred on a grand scale with regard to whales, commercial hunting of elephant seals for oil and sea otters, fur seals and harp seals (*Pagophilus groenlandicus*) for their coats had disastrous results on pinniped populations throughout the world and sea otter populations throughout their range. The hunt for sirenians has never progressed to anything near an industrialized effort. A combination of subsistence and small-scale commercial hunting has generally been sufficient to reduce known populations to extinction (in the case of Steller's sea cow) or near extinction [in the case of manatees (*Trichechus* spp.) and dugongs (*Dugong dugon*)]. Hunting of small cetaceans throughout the world has also been marked by the shortsighted exploitation of pilot

Figure 4 *By the 1950s, commercial whaling had become a sophisticated industrialized operation. Courtesy of The Kendall Whaling Museum, Sharon, Massachusetts.*

whales (*Globicephala* spp.), killer whales (*Orcinus orca*), bottlenose whales (*Hyperoodon* spp.), spinner dolphins (*Stenella longirostris*), spotted dolphins (*S. attenuata* and *S. frontalis*), and common dolphins. What is unique to the history of human interaction with dolphins, compared with our exploitation of other marine mammals, is the massive destruction of pelagic species through bycatch mortality associated with modern drift nets and purse seining. Industrialized fishing techniques have killed more dolphins in the last 50 years than were killed in the entire prior history of humankind. The late David Gaskin succinctly described the attitude underlying the period of industrialized whaling as an ethical failure. "We could have conserved many other resources than just the stocks of large baleen whales, if the dead-end philosophy of the economic industrial growth ethic could be circumvented, and if the aces in the deck of cards with which we play were not invariably short-term economic gain and political expediency."

II. The 1950s: Out with the Old

Beginning in the 1950s there was growing scientific evidence of the complexity of marine mammal BEHAVIOR. Stimulated by the work of John Lilly in the United States, researchers in European, Japanese, and other American laboratories conducted neuroanatomical and electrophysiological studies of cetacean brains that challenged assumptions about the importance of BRAIN SIZE and identified a number of unique characteristics in cortical architecture, structural morphology, degree of lateralization, and brain-wave patterns. Philosopher, anthropologist, and ecologist Gregory Bateson explored the intricacies of dolphin social behavior by studying a group of spinner and pantropical spotted dolphins at Sea Life Park in Hawaii. William Schevill and colleagues (including his wife Barbara Lawrence) began collecting acoustic recordings that would eventually document the underwater sounds of nearly three dozen species of marine mammals, including odontocetes, mysticetes, and pinnipeds. David and Melba Caldwell explored the acoustic and social behaviors of whales and dolphins in the wild.

These researchers heralded an important shift in scientific focus that accompanied the end of the grand age of whaling during the 50s and the beginnings of "modern" marine mammal studies in the 60s. Earlier studies of marine mammals had been carried out, for the most part, on the flensing decks of whaling ships, on the slipways of coastal whaling stations, or on the rocky shores of pinniped haul-out and ROOKERY sites. Information gleaned from such studies was applied to statistical determinations of the size of harvestable stocks and the development of new commercial applications for whale products. R. B. Robertson's account of life aboard an Antarctic factory whaling ship ("Of Whales and Men," A. A. Knopf, 1954) describes such an ap-

proach. In one chapter, the author notes some of the questions entertained by the chemist and biologist on board the ship:

> Why has no female sperm whale ever been sighted or killed in the Southern Ocean, though many thousands of old males are killed there every year. . . . At what rate would whale tendon from the flukes be absorbed by the human body if it were put on the market in huge quantities of twenty-foot strands to replace the rare and expensive kangaroo tendon presently used as surgical sutures to repair hernias. . . . What is the nutritive value of a properly cooked fin-whale steak. . . . How could one make the whale—as it should be—the world's main supply of the valuable new pituitary and adrenal hormones (pp. 240–241)?

A similar drive to collect field data to better inform the management of a commercial harvest prompted a group of American biologists to investigate the life history of gray whales by studying dead ones during the 1960s. From 1959 to 1969 special permits were issued to the Del Monte and Golden Gate Fishing Companies in Richmond, California, by the federally run Marine Mammal Biological Laboratory in Seattle, Washington. The permits allowed the collection of 316 gray whales as they traveled along the west coast of the United States during their annual north–south migration between Mexico and the Bering, Chuckchi, and western Beaufort seas. The description of the whales' life history was based on shipboard and aerial observations of their migration numbers and timing, and documentation of a series of body measurements from the 316 whale carcasses. Data included overall length and weight; width of fluke and length of flippers; thickness of blubber; number and size of baleen plates; degree of vertebral fusion; condition of mammary glands, size of ovaries, and diameter of uterine horns in females; length of penis and weight of testes in males; number of wax ear plug growth layers; number and type of external body scars; number and type of endo- and ectoparasites; and stomach contents. Data were used to determine numbers and migratory patterns of different age/sex classes; prey species; reproductive patterns; and susceptibility to parasites and predators (other than humans). Dale Rice and Allen Wolman reported the results of the study in 1971. The expressed purpose of the work was to provide sound biological knowledge to ensure a wise management program if commercial exploitation, ended by international agreement in 1946, should resume.

Compare the questions of Robertson's chemist and the Marine Mammal Biological Laboratory's biologists with those posed by the legendary Kenneth Norris, who studied both captive and wild dolphins in California and Hawaii during the 1960s and early 1970s. In "The Porpoise Watcher" (W. W. Norton, 1974), Norris considers the intricacies of social organization in Hawaiian spinner dolphins:

> . . . most of the subgroups we see in active schools have no clear function. Are they family groups, play groups, are they divided by sex or age. . . . What is it that regulates porpoise school numbers? Why don't their schools grow and grow until every scrap of natural resource is used, as humans are busy doing? What racial wisdom, somehow lost by humans as they adopted civilization, keeps them in balance (pp. 199–200)?

Norris' approach to the study of live animals represented a significant change in marine mammal science that ultimately reshaped the public's perception of marine mammals in many parts of the world (Fig. 5). The change appears to have been born in the observations of live animals by scientists whose first view of their subjects was not from a flensing deck or slaughtering beach. Many of the scientists who developed an interest in marine mammals during the 60s, unlike those of previous decades, did not come out of the whaling industry or from government agencies responsible for managing various types of "fisheries" (including whaling and sealing). Access to marine mammals is logistically and therefore economically challenging. Until World War II there were generally two ways one could study a marine mammal: stumble across a stranded one on a remote beach or accompany commercial harvesters on their hunts. These were the settings that provided material to shape cultural perspectives on marine mammals right up until the 1950s.

Books available to the public during the first half of this century were based primarily on popularized accounts of whaling voyages, or historical descriptions of commercial whaling. For example, in 1913 the Boy Scouts of America sponsored the publication of Frank Bullen's 1898 whaling account, "The Cruise of the Cachalot," as part of the Every Boy's Library series. In the preface the book is proffered as an antidote to "cheap juvenile literature" and as a means of capturing a young

Figure 5 *By the 1960s, biologists such as Ken Norris were becoming more interested in observing the behavior of marine mammals in the wild. © Flip Nicklin (Minden Pictures).*

man's attention with "tales of daring enterprise and adventurous good times." There were few natural history descriptions produced for public consumption prior to World War II. Approximately 230 works of fiction are listed with dates of publication in an informal bibliography of fiction books for adults produced by Trisha Lamb Furstein and colleagues in 1998 that have cetaceans as major or secondary subjects (www.physics.helsinki.fi/whale/literature/fic_main.html). The list shows only two books printed between 1900 and 1950. One is a play and the other appears to be based on ancient myths about a friendship between a dolphin and a boy.

III. The 1960s and 1970s: In with the New

The landscape changed dramatically after World War II, and by the 1960s a significant transition was underway in human perceptions of marine mammals. It would be simplistic to point to one central mechanism behind the groundswell of interest in marine mammals (more specifically, cetaceans) that occurred during this period. The exotic undersea portraits and exciting escapades of Jacques Cousteau; the new age writings of John Lilly; the increasing exposure to whales and dolphins in zoos, parks, and oceanaria; the "protest" mind-set of the 60s and 70s; and the growing awareness of conservation issues due to books by (among others) Aldo Leopold, Rachel Carson, and Victor B. Scheffer all played pivotal roles. The combined effect of these elements was to generate an entirely new look at marine mammals. Four predominant themes emerged quickly and simultaneously throughout North America, the United Kingdom, Europe, and Australia/New Zealand during the 1960s and 1970s: dolphins (and whales) exemplify cognitive capabilities rivaling human capacity; the opportunity to watch dolphins and whales is exciting and entertaining; the worldwide slaughter of whales is unethical and biologically disastrous; and marine mammals demonstrate a number of adaptations to the marine environment that may have important applications to human technology. These have remained the four corners of the box in which humans appear to have marine mammals contained: intelligent, entertaining, endangered, and valuable to humans.

The popularization of cetaceans as highly intelligent animals has been largely due to the writings of John Lilly, beginning with his book "Man and Dolphin" (Pyramid Publication, 1961), chronicling his work with dolphins during the late 1950s. Lilly was not the first scientist to note the possibility of complex cognitive capability in cetaceans—that honor probably goes to psychobiologist Arthur McBride, the first curator of Marine Studios, a facility built in St. Augustine, Florida, in 1938. In 1948 he and the Canadian psychologist Donald Hebb published observations of bottlenose dolphin social behavior. However, Lilly used his position successfully as an acclaimed neurophysiologist with the National Institutes of Health to foster an enduring and widespread public perception of whales and dolphins as near-mythical species with mental capacities rivaling or surpassing those of *Homo sapiens*. Lilly's succession of books for the popular press (but especially "Man and Dolphin," 1961; "The Mind of the Dolphin," Doubleday, 1967; and "Communication Between Man and Dolphin," Crown Publishers, 1978) led to a hostile reaction from the scientific community, which disputed the validity of his claims. Overall, however, this characterization of cetaceans as socially and cognitively complex animals with rich emotional lives guided by a code of ethics resonated with the public. Paraphrasing one of his lectures, John Lilly wrote in "The Mind of the Dolphin" (1967, reprinted in "Lilly on Dolphins," Doubleday, 1975):

> I wish to tell you something of what we have learned of a group of uninhibited nudists who have never worn clothes. They have never walked on their own two feet. They have no property. They cannot write their own names. They have no commerce or stores. They have no radio, no TV. They have no fireplaces, nor furnaces, or any fire at all. They have no atomic or nuclear bombs, or power plants. They have no written or printed records. They have no libraries or paintings. In spite of all these handicaps, they are successful. They have big brains and have readily available food supplies. They have the sense to go south in the winter and to go north in summer. They have the ability to out-think, outmaneuver and fight successfully against their enemies. Finally, they think enough of us to save each of us when they find us in trouble (p. 291).

Sexually liberated, antimaterialistic, antiwar, self-sufficient, intelligent, and altruistic. What suite of characteristics could have more poignantly caught the attention of an up-and-coming generation of "baby boomers" protesting post-World War II materialism, the Vietnam war, restrictive social mores, and cutthroat international capitalism? Lilly's message is clear—sun, surf, and sex—with big brains, and no guilt. Could it get any better?

Lilly's writings and public lectures generated a backdrop against which a new-age philosophy of dolphin as genius, healer, therapist, and spiritual advisor flourished. Although Lilly's interpretations of his findings were frequently based upon gratuitous explanations, he was instrumental in a number of critical discoveries concerning the peculiarities of dolphin acoustic behavior (Fig. 6).

One can hardly discuss the work of the new brand of marine mammal scientist that emerged in the 60s without noting the importance of marine mammal display facilities, beginning with Marine Studios (later called Marineland, Florida). Records of marine mammals being kept in captivity for public amusement date back to ancient times. By far, pinnipeds comprise the majority of display animals. They are relatively easy to take from the wild, adapt well to captivity, and in many cases are trained easily to amuse human spectators. Cetaceans, however, require a degree of knowledge, resources, and commitment that few display facilities are able to meet. Marine Studios was the first facility to make a dedicated commitment to maintaining bottlenose dolphins (*Tursiops truncatus*) in captivity in its role as an "oceanarium" rather than aquarium or zoo. Once Marine Studios established that dolphins could be placed successfully on display, however, the postwar climate fostered the rapid growth of similar facilities, first in the United States and then throughout the world.

From the beginning those responsible for cetaceans at oceanaria encouraged outside scientists to explore the biology and

Figure 6 *Dr. John Lilly, neurophysiologist, was a pioneer in the study of dolphin cognition.*

behavior of the animals at their facilities. Arthur McBride, and later Forrest Wood at Marine Studios; Kenneth Norris, the first curator at Marineland of the Pacific (the west coast "sister" institution of Marine Studios); his graduate students and colleagues William Evans at Hubbs-Sea World Research Institute and John Prescott at the New England Aquarium; Tap and Karen Pryor at Sea Life Park; and Murray Newman at the Vancouver Public Aquarium all opened their doors to biologists, neuroscientists, anthropologists, physiologists, psychologists, acoustical engineers, and an ever-widening range of other professionals with an interest in studying live animals. At a time when television and Jacques Cousteau were flooding into American homes, the collaboration between science and the entertainment industry had a tremendous impact on the public perception of marine mammals. Scientists were not used to dealing directly with the public, but those who ran the oceanaria were. As scientists began to discover more and more about the hidden world of whales and dolphins, the oceanaria incorporated much of that knowledge in their decisions about what animals to capture, improvements to their husbandry programs, and, most importantly, in the subject matter of their shows.

One indication of the "coming of age" of dolphins as a significant cultural phenomenon in the United States was the 1960s production of two movies and a television series based on the adventures of "Flipper," a common bottlenose dolphin, and Sandy Ricks, the young son of a fisherman (later changed to a park ranger). The original movie, released in 1963, hinted of the ancient stories of the relationship between a boy and a dolphin, such as described in Iassos, Greece, and the Roman town of Hippo in Africa. In the movie, a dolphin met a young boy and they developed a friendship that led to a bonding that surpassed species distinctions and spawned a sequel. The mythical proportions of the story did not survive long, however, and the subsequent television series seemed to quickly develop into a marine version of "Lassie, Come Home."

While the 1960s initiated a true Renaissance in the portrayal of marine mammals, oceanaria helped emphasize a conceptual "divide" that continues to the present. With limited exceptions, modern public attitudes about marine mammals became (and continue to be) strongly predisposed toward whales and dolphins. In reviewing the status of marine mammals in popular literature and culture, it is important to bear the following caveat in mind. The typical representation of "marine mammal" does not reflect the diversity and extent of actual species. Marine mammals include over 120 SPECIES, divided into four general categories [whales, dolphins, and porpoises; seals, sea lions, and walruses; manatees and dugongs; sea otters and polar bears (*Ursus maritimus*). However, the preponderance of available information on nature excursions, visits to display facilities, and the sales of books, videos, and other merchandise suggest that the prototypical representative of the category "marine mammal" is one of a small set of relatively well-known cetacean species [e.g., common bottlenose dolphin, killer whale, humpback whale, sperm whale].

Although occasional interest in other marine mammals has developed with respect to specific issues [e.g., the killing of neonatal harp seals (*Pagophilus groenlandicus*) for their white fur coats in Canada; the decimation of Caribbean manatee (*Trichechus manatus latirostris*) populations from boat collisions in Florida; competition between sea otters and abalone fishermen in California], it remains clear that cetaceans have drawn public attention in a way that far outdistances the attention generally paid to pinnipeds, sirenians, or sea otters. This difference is despite the fact that about two-thirds of the marine mammals held in captivity since 1973 in North America are either California sea lions (*Zalophus californianus*) or harbor seals (*Phoca vitulina*). The most commonly displayed cetaceans is the common bottlenose dolphin, which generally makes up about 20% of the total number of animals on display. Killer whales, although small in number, have generated a huge marketing success for their keepers. Much of the attraction of cetaceans appears to be related to a fascination with the size, beauty, strength, and perceived INTELLIGENCE of these two most frequently seen examples. While sea lions balance balls on the end of their nose and make hilarious barking sounds on cue in oceanaria and marine parks, captive whales and dolphins cooperate in the development of spectacular water shows that train audiences to see them as powerful, beautiful, fun-loving, and intelligent (Fig. 7).

Marine mammals generated an exponential growth in interest among the public during the 1970s. Expansion in the number of facilities displaying marine mammals, the high-profile efforts of the "Save the Whales" movement, and the development of marine tourism excursions targeting marine mammal viewing

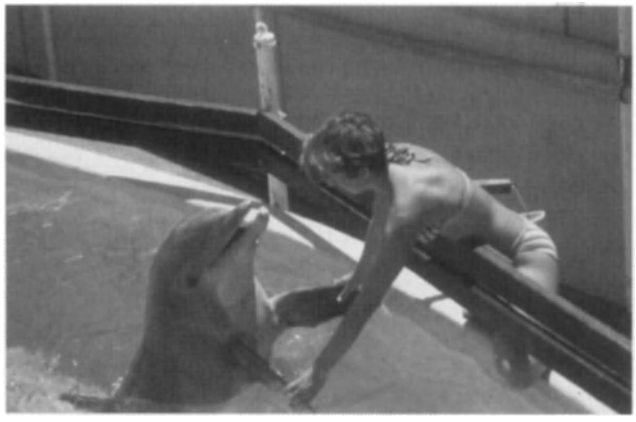

Figure 7 *The common bottlenose dolphin* (Tursiops truncatus) *is the prototypical marine mammal for most humans. Paul H. Forestell.*

were all symptomatic of the increasing interest. One significant influence in the perception of marine mammals by the public was the rapid growth in underwater images of whales and dolphins. Although television had introduced the world to the accomplishments of Jacques Cousteau and the crew of the *Calypso*, their exploits seemed far out of reach for the average individual. Cousteau's books and television programs emphasized the dramatic nature of exploring beneath the surface of the ocean. Using scuba, sophisticated oceanographic equipment, and sheer nerve, Cousteau and his men peeled back the layers of the ocean in a fashion few members of the public thought possible. Until the late 70s, a sense of the impenetrability of marine mammals was perpetrated based on the accounts of explorers, whalers, sealers, and fishers. As late as 1975, an article in *Aubudon* magazine on marine mammals had no photographs, but was illustrated with artwork. *National Geographic* magazine featured articles on killer whales in 1966, gray whale in 1971, and right whales in 1972 and 1974. The photographs and accompanying stories leave one with the clear impression that such experiences were the prerogative of a highly specialized breed of underwater adventurer—pioneer underwater photographers such as Howard Hall, William Curtsinger, Charles (Chuck) Nicklin, Jen and Des Bartlett, Stan Waterman, and Al Giddings—generally working in the company of field scientists in exotic places.

Then the landscape changed significantly. James Hudnall, a freelance photographer and self-styled whale researcher, helped lead the way. In a 1977 *Audubon* article, Hudnall wrote of venturing into the winter home of the North Pacific humpback whale offshore of Maui, Hawaii, beginning in 1974. Diving from a small inflatable boat, often by himself, with no more equipment than a mask, snorkel (sometimes a scuba tank), fins, and underwater camera, Hudnall revealed the first protracted look at living whales. He described the huge animals with which he swum in tropical waters as "gentle, clever, passive, and rational beings," and he provided the spectacular images to prove it. Hudnall's photographs brought a very different image of marine mammals to the public (Fig. 8).

By the end of the 1970s the public was sensitized to a perception of marine mammals, especially the great whales, as objects of wonder and mystery; to be held in awe rather than fear; and to be protected rather than hunted. A popular video for *National Geographic* in 1978 (*The Great Whales;* written, produced and directed by Nicholas Noxon) represented the changing view rather well. Included in the video was actual footage of modern whaling operations—and it was poignantly contrasted with footage of killer, blue, humpback, and gray whales that mirrored the message in Hudnall's article for *Audubon* magazine.

Just as Hudnall's photographs softened the public's perception of whales, additional discoveries about the sounds that whales make reinforced the idea that whales and dolphins engage in complex communication behaviors. Sounds made by humpback whales had been documented as early as 1952 by U.S. Navy personnel using deep-water eavesdropping systems developed to detect submarines. In 1971, however, Roger Payne and Scott McVay reported the first detailed characterization of the sounds in the journal *Science*. Because of the complex nature of the sounds, and on the basis of their structure and orderly sequence, Payne and McVay referred to the acoustic displays as SONGS. Subsequently, Roger Payne, his wife Katy, and a number of their students showed that the songs, produced only by males during the breeding season, changed slowly over successive years. In any given season, however, all males within a breeding group appeared to sing the same song. It was shown ultimately that song characteristics could be used to identify separate stocks of whales.

The impact of the song on the public was dramatic. Musicians like Paul Winter incorporated the sounds into their recordings. Roger Payne, a creative and charismatic individual, even managed (with Carl Sagan's help) to get a recording of humpback song included in the materials placed aboard the Voyager spacecraft to provide potential "other intelligences" in the galaxy with artifacts of earth. In January of 1979 a plastic 45-rpm recording of humpback whale song was included as an insert accompanying an article in *National Geographic* on

Figure 8 *James Hudnall was one of the first to introduce the public to images of whales as gentle, curious animals. Pacific Whale Foundation/Greg Kaufman.*

Payne's work. The hauntingly beautiful sounds of the humpback whale constituted one more piece of evidence that marine mammals demonstrate a high level of cognitive capability.

Lavigne *et al.* (1999) noted that during the 1970s the rate of marine mammal publications increased from fewer than 10 titles per year to more than 20. As noted earlier, there was also a significant change in the nature of books published. Farley Mowat's "A Whale for the Killing" (Atlantic Monthly Press, 1972) emphasized the clash between old values and new sensitivities in his fictionalized account of a true incident in Newfoundland, in which locals used a stranded fin whale for target practice. The growing perception that cetaceans are uniquely worthy of our attention because of their intelligence is evident in "Mind in the Waters," edited by Joan McIntyre (Scribners, 1974). The book is an attractive compendium of art, editorial, history, science, and philosophy regarding human association with marine mammals. Scientist Ken Norris ("The Porpoise Watcher." W. W. Norton, 1974) wrote eloquently about the day-to-day lives of dolphins and whales. One of the first "inside" views of a display facility occurred in "Lads Before the Wind" (Harper & Row, 1975) by Karen Pryor, head trainer at Sea Life Park in Hawaii. Other books for the popular press included resource texts such as L. H. Mathews' "The Natural History of the Whale" (Columbia University Press, 1978) and the fictionalized natural history account of "The Last Blue Whale" (Harper & Row, 1979) by Vincent Smith. Fictional writings with marine mammals as central characters were few and largely forgettable.

Dolphins often appeared as science fiction creatures, based on characterizations extrapolated from John Lilly's writings, and demonstrating extraordinary powers of perception, intelligence, and COMMUNICATION. The biggest market for books during this period appears to have been for natural history accounts of whales and dolphins, and children's literature. Television productions featuring marine mammals were few in number, and the most notable movie representation was *The Day of the Dolphin*, starring George C. Scott and directed by Mike Nichols (1973). This box-office hit helped solidify public attitudes about the intelligence of dolphins and raised questions about the training of dolphins by the military for a variety of warfare applications.

One of the effects of the exposure to whales and dolphins in oceanaria and in limited television coverage during the 1970s was the realization among the public that at least some species of marine mammals were very accessible in the wild. Whale watching became a rapidly growing industry. Whale watching first began in California and Mexico in 1955 (gray whales). In the 1970s it developed off the New England coast [humpback, fin, minke (*B. acutorostrata*) and right whales] and in Hawaii (humpback whales). It soon spread to other areas in North America [e.g., killer whale and gray whale watching in the Pacific Northwest; humpbacks in Alaska; blue whales and beluga whales (*Delphinapterus leucas*) in the St. Lawrence River, Canada].

The changing interest in whales and dolphins throughout the 70s was one of the discovery—the realization they were ENDANGERED (which launched the "save the whales" movement); that they are cognitively complex; that they can be maintained in captivity to the delight of the public; and that they can be found easily virtually throughout the world. All these discoveries opened the door to a changed relationship between humans and marine mammals. Whales and dolphins became valuable for their biological and aesthetic significance rather than for their consumptive significance. However, it did not necessarily follow that they were no longer viewed in a utilitarian manner. In fact, it appears that a wide variety of nonconsumptive uses of marine mammals has increased their economic value to the extent that commercial whaling is viewed as undesirable because killing marine mammals interferes with other opportunities to exploit them. During the 1970s, however, saving whales from whalers became a worldwide issue of profound social significance.

The increased display of marine mammals in oceanaria and the growing opportunity to view them in their own world accelerated the idea that industrialized whaling had become a desecration of nature. The insistence of some nations on continuing to hunt in the face of collapsing populations of whales was viewed by many as an outrage, and efforts to thwart commercial whaling grew increasingly strident. In 1972, the politics of the International Whaling Commission (IWC) spilled over into a more public international forum when the United Nations Conference on the Human Environment passed a resolution calling for a 10-year moratorium on whaling. However, the IWC was unable to resolve its internal disagreements about the rate at which whaling should continue, and it seemed clear that politics and greed were preventing the rational consideration of resource conservation. A broad, international coalition of objectors joined forces in launching what David Day had described as "The Whale War" (Routledge and Kegan Paul, 1987). The war was fought on many fronts, and the participants acted more often in independent assaults, but the overall effect was to galvanize the public into a growing chant of "save the whales" (Fig. 9).

The effort to save the whales is frequently described in one form or another as the "greatest environmental success story of the 20th century." However, of course, it was not. Even after a moratorium on whaling was passed by the IWC in 1982 and put

Figure 9 *The save-the-whales movement was a media-genic and culturally diverse phenomenon of the 1980s. Pacific Whale Foundation/Greg Kaufman.*

into effect in 1986, both "pirate" whaling and "scientific" whaling continued. Reports by Soviet scientists about illegal and unreported captures of thousands of whales throughout the world between 1950 and 1970 painted an even more destructive picture than determined previously. In addition, tens of thousands of marine mammals have continued to die each year as a result of other forms of human activity (e.g., pollution, bycatch, habitat degradation, ship strikes, overfishing). The "save the whales" movement was, however, one of the most media-genic and culturally diverse platforms for environmental activism during the 20th century. Confrontation between catcher boats and rubber inflatables on the high seas provided a dramatic backdrop to land-based efforts to convince whaling nations to cease the hunt. The story of the persistent efforts to end industrialized whaling is detailed by a number of authors (e.g., Day, 1987). Saving whales constituted a natural complement to the changing perception of marine mammals generated by oceanaria, whale watching excursions, and media attention.

It was also during the 1970s that the United States incorporated changing public opinion in revised federal legislation. Both the Marine Mammal Protection Act of 1972 and the Endangered Species Act of 1973 became international models of marine mammal protection by affording broad powers to federal agencies to prevent not only the killing of marine mammals, but even their disturbance or harassment. These acts were broadly developed to ensure protection of species considered to be of special interest to the public, in part through ecosystem protection, but in general as single species efforts. Both acts provided wide latitude for research and international cooperation in fulfilling conservation agendas. Although revised many times since the original enactment, both these legislative initiatives have received considerable attention around the world as mechanisms for increasing marine mammal protection.

IV. The 1980s and 1990s: Loving Marine Mammals Becomes an Industry

Undoubtedly the most significant demonstration of the cultural importance of marine mammals in modern times is the virtual explosion of interest in excursions to view marine mammals in the wild that has taken place over the past two decades (Fig. 10). The growth of the whale and dolphin watching industry has been detailed in a number of places, but the sheer speed and dimension of the changes that took place during the 1980s and 1990s warrant mention here. A detailed report on worldwide trends in whale watching by Erich Hoyt (2000) documents the dramatic growth of whale and dolphin watching from the 1950s to the present. Since 1980, the number of people, the number of venues, the number of operators, and the number of targeted species have all increased exponentially. The number of countries with marine mammal excursions has tripled since 1990 alone, while the number of passengers has more than doubled to some 9 million people each year. Direct revenues from marine mammal watching excursions now exceed 1 billion U.S. dollars a year. If one considers the "multiplier" effect of the other expenditures associated with whale watching (travel, accommodations, food, and souvenirs), the economic impact must be seen as quite substantial.

Figure 10 *Whale watching grew into a worldwide industry worth hundreds of millions of dollars a year during the 1980s and 1990s. © Pacific Whale Foundation.*

The media focus on whale and dolphin research, the oceanariums' "taming" of cetaceans, and public access to marine mammals through commercial whale watching trips during the 1980s were accompanied by a unique phenomenon: the use of laypeople as research assistants in return for financial support of the research project. One of the first instances of such a program took place aboard the *R/V Regina Maris,* a trimasted schooner that operated out of Gloucester, Massachusetts, under the direction of Dr. George Nichols and the nonprofit Ocean Research Expedition Society. This was soon followed by Earthwatch's Center for Field Research in Massachusetts; the School for Field Studies, also in Massachusetts; the Pacific Whale Foundation in Hawaii; Oceanic Society Expeditions in California, and ultimately a host of organizations throughout the world. Such efforts allowed members of the general public, without any prior experience in conducting whale research, the opportunity to participate in field studies of marine mammals. The programs have proven to be immensely popular. Participants are able to spend time in the field with prominent researchers they may have learned about through television documentaries or college courses. Participants generally have the opportunity to observe marine mammals from a perspective that is seldom enjoyed by the layperson on a commercial tour. They also have the satisfaction of some sense of accomplishment in furthering the goals of science and/or conservation. Lavigne *et al.* (1999) pointed out that funding from government agencies in the United States for marine mammal research has shown no real growth in the past three decades. However, the contribution to research efforts from public participation programs has grown tremendously during the same period.

The increase in whale watching has been accompanied by increased concerns that human interest in marine mammals may have undesirable effects on target populations or species. Specific regulations to control human activities around marine mammals have been enacted in a number of countries, including the United States, Australia, New Zealand, Scotland, Ar-

gentina, Mexico, and South Africa. Many other countries (Canada, Japan, Norway, and Iceland) are considering such legislation or propose recommendations or voluntary guidelines. The resulting controls vary widely in both philosophy and effectiveness. In the United States, animals may be used in captive swim programs, but it is generally considered to be illegal to swim with them in the wild. In Australia and New Zealand, the display of cetaceans is essentially restricted, but wild swim programs are allowed. In most areas, multiple layers of government controls and restrictions on research activities exist.

The most frequent form of control of human activities around marine mammals throughout the world is to regulate approach distances. However, there is little known empirical basis for the often-used 100 m, and recent studies of distance estimation over water suggest extremely high variability in the accuracy of human performance. A workshop in Italy hosted by the International Fund for Animal Welfare in 1995 focused on developing scientifically based management programs to protect marine mammals from tourism activities around the world. Noting the difficulty in establishing links between human activity and impacts on wild populations, participants in the workshop recommended a precautionary approach based initially on common-sense rules, followed by an iterative process of scientifically monitoring impacts and adjusting rules accordingly. At this time such a procedure seems to have been employed only in New Zealand to develop science-based management of controls. In general, it appears that government regulation is driven by political and socioeconomic considerations, and once implemented, management policies tend not to be amenable to change. When changes do occur, they tend to be based on additional political and socioeconomic considerations rather than sound scientific evidence.

Throughout the 1980s the "discovery" of marine mammals as objects of wonder allowed those with artistic and entrepreneurial abilities the opportunity to develop a wide variety of commercial ventures. Availability of marine mammal books, magazine articles, visual art works, decorated clothing, jewelry, videos, souvenirs and trinkets, marine expeditions, and oceanarium displays increased dramatically during this period. Artistic visual representations of marine mammals benefited enormously from the artists' exposure to live animals (or, perhaps, photographs of live animals). At least two major styles of visual art emerged during the 80s: one incorporated attention to detail based on biological and morphological data and the second attempted to represent the artist's interpretation of the animal in its world. Prominent examples of accuracy in detail include the paintings of Larry Foster (cf. Fig. 2), Pieter Folkens, Janet Biondi (all of California), and Richard Ellis (New York). Realism also characterized the work of sculptors John Perry, Randy Puckett, and Steve Aikenhead. Interpretations of the whale in its world, with less adherence to detailed accuracy, were represented prominently in the works of Robert Lyn Nelson (Fig. 11), Wyland, and Christian Riese Lassen, who reached their pinnacle of commercial success from the island of Maui in Hawaii during the 1990s. There were, of course, a number of other artists who produced work during the 1980s, but those just mentioned comprise a cross section of the most representative and prolific.

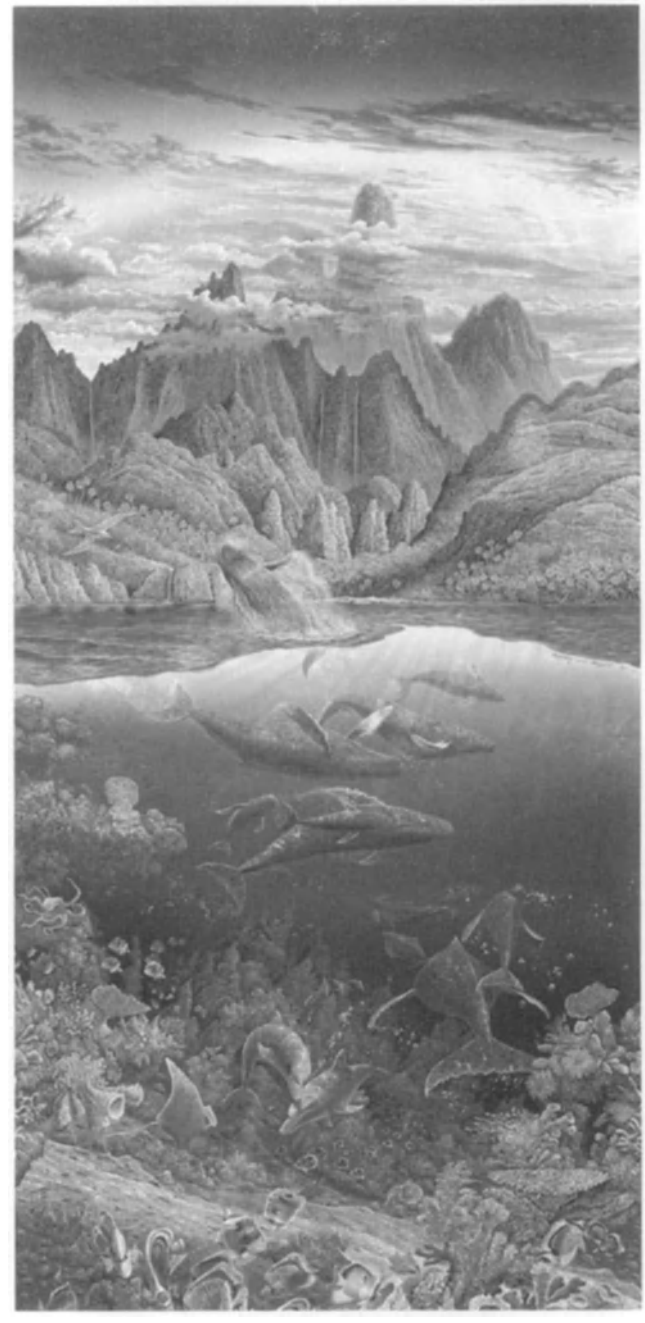

Figure 11 *Marine artist Robert Lyn Nelson is a preeminent figure in the marine art world.*

The marketing of marine mammal images grew through the 80s and 90s into a multimillon dollar enterprise, driven largely by art galleries catering to wealthy tourists in places like Lahaina, Monterey, and Provincetown. New techniques were developed to produce prints, posters, lithographs, and other facsimiles of original works that made art available to everyone. Additional products include T-shirts, coffee mugs, note cards, coffee table books, shopping bags, and stickers. Media attention to public relations extravaganzas such as the air brushing

of "Whaling Walls" by Wyland in high-visibility settings in major cities throughout the world helped generate a public perception of marine mammals as beautiful, powerful, friendly, and intelligent. Jewelry, sculptures, and a wide variety of trinkets and other memorabilia were produced in mass quantities for the increasing population of whale watchers and marine mammal lovers with money to spend. A major outlet for such products became the retail centers associated with display facilities. Virtually every aquarium or oceanarium in the world that has marine mammals on display has a retail center strategically located so visitors must move past or through it on the way to the exit. Artifacts related to marine mammals constitute a huge source of related income.

As the market for watching marine mammals in the wild and the purchase of memorabilia grew, the increase in publication of books and videos continued. It is possible to identify three major trends in modern published materials for adult readers: new-age, science fiction, and naturalist accounts. The dolphin as a mystic, healer, ancient communicator shows up in books by Horace Dobbs (British), Patricia St. John (American), Olivia de Bergerac (French), Frank Robson (New Zealand), and a host of like-minded writers. The popularity of new-age musings on the significance of marine mammals is based on the use of personal transformation stories that foster an emotional response on the part of the reader. It is important to note that, in most cases, the new-age perspective on marine mammals emphasizes what they (most often cetaceans) can do for humans: as teachers, as healers, as models of a better social order, and as indicators of human mistreatment of the oceans.

A second type of modern adult literature provides science-fiction accounts of marine mammals. These works incorporate extensions of scientific studies of communication and other cognitive capabilities of marine mammals into stories based on themes such as military abuse of power, destruction of the environment by corporate greed, mistreatment of marine mammals by egotistical scientists, or cataclysmic events of nature. "Into the Deep" by Ken Grimwood (William Morrow and Co., New York, 1995) weaves a complex plot that has dolphins communicating with humans to warn of impending natural disaster; representatives of each species eventually combine talents to use telepathic communication to prevent massive destruction of both humans and dolphins. "The Secret Oceans" by Betty Ballentine (Bantam Books, New York, 1994) tells of a group of scientists who become captive subjects in a study of humans conducted deep in the ocean by a form of cetacean more intelligent than humans. "Sounding" by Hank Searls (Ballantine Books, New York, 1982) uses two main characters, an aged bull sperm whale and a sonar officer on a Russian submarine, to explore cetacean behavior and the possibilities of interspecies communication.

The third, and largest, category of books printed during the past two decades includes nonfiction, naturalist accounts of a wide variety of species, including books on all the orders of marine mammals. These books bring together interpretations of scientific findings, stunning art or photography, and personal accounts of fieldwork by accomplished researchers. Two of the earliest are the "Book of Whales" (Alfred A. Knopf, 1980) and "Dolphins and Porpoises" (Alfred A. Knopf, 1982), both by naturalist, painter, and writer Richard Ellis. In "Hawaii's Humpback Whales" by Gregory Kaufman and Paul Forestell (Island Heritage Press, 1986), the authors describe the biology and behavior of humpback whales, based largely on their observations and field studies in Hawaii and Australia. The writing style is meant to model the authors' experiences narrating whale watches and provides a lively, but science-based interpretation of the life of one species. A photographic example of equivalent style is the Japanese photographer Mitsuagi Iwago's "Whales" (Chronicle Books, San Francisco, 1994), which documents his year-long journey to observe humpback whales from Hawaii, to Alaska, to the Ogasawara Islands of Japan.

Attractive, informative, and entertaining treatments of many species of marine mammals are now available. The *National Geographic* production of "Whales, Dolphins and Porpoises" (National Geographic Society, Washington, DC, 1995) featuring photographs by Flip Nicklin (son of pioneering underwater photographer Chuck Nicklin) and edited by James Darling is an unsurpassed synthesis of prominent research findings from around the world. Frank Breummer's "Seals in the Wild" (Laurel Glen Publishing, San Diego, 1998) offers an elegant collection of facts and photographs about pinnipeds. Barbara Sleeper and Jeff Foott team up to present an excellent description of the much overlooked manatee in their book "In the Company of Manatees" (Three Rivers Press, New York, 2000). Ken Norris, Roger Payne, Hal Whitehead, Peter Beamish, Jim Darling, and Carol Howard have written intriguing personal accounts of careers spent investigating marine mammals. A number of field guides for whale watchers in many settings throughout the world are also currently available. These books not only provide a great deal of current information on marine mammals, but serve as important vehicles for conservation efforts.

Certainly not all books published during the 80s and 90s can be categorized according to the three styles just described. Two books that deserve mention in this regard are Heathcote Williams' "Whale Nation" (Harmony Books, New York, 1988) and "The Delicate Art of Whale Watching" (Sierra Club Books, San Francisco, 1982) by Joana Varawa (formerly Joan McIntyre). "Whale Nation" is a celebration of the history of whale/human interactions through a book-length poem and a collection of whale-related excerpts from other sources. Following its publication the author did a world tour of highly acclaimed public readings. Varawa's book is a deceptively small but powerful series of meditations on being in the presence of the sea and its creatures.

More than 300 videos and movies on marine mammals have been produced in the last two decades, more than half of them since the mid-1990s. Most of these are documentaries, generally based on describing the research of one or a few scientists. In some cases, researchers are simply followed in their work while the significance and findings of their efforts are detailed. In other cases, celebrities such as Robin Williams or Chris Reeves accompany scientists to get a first-hand look at their work. A number of television programs have dealt with controversial issues such as dolphins in captivity (*A Whale of a Business*, PBS Frontline, 1997); scientific whaling (*Whale Fever*, BBC News & Current Affairs, 1993); captive-dolphin swim programs (*Dying to Please*, Biosphere Films, 1990); and

bycatch of dolphins by the tuna fishery (*If Dolphins Could Talk*, PBS Video, 1990).

The invention of a large-format (70-mm) camera by IMAX in the early 1970s has resulted in three big-screen movies that are based on marine mammals. The first was *Nomads of the Deep*, featuring humpback whales, released in 1979 by IMAX. In 1996, Destination Cinema produced *Whales*, a highly acclaimed and popular big-screen documentary covering a variety of whale species. In 2000, McGillivary Freeman Films released *Dolphins*, a documentary on dolphin communication that focuses on the research being carried out by Kathleen Dudzinski, Alejandro Acevedo-Gutiérrez, Louis Herman, and others.

There have been a handful of feature movies with marine mammals as central characters. A bottlenose dolphin named Snowflake appeared in the comedy *Ace Ventura, Pet Detective* (starring Jim Carrey, 1994). Humpback whales were brought back to the future in the science fiction adventure *Star Trek IV: The Voyage Home* (William Shatner and Leonard Nimoy, 1987). A dog and a dolphin learned to communicate with each other and sparked a romance between the dog's owner and the scientist studying the dolphin in *Zeus and Roxanne* (Steven Guttenberg and Kathleen Quinlan, 1997). *The Secret of Roan Inish* (Jeni Courtney, 1994) was based on a Celtic myth about selkies (seals) and a young girl's search for her lost brother. None of these movies achieved much success on the basis of their representation of marine mammals, however. In 1993 the movie *Free Willy* became a worldwide sensation and was ultimately followed by two sequels. The series chronicled a friendship between a 12-year old boy (Jesse) and an adult male killer whale (Willy). When they met in the first movie, the whale was held captive in a small enclosure in a seaside marine. When Willy refused to perform for audiences and the owner threatened dire consequences, Jesse arranged for the whale's dramatic release. In the second movie, Jesse and Willy ran into each other in the wild and discovered they must work together to avoid the perils of an offshore oil spill. In the third and final movie, the whale was threatened by an illegal whaling operation, but the whaler's son helped Jesse (who had grown into a 17-year old whale researcher) save Willy and his family.

The *Free Willy* movies brought the question of captivity to the forefront of public consciousness and resulted in a long and expensive campaign (still underway) to return the killer whale that was used in the first movie to the ocean. That animal, Keiko, had been kept in rather miserable circumstances in a substandard facility in Mexico. With monies raised through a publicity campaign sponsored by the movies' producers (Richard Donner and Lauren Shuler-Donner), Keiko went through a reorientation program in an Oregon facility and was then moved to Iceland, where he is being reintroduced to the wild.

The public response to *Free Willy* was indicative of an increase in public questioning throughout the 90s about the appropriateness of keeping marine mammals in captivity for public display. With increasing access to information about marine mammals in the wild (through excursions, books, and videos), it became clear that life in a captive facility was a poor substitute for nature. In response, the display industry made significant strides in upgrading facilities, improving husbandry, and refocusing shows to emphasize education and demonstration of the display of animals' natural behaviors. The debate continues on many fronts about the pros and cons of maintaining marine mammals in captivity.

The removal of animals from the wild has decreased significantly in the past two decades. Improved health of captive animals and an increase in the number of animals born in captivity provide an ongoing supply of display animals that have never been in the wild and would be unlikely to survive if released. There seems to be an increasing tendency to move away from keeping cetaceans in captivity, however. A number of facilities (e.g., the Vancouver Public Aquarium) have chosen not to replace whales or dolphins that have died, and others (Maui Ocean Center; Monterey Bay Aquarium) decided from the outset not to hold cetaceans. In a graphic display of the continuing debate about animals in captivity, the producers of the *Free Willy* movies have threatened a Hollywood-sponsored boycott of filmmaking on the Island of Maui if a plan to put the research dolphins from a University of Hawaii laboratory in Honolulu on display at a planned "theme park" on Maui is carried out.

V. International Perspectives

It would be a mistake to assume that North American cultural perspectives are mirrored elsewhere in the world. Clearly, one might expect to find attitudes toward marine mammals to differ across cultures that depend on traditional subsistence hunting practices (such as the Inuit, Aborigines, and some areas of the South Pacific); cultures that opportunistically use marine mammals to prop up collapsing fisheries (as is true throughout much of the Indian subcontinent, parts of Asia, Central and South America, and Africa); cultures that pursue relatively modern programs of commercial exploitation (including Japan and Norway); and cultures that currently forego commercial exploitation (many former whaling nations such as the United States, Canada, Australia, New Zealand, the United Kingdom, and South Africa).

As faulty as simplistic generalizations may be, one can recognize an important dividing line in perspectives on marine mammals that is based more on economic considerations than fundamental differences in cultural attitudes toward nature. Wealthier countries enjoy the luxury of debating whether marine mammals should be harvested. Japan, Norway, the United States, Britain, Australia, and New Zealand are remarkably alike in their common appreciation of marine mammals as intelligent, amusing, and useful. The difference in current behaviors toward marine mammals is one of time, and perhaps degree, for all have participated in the slaughter of marine mammals and each currently reaps the benefits of the worldwide fascination with marine mammals. Less wealthy nations must face immediate considerations of survival before exploring programs devoted to environmental protection or species conservation. Marine mammals are viewed more directly in terms of immediate economic benefit. A major factor in the reduction of a number of small cetacean populations is the readiness with which INCIDENTAL TAKES (accidental ENTANGLEMENT in fishing nets) can be converted into a directed hunt in those areas where there is a market for the meat.

The enthusiasm with which a wide cross section of nations have begun promoting whale and dolphin watching reinforces the notion that marine mammals are regarded neither as sacred nor profane in most parts of the world; they are primarily a commodity whose particular value can change from time to time. Surveys of attitudes and feeding programs in Australia, New Zealand, and the United States make it clear that, regardless of the qualities that participants may attribute to marine mammals, their primary value is in terms of satisfying human needs, and this perspective appears even more entrenched in less affluent areas where marine mammals are harvested directly for food.

One of the most striking demonstrations of the role of marine mammals in modern cultural perspectives in affluent countries is the use of marine mammal images in corporate advertising. The author recently sent a request for information on corporate use of marine mammal images to subscribers of a bulletin board for marine mammal science (http://www.escribe.com/science/marmam/). The query resulted in approximately 100 different examples of advertisements. Most of these were print media, but a number of television advertisements were described as well. Almost half the images used were of bottlenose dolphins (Fig. 12). The next most frequent use was of killer whale images. Other species included humpback whale, sperm whale, right whale, beluga whale, false killer whale (*Pseudorca crassidens*), sea lion, walrus, spinner dolphin, humpback dolphin, and polar bear. In general, usage appeared to reflect anticipated familiarity on the part of the public for particular species (i.e., bottlenose dolphin, killer whale, humpback whale, and California sea lion), availability of professional quality images, and the extent to which the image symbolized the message of the advertisement (e.g., speed, power, size, intelligence).

The diversity of products marketed with the help of marine mammal images was extremely broad. In some cases the connection between the product or service and marine mammals was obvious. A number of advertisements used images of marine mammals to promote travel to destinations where marine mammals may be observed. (e.g., Olympic Airways in Europe, Air Nippon in Japan). In some cases there was an identifiable link between the product or service and some perceived feature of the marine mammal. The ruggedness of a Leatherman tool was highlighted with the help of a humpback whale; the warmth of Eddie Bauer clothing was symbolized by a polar bear; and a "school" of dolphins helped promote educational software for children (Fig. 12). More often the relevance of the image to the product was quite obscure. Marine mammals have been used to sell aspirin, automobiles, batteries, beer, chewing gum, chocolates, cigarettes, computers, diapers, electronics, film, gold coins, jet skis, life insurance, orange juice, mobile phones, petrochemicals, potato chips, shower stalls, silverware, televisions, tires, video cameras, and a myriad of investment, real estate, interior decorating, and cosmetic services. One can only wonder about the cultural perspective that associates marine mammals with alcohol, tobacco, and petrochemicals.

Not surprisingly, use of marine mammal images in advertising occurred most frequently in more affluent countries, especially in Asia and Europe. North American and Australian use seemed to be more recent and less frequent, but a comprehensive assessment of corporate use of marine mammal images has yet to be conducted. It is clear, however, that over the past two decades, increasing public attention to marine mammals has created a kind of "rock-star" status that elicits a classically conditioned positive emotional response to marine mammal images that can be exploited by marketing experts.

VI. Conclusions

The one constant element in human perspectives on marine mammals throughout the 20th century is our recognition of their economic significance. We have never stopped making money from them. They are still a resource. We still regard our needs as more critical than theirs. The proof can be seen in the peculiar and contradictory steps that we take to protect them. Consider, for example, the degree of attention that focused on "Humphrey" the "wrong-way whale" that wandered up the Sacramento River in 1985 and would not come out, or the three gray whales that became caught in ice in Barrow, Alaska, in 1988 and could not get out. Tremendous resources in time, money, and emotions were devoted to "saving" these animals. Compare those situations with the decision to cull seals hanging out at fish ladders in Seattle a few years ago to prevent them from feeding on depleted salmon stocks. On the one hand, no expense was spared to release the whales from natural disasters, while on the other hand, the seals were basically held accountable for the precarious status of salmon stocks that had been decimated by human overfishing and habitat degradation. Japanese scientists have been ridiculed for suggesting that Antarctic minke whale (*Balaenoptera bonaerensis*) numbers need to be culled to promote the recovery of blue whales by reducing competition for prey. At the same time, pinniped populations in North America have been culled to promote the recovery of fisheries by reducing prey competition with humans.

We pass laws to prevent approaching marine mammals too closely, but allow them to be killed if they eat too many fish or get in the way of our fishing equipment. The struggle between nations for military supremacy dictates that we degrade the oceans with the loud sounds of our technical wizardry, reducing its suitability for many marine species. Our inability to control our own population growth forces us to compete against other species for food and then poison them with our waste. Insofar as we can identify interesting features about marine mammals, we subjugate them to serve our needs, whether for amusement, therapy, revelation, or money. While once we killed marine mammals to get their oil, now we kill them by spilling oil on them. While once we chased them and captured them for food, today we chase them and capture them for amusement. Instead of using their baleen for corsets, we use their images to sell diapers.

The development of "whale as icon" during the 1970s seemed to usher in an enlightened period meant to liberate cetaceans from modern commercial whaling. Television shows and oceanaria introduced us to a new understanding of whales and dolphins as entertaining, highly trainable, and utterly fascinating. As a consequence of the discovery of how entertaining and trainable many cetacean species were, scientists began to probe their physiological, behavioral, and even cognitive capabilities. On the surface at least, it looked as if a new age of enlightenment had begun.

Figure 12 *A wide range of products and services are marketed with the help of marine mammal images. Not all advertisements seem as relevant or appropriate as those shown here. Courtesy of (A) Learning Outfitters, Inc.; (B) Leatherman Tool Group, Inc.; (C) Eddie Bauer. (continues)*

While it is reasonable to conclude that display facilities and laboratory-based research programs have been extremely important in energizing efforts to limit commercial hunting, they have not led to the liberation of whales and dolphins. Instead they have helped create a different kind of exploitation, a kind of domestication or colonization. Whether we limit the lives of cetaceans by keeping them in tanks, artificial lagoons, open ocean pens, or even let them roam free and control them using standard operant training procedures, one way or the other, we are compelling them to live their lives for our purposes. That is not liberation. Even when we do not remove animals from their natural environments and even when our only contact is based on "watching" them, rather than directly controlling them, our intrusive presence can alter their natural behaviors. When this is done without their choice, with little or no benefit to them, and only in service to our own needs, we are engaging in a form of colonization.

However, of course all the news is not bad. There does seem to be a tremendous groundswell of respect, hope, and compassion for cetaceans. Thousands of individuals all over the world

Figure 12 *(Continued)*

work tirelessly to assist marine mammals in need. When a humpback whale stranded on a beach near Brisbane, Australia in 1992, more than 5000 people showed up to save it. Our ability to form emotional attachments to individual animals seems boundless (Fig. 13). However, this encourages what right whale biologist Scott Krauss calls "Madison Avenue whale saving"; small-scale, high-profile publicity events that seem noble but do little to save marine mammal populations. Our activities will have little real conservation value as long as we ignore the intrinsic value and importance of marine mammals carrying out their natural behaviors in their natural habitat, unimpeded by the presence of humans or the POLLUTION we produce.

There are rapidly increasing opportunities for people all over the world to observe marine mammals in the wild. Most of these opportunities involve going out on boats: observing animals at close range for brief periods of time and then returning to shore. Increasingly, however, more varied options are available. In some areas (e.g., Monkey Mia in Western Australia, Tangalooma in Queensland, Australia, and in the Red Sea), dolphins can be approached and fed in shallow water. As we have

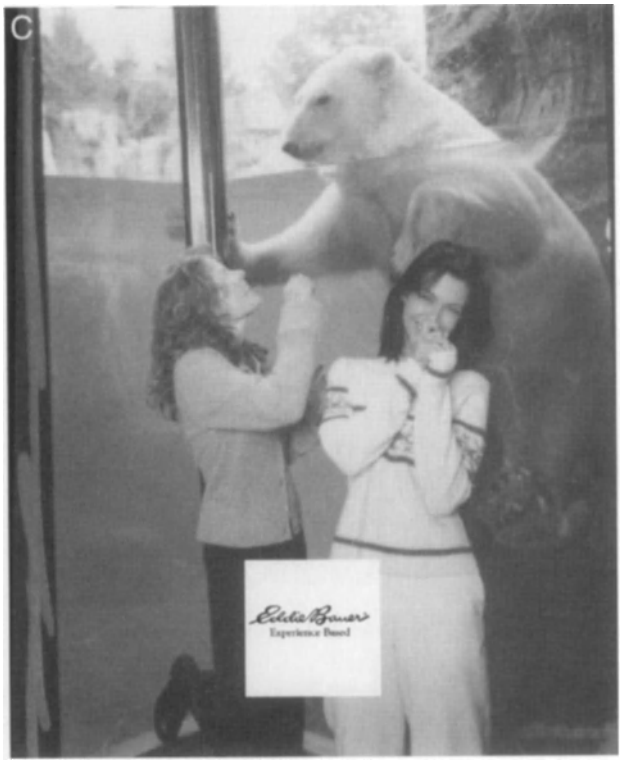

Figure 12 *(Continued)*

found out that whales and dolphins are generally friendly and frequently curious, more and more locations around the world are offering chances to swim with dolphins in the wild. For the most part, these types of interactions are based on a fundamental belief in the inherent positive value of whales and dolphins. People who watch marine mammals, feed them, or swim with them seem generally driven by good motives. Unfortunately, people who seek contact with marine mammals are being catered to by an increasingly large and diverse entertainment industry that may soon be as out of control as the whaling industry was in earlier times. Economic competition drives some to place more importance in the gain from selling thrills (such as parasailing over herds of dolphins or being towed off the back of a boat through groups of seals, whales, or dolphins) than in the possible harm such activities may cause.

We are faced with a fundamental conflict of interest: our need to exploit marine mammals for our own purpose and their need to be protected from our various forms of interference. Our interest in marine mammals is based on satisfaction of our own needs. In our approaches to whales and dolphins, we make them become what we hope they are and ignore what they may be in reality. We see what we want to see. For example, the sight of a whale or dolphin slapping its tail on the water is often an exciting thing for most people—they want to get closer and see more. The truth is that in most cases, tail slapping is a sign of an angry or otherwise distressed animal. Although the display may not always be related to the presence of a boat or swimmer, it frequently indicates the animal does not want us there. Figure 14 shows two spinner dolphins surfacing. At first it may look like they are having fun. The one on the top seems to be smiling and has its pectoral fin wrapped around the other, like an old friend. On looking closer, however, you can notice that the top dolphin is covering the other dolphin's blowhole, preventing it from breathing as it comes to the surface. That is probably not a friendly gesture. The bottom dolphin has its mouth partly open, which is a common threat gesture. Most people simply cannot interpret dolphin behavior properly, which makes it very likely that they will not know how to avoid disturbing whales and dolphins when they go out on the ocean.

Spinner dolphins got their name because of their habit of jumping above the ocean and spinning in the air. Why do they do it? Well, to most people it seems like something that dolphins do just because it is fun. In fact, the spins may serve a number of purposes. When we look more closely, we notice that many of the spinners have REMORAS, a suckerfish that often attaches itself to the dolphin. One reason for the spinning may be to get the remoras off. The spins may also be a form of social

Figure 13 *When a marine mammal strands, the public response is typically immediate and highly emotional. Paul H. forestell/Pacific Whale Foundation.*

Figure 14 *Our interpretations of animal behavior are frequently clouded by anthropomorphism. Paul H. Forestell/Pacific Whale Foundation.*

communication. It is just too easy to miss the real explanations. When dolphins come to ride the bow wave of a boat, how often do we assume that the animals are intending to play with us? Generally, only a small subset of individuals attempt to associate with the boat (for reasons that are not clear), while the remainder engage in avoidance behaviors. It is commendable that we so often approach whales and dolphins in friendship. Many would rather idolize marine mammals in the wild than colonize them in oceanaria, but naïve idolization can be as questionable as intentional colonization.

If we are to achieve the status that Lavigne *et al.* (1999) have described (i.e., an aesthetic interest that reflects increased understanding and a change in ethical values), we must undergo a universal transformation in perspective: the ability to value something independently of its potential for meeting our needs. Until that point we may continue to find less cruel ways to put marine mammals in our service, but their value will continue to be defined in anthropocentric terms. Philosophically, that may not seem to be a problem of significant proportion, but insofar as our behaviors put our needs ahead of theirs, they will continue to be at risk.

Acknowledgments

The ideas expressed reflect many years of involvement with the whale and dolphin watching industry in Hawaii and Australia, with occasional visits to Japan, Costa Rica, New Zealand, Alaska, and New England. Many researchers, educators, operators, and members of the public have provided "grist for the mill" during those excursions. I thank Greg Kaufman and the Pacific Whale Foundation for support throughout that time. Japan International Cetacean, Education and Research Center (ICERC) has also provided support and encouragement on a continuing basis. I thank the many individuals who responded to my request for information on the use of marine mammal images in advertising. Trisha Lamb Furstein's web-based bibliographies have been tremendously helpful to me. David Lavigne kindly provided a preprint of his excellent discussion of North American attitudes toward marine mammals. Joana Varawa has given both critical and encouraging insight and much wisdom over the past 5 years. Southampton College of Long Island University provided valuable released time from teaching.

Population Dynamics

PAUL R. WADE
National Marine Fisheries Service, Seattle, Washington

Population dynamics is the study of changes in population size through time. In other words, it is the study of why populations increase, decrease, or remain the same. One fundamental concept in population dynamics is that the maximum rate at which a population can increase is determined by the intrinsic life history characteristics of the species. Thus, much of the research on marine mammal population dynamics is focused on the better definition of life history parameters. Additionally, many extrinsic factors can potentially influence the dynamics of a population. These include environmental variability, disease, competition, and predation. There is also much interest in the role of density dependence in controlling marine mammal population dynamics. In addition to being scientifically interesting, basic concepts of density dependence have become important to the management and conservation of marine mammals.

I. Rates of Population Increase

A. Population Growth of Long-Lived Animals

Most long-lived animals, such as marine mammals and large terrestrial mammals, have relatively slow intrinsic rates of in-

crease compared to most other kinds of animals. The modest population growth rates are the consequence of their life history characteristics. Characteristics such as the age at which females start reproducing, the number of years between births, and how many years a female will live and reproduce, determine how quickly a population can increase. Most marine mammal species take many years to reach sexual maturity and have long gestation periods that result in the production of, at most, only one young a year. In fact, most species give birth only once every several years. Even when annual rates of survival are very high, these characteristics cause populations to grow slowly. Low rates of population growth make most species of marine mammals vulnerable to overexploitation, as shown by the rapid depletion of many whale populations by commercial harvest.

B. Measuring Population Growth

Population growth can be measured in two ways. In general, the most reliable estimates of population growth come from abundance data collected over many years. Population abundance can be estimated from surveys or counts, and when repeated over several years, the trend (percentage change per year) in a population can be estimated. Specifically, the slope of a linear regression on the natural logarithm of abundance represents the rate of increase (r) of a population experiencing exponential growth. Because population growth is slow and population estimates are imprecise, 10 or more years may be required to directly measure population growth rates.

A less direct way of estimating population growth is from life history data. Estimates of age of sexual maturity, birth rate, survival rate, and maximum age can be compiled in a Leslie matrix or similar model, which can then be used to estimate the rate of increase (usually estimated as $\lambda = e^r$). Although such calculations have been useful for exploring potential population growth rates, relatively few estimates of actual population growth have been made in this way. The main hindrance is the lack of direct data on survival rates of marine mammals. Only a few species have been amenable to survival estimation, usually from mark-recapture studies using individuals recognizable from tags, unique scars, or other markings. Such studies have been undertaken in California sea lions (*Zalophus californianus*), bottlenose dolphins (*Tursiops truncatus*), and killer (*Orcinus orca*), humpback (*Megaptera novaeangliae*), bowhead (*Balaena mysticetus*), and right whales (*Eubalaena* spp.)

C. Taxonomic Differences

Although population growth is comparatively slow for all marine mammal species compared to other vertebrates, there is a considerable range in life history strategies within marine mammals. For example, just within the cetaceans one can contrast a harbor porpoise that becomes sexually mature after a few years, can give birth annually, and rarely lives past 12–15 years with a bowhead whale that becomes sexually mature after perhaps 10–20 years, only gives birth every 3–5 years, and lives for decades, with some individuals apparently living to greater than 100 years. Broad patterns are evident in maximum population growth rates when available information from trend or life history data is examined for different taxonomic groups. Sea otters (*Enhydra lutris*) with maximum observed rates on the order of 20% per year, are perhaps capable of the fastest growth. Next are pinnipeds, many with the potential to reproduce annually, with observed rates ranging from 8 to 13% for otariids [from northern fur seals (*Callorhinus ursinus*) at the low end to Antarctic fur seals (*Arctocephalus gazella*) at the high end] and 6 to 13% for phocids [from Hawaiian monk seals (*Monachus schauinslandi*) at the low end to harbor (*Phoca vitulina*) and gray seals (*Halichoerus grypus*) at the high end]. Maximum rates of increase for mysticetes likely range from about 4 to 10%, or perhaps even higher. Observed rates for gray (*Eschrichtius robustus*) and bowhead whales (3–4%) are at the low end, although the populations that have been studied are likely at high population levels and therefore their growth rate may have already slowed (see Section III). Southern right whales (*Eubalaena australis*) have shown the ability to increase at 7% per year, and humpback whales have been estimated to increase at 7–10% per year. Manatees (*Trichechus* spp.) appear to have maximum population growth rates of at least 7% and perhaps higher, whereas dugongs (*Dugong dugon*) are likely only capable of growing at 5–6% per year. Much uncertainty exists about the maximum rates of increase of odontocetes; what little is known suggests that this group generally has very slow annual population growth rates, as low as 2–3% in some species such as killer whales, and most species are considered unlikely to have a maximum growth rate of more than 4%. There is speculation that a few species, such as harbor porpoises (*Phocoena phocoena*), may have higher rates of increase because of their life history, but such higher rates have not yet been documented.

II. Extrinsic Factors Affecting Population Size

A. Environmental Variance

Another aspect of population dynamics is the study of the effects of extrinsic factors on population growth. The difficulty in precisely estimating population size and life history parameters has made the study of variation in population growth rates of marine mammals difficult. However, at least a few conclusions can be made. Long-lived animals with relatively older ages of sexual maturity cannot respond quickly to favorable environmental conditions. As discussed earlier, many species are limited to relatively slow population growth, even when conditions are good. Consequently, such species cannot decline too often or too rapidly when conditions are bad or they would not have persisted on an evolutionary time scale. Therefore, marine mammals have evolved life history strategies that keep them relatively buffered from interannual variability in environmental conditions, at least compared to other animals such as small terrestrial mammals. From this evolutionary perspective, one can predict that the slower the maximum population growth rate, the lower the variance in growth rate one might expect. Species with these traits are often referred to as "*K*-selected species," meaning they have evolved to maintain relatively stable population sizes at or near the carrying capacity (typically represented by the letter "*K*") of the environment. Therefore, one would expect that cetaceans, in particular, would be less subject to large fluctuations in survival and fecundity from year to year than would sea otters or pinnipeds.

Data sufficient to examine such patterns are rare for marine mammals. Studies of pinnipeds provide the best evidence of the effect of changing oceanographic conditions, particularly because of the ability to closely monitor numbers of pups or adults at rookeries from one year to the next. El Niño oceanographic events, through reductions in prey availability, have led to changes in the life history parameters of several species of otariids in places such as California and the Galapagos. These changes include lower fecundity, lower pup survival, and even lower adult survival during extreme events. In some cases, such as northern fur seals at San Miguel Island, conditions have been bad enough to result in nearly 100% mortality of pups in a given year. In addition, several populations of pinnipeds have experienced long-term (20–30 year) declines that have been mostly unexplained; while some believe that these declines are due to oceanographic regime shifts on that time scale, others believe that direct human-caused mortality or depletion of prey species by commercial fisheries may be at least partially to blame.

Cetaceans probably experience similar responses to environmental change, but these changes are harder to detect. One study did find evidence of nutritional stress in the teeth of dusky dolphins (*Lagenorhynchus obscurus*) off Peru during the 1982–1983 El Niño. Similarly, pregnancy rates of fin whales (*Balaenoptera physalus*) off Iceland have been correlated with changes in food abundance. Within the sirenians, manatees can experience higher mortality during periods of colder water temperatures.

B. Disease and Natural Toxins

Disease or natural toxins also have the potential to cause declines in marine mammal populations. Many species of marine mammal have experienced large mortality events from disease. Although there is often the suspicion by some that such outbreaks of disease have been ultimately triggered from anthropogenic causes, such as degraded habitat or exposure to contaminants, this has proved difficult to confirm from field studies. Disease and toxin-related die-offs may thus represent natural events for marine mammals. Some of these events have been severe enough to be considered a significant influence on the dynamics of these populations. For example, more than 18,000 dead harbor seals were reported from European coasts during a morbillivirus infection in 1988. In the western North Atlantic Ocean, large numbers of common bottlenose dolphins died during a disease-related event in 1987–1988 that may have been triggered by a toxin, and the mortality was thought to have caused a significant decline in the population. Humpback whales in the Atlantic have also experienced mortality events on at least two occasions; in one case at least 14 whales died apparently from consuming toxic dinoflagellates concentrated in fish prey. However, it is not known if such mortality is frequent enough to exert a strong influence at the population level. Such die-offs are particularly dangerous for small populations. The endangered Mediterranean monk seal (*Monachus monachus*) recently experienced a loss of 60–70% of its population off Africa due to a toxin or disease, which has seriously compromised the long-term survival of this species.

C. Competition

Competition from other species may influence the population dynamics of marine mammals, although there is little evidence for this. Whether this is due to competition being unimportant or whether it is simply too difficult to demonstrate is an open question. An increase in crabeater seals (*Lobodon carcinophaga*) was directly attributed to a release from competition following the severe depletion of several species of baleen whales in the Antarctic, leading to an increased availability of KRILL. This explanation has been reevaluated in light of evidence of environmental influences on the population dynamics of Antarctic pinnipeds. It should be noted that some general textbooks (such as books on oceanography) state that competition for krill from Antarctic minke whales (*Balaenoptera bonaerensis*) has prevented the recovery of depleted blue whales (*B. musculus*) in the Antarctic. However, the recent information indicates that the lack of recovery of blue whales in the Antarctic can be fully explained by previously unknown ILLEGAL HARVESTS by the former Soviet Union.

D. Predation

Many marine mammals, especially smaller ones, are preyed upon by other animals, but predation has rarely been suggested as a strong controlling factor in their population dynamics. One exception is a recent study that suggested sea otters may have declined in one part of Alaska because of killer whale predation. Pinniped pups are often vulnerable to predation from predators such as leopard seals (*Hydrurga leptonyx*), great white sharks, and killer whales. While such predation has been shown to affect the growth of local ROOKERIES, it is unclear if it exerts a strong influence on the dynamics of an entire population. Similarly, some pelagic dolphin species experience predation from sharks, and killer whales prey on many cetacean species. Again, even though predation of cetaceans occurs, it is difficult to know whether it influences the dynamics of these populations.

III. Density Dependence

A. Compensation

Another area of great interest is the role of density dependence in controlling the population dynamics of marine mammals. It is generally accepted that marine mammal populations experience density dependence. In other words, as populations become relatively large, they tend to have lower population growth, and eventually stop increasing. This form of density dependence is termed compensation. The level at which a population stabilizes is called its carrying capacity. Evidence has been found for density dependence in life history parameters such as the age of sexual maturity. Females from a population at a level well below K become sexually mature and start reproducing at an earlier age than females from a population at a level close to K. Presumably this is because of access to greater resources such as prey. For example, the age of sexual maturity apparently became younger for fin (*Balaenoptera physalus*) and sei whales (*B. borealis*) in the Antarctic as their populations were depleted by commercial harvest.

It has been hypothesized that the mechanism of the regulation of populations of long-lived mammals would follow a se-

quence as a population increased, with density dependence first affecting the rate of immature survival, then the age of sexual maturity and the birth rate, and finally the adult survival rate. This hypothesis partially follows from the recognition that a long-lived species that reaches sexual maturity slowly and has a low intrinsic rate of increase must maximize adult survival in order to persist. Adult females of long-lived species may be able to forgo reproduction to maximize individual survival when conditions are poor, but it is unclear if there is necessarily a specific sequence in how density dependence affects all life history traits that are common to all marine mammals.

B. Linear vs Nonlinear Density Dependence

It is difficult to assess how these changes in life history translate into changes in population growth, as few direct data are available on changes in population growth at different population sizes. One debate is whether marine mammals experience linear or nonlinear density dependence. Linear density dependence is a constant decline in the per capita population growth rate as a population increases, illustrated by the simple logistic population model (Fig. 1). Nonlinear density dependence is where a population has no decline in the per capita growth rate as it increases until it reaches a level close to *K*, where it then has a rapid decline, illustrated by the θ-logistic population model where the value of θ is greater than 1 (Fig. 1). Both linear and nonlinear density dependence occurs in single life history parameters of marine mammals and other large mammals. However, population modeling indicates that nonlinear density dependence in a single life history trait (such as fecundity) may not translate into non-linear density dependence at the population level, particularly if density dependence in other life history traits is more linear. The form of the density dependence (linear vs nonlinear) will determine which population size will have the greatest increase in numbers from one year to the next, called the maximum net productivity level (MNPL). For long-lived animals, nonlinear density dependence will generally lead to populations having their MNPL closer to carrying capacity (Fig. 2). A recent review concluded that most marine mammal populations likely have their MNPL between 50 and 85% of their carrying capacity. It has been shown, however, that it is very difficult to estimate MNPL for any marine mammal population given the data that are currently available.

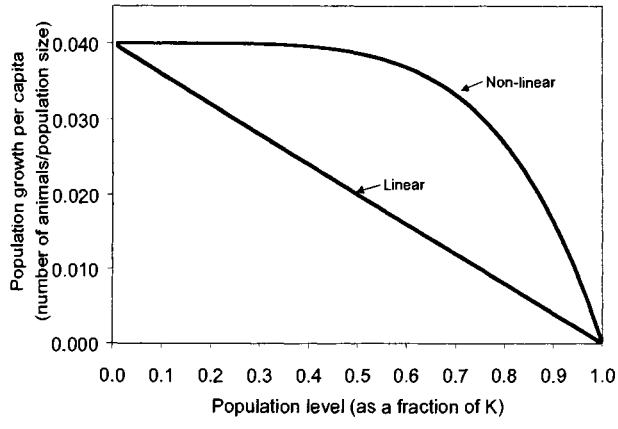

Figure 1 *An illustration of two forms of density dependence. "Linear" density dependence represents a constant decline in population growth per capita as the population level approaches carrying capacity* (K). *Per capita population growth is the number of animals added to the population divided by the total population size, which also represents the population growth rate. "Nonlinear" represents a curved response, where the population growth per capita does not decline until a population level close to* K, *where it declines rapidly. Both curves represent cases where the maximum population growth rate is 0.04 (4% per year).*

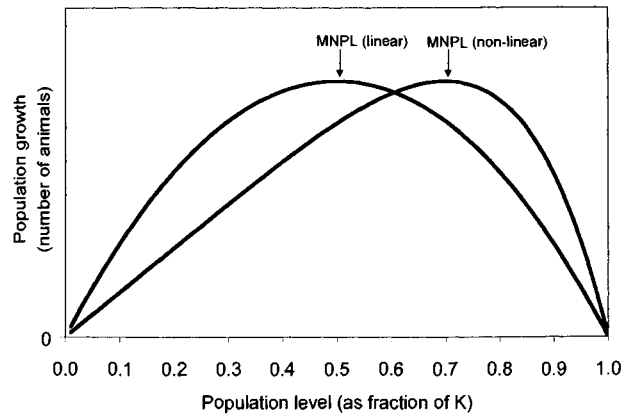

Figure 2 *Population growth (in numbers of animals added to the population each year) as a function of population level, expressed as a fraction of* K. *This quantity is also called the "net productivity," and therefore the peak of this curve is referred to as the maximum net productivity level (MNPL). For linear density dependence, the MNPL is at one-half of* K. *For nonlinear density dependence, the MNPL is closer to* K, *in this case at 0.7*K.

C. Density Dependence and Management

These concepts of density dependence have been incorporated into the management and conservation of marine mammals. Both the International Whaling Commission, in its proposed scheme for the regulation of whale harvests, and the U.S. government, in managing human-caused mortality of marine mammals in U.S. waters, refer to concepts like MNPL, with populations above MNPL considered "healthy."

Many populations of pinnipeds and whales are recovering from unregulated harvests that left them at severely depleted population levels. It will be interesting to observe the recovery of these populations over the next few decades, as many are likely to approach previous population levels and are expected to stop growing at some point. Some populations [such as the eastern North Pacific gray whale (*Eschrichtius robustus*) and some harbor seal populations] are suspected of already having recovered to levels close to their carrying capacity. It is important to understand when density dependence is taking place so that it can be distinguished from human-caused effects on population growth that might require conservation action.

D. Allee Effect (Depensation)

Density dependence can also work in the opposite direction, where per capita population growth is slowed at very small population sizes (Fig. 3). This is called the Allee effect by ecologists (and is also called depensation by fisheries biologists). One simple example of the Allee effect would be a reduction in reproduction at very small population sizes due to the inability to find a mate. Allee effects could also occur from inbreeding depression associated with small populations or from behavioral changes that might accompany a reduction to small numbers of animals, such as decreased foraging success or protection from predators. Unfortunately, the difficulties in studying the population dynamics of marine mammals are compounded by the difficulty of studying rare populations so it may take a long time before much is learned about depensation and its role in the dynamics of marine mammals. Several severely depleted baleen whale populations have shown little or no recovery despite decades of apparent relief from human exploitation, raising the possibility that these populations are experiencing Allee effects. However, it has been realized that many of these populations may have continued to experience human-caused mortality from a variety of sources, such as illegal harvest, entanglement in fishery gear, and collisions with ships. This makes it difficult to determine if depensation does play a significant role in the dynamics of small populations of cetaceans.

Similarly, many pinniped species were once harvested to commercial extinction and have since shown recovery, but it is rarely known how small these populations actually were at their low point. One exception is the remarkable story of northern elephant seals (*Mirounga angustirostris*), which were thought to be extinct around 1880 and are now thought to have numbered no more than about 100 individuals around the turn of the century, concentrated in a single colony in Baja California, Mexico. The number of northern elephant seals now exceeds 80,000 animals, and they have recolonized many BREEDING SITES in the United States and Mexico. However, the apparent lack of depensation in one population does not preclude it from being important to other populations or species. Although difficult to study, a decline in growth rate at small population sizes can substantially increase the risk of extinction for a population, so it will continue to be important to consider depensation despite the lack of solid evidence for its occurrence.

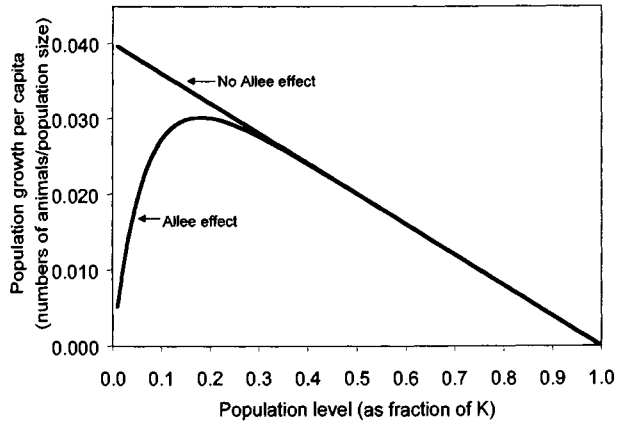

Figure 3 *An illustration of the Allee effect. One curve represents linear density dependence without depensation ("no Allee effect"). The second curve represents linear density dependence with depensation ("Allee effect"). Under depensation, population growth per capita declines at low population levels.*

Population Status and Trends

JAY BARLOW
Southwest Fisheries Science Center, La Jolla, California

RANDALL R. REEVES
Okapi Wildlife Associates, Hudson, Quebec, Canada

For marine mammals, *status* is a measure of the size or general HEALTH of a population relative to some management standard. A *trend* is a measure of the rate at which a population grows or declines over some (usually long) time period. Taken together, status and trends form the basis for assessing whether management objectives are being met for a given population or management unit.

I. Status

Inherent in the concept of status is the evaluation of populations relative to some standard or metric. Absolute estimates of population size may be included in an assessment of the population status, but an evaluation of status is incomplete without evaluating the significance of this population size relative to some goal. The standards for evaluating the status of populations are typically related either to a harvest or to a conservation objective.

A. Harvest Objectives

Traditionally, to evaluate harvest objectives, population size was evaluated relative to the population level (MSYL) that would give the maximum sustainable yield (MSY). Populations are expected to decline as a result of harvests, but as population size decreases, the population growth rate is expected to increase to compensate for this harvest. The implicit assumption is that populations are resource limited, and as density declines, more per-capita resources are available to support enhanced production, survival, or both. Harvest and growth rates may balance each other over a wide range of possible equilibrium population sizes, but typically harvest will be maximized at one specific equilibrium level (MSYL). Although the MSYL concept has persisted for many years, it was widely recognized by the 1970s that, in practice, it was seriously flawed as a basis for management. Management of populations at their MSYL is a knife-edge balancing act that requires constant conditions and near-perfect data. Usually, when populations slip below that level, the drastic management actions that are required cannot be implemented in time to prevent the collapse of the population as an economic resource. This realization has led to more risk-averse management models that strive to keep populations above their MSYL; this higher target level is sometimes called the optimum sustainable yield level.

Currently, few marine mammal species are managed with explicit harvest objectives. Although a moratorium on commercial whaling has been in place since 1986, the INTERNATIONAL WHALING COMMISSION (IWC) still maintains a harvest-based management framework for large whales [baleen whales, sperm whales (*Physeter macrocephalus*), and bottlenose whales (*Hyperoodon* spp.)]. To determine status, population size is compared to a standard that is based on MSYL. Protected stocks (PS) are less than 0.9 MSYL; sustained management stocks (SMS) are between 0.9 and 1.2 MSYL; and initial management stocks (IMS) are greater than 1.2 MSYL. Using this scheme, the IWC has assessed the current status of many, but not all, of their management stocks (Table I). Acknowledging the risk of managing at the MSYL knife edge, the IWC has, since the mid-1970s, limited harvests to 90% of the estimated MSY. The IWC has been working on a "revised management procedure" (RMP) to replace this MSYL-based management when the moratorium on commercial whaling ends. The performance of the RMP has been tested in simulations where the objective is to maintain populations above 72% of their preexploitation population size.

The Stock Assessment Secretariat of the Canadian Department of Fisheries and Oceans coordinates the production of stock assessment reports for hunted species, notably including harp seals (*Pagophilus groenlandicus*), narwhals (*Monodon monoceros*), and bowhead whales (*Balaena mysticetus*). These reports, prepared by scientists in close consultation with representatives of regional bodies and hunting communities, are intended to provide the basis for managing harvests. However, in the absence of a legal framework equivalent to the U.S. Marine Mammal Protection Act (see later), harvest objectives are ad hoc. A stock assessment report recently completed for the Hudson Bay-Foxe Basin stock of bowhead whales, for example, invokes "sustainability" as an implicit management objective, with no reference to recovery or maximizing yield.

B. Conservation Objectives

The goals of conservation efforts can range from preventing the extinction of species to returning populations to their carrying capacity level. The metrics used to measure the conservation status of populations range over this same spectrum.

When populations become very small or are declining rapidly, their status is often determined by estimating the probability of extinction within a defined time period. For example, the "critically endangered" category of the IUCN Red List includes species whose probability of EXTINCTION is estimated to be at least 50% within 10 years or three generations, whichever is longer. Clearly this is nature's intensive care unit for the nearly hopeless cases. In the IUCN categories of "endangered" and "vulnerable," the values change to 20% chance of extinction within 20 years or five generations and 10% chance within 100 years, respectively. The risk of extinction is estimated using a technique developed in conservation biology known as

TABLE I
Status Classification for Whales Managed under the Authority of the International Whaling Commission[a]

Species	*Stock*	*Status*
Blue whale (*Balaenoptera musculus*)	All stocks	Protection stock (PS)
Fin whale (*B. physalus*)	Southern Hemisphere	PS
	North Pacific	PS
	Nova Scotia	PS
	East Greenland–Iceland	Sustained management stock (SMS)
	All other stocks	Not classified
Sei whale (*B. borealis*)	Southern Hemisphere	PS
	North Pacific	PS
	Nova Scotia	PS
	All other stocks	Not classified
Bryde's whales (*B. brydei* and *B. edeni*)	Southern Indian Ocean	Initial management stock (IMS)
	Solomon Islands	IMS
	Western South Pacific	IMS
	Eastern South Pacific	IMS
	Western North Pacific	IMS
	Eastern North Pacific	IMS
	East China Sea	PA
	North Atlantic	IMS
	All other stocks	Not classified
Minke whales (*B. acutorostrata* and *B. bonaerensis*)	Southern hemisphere[b]	Not classified
	Okhotsk Sea–West Pacific	Not classified
	Sea of Japan–Yellow Seal–East China Sea	PS
	North Pacific remainder stocks	Not classified
	West Greenland	PS
	Northeast Atlantic	PS
	Other Atlantic stocks	Not classified
	Indian Ocean	IMS
Right whales (*Eubalaena* spp.)	All stocks	PS
Bowhead whale (*Balaena mysticetus*)	All stocks	PS
Humpback whale (*Megaptera novaeangliae*)	All stocks	PS
Pygmy right whale (*Caperea marginata*)	All stocks	PS
Gray whale (*Eschrichtius robustus*)	Eastern North Pacific	SMS
	Western North Pacific	PS
Sperm whale (*Physeter macrocephalus*)	Western North Pacific	PS
	All other stocks	Not classified
Bottlenose whales (*Hyperoodon* spp.)	North Atlantic	PS
	All other stocks	Not classified

[b]Actually including two species: *Balaenoptera acutorostrata* and *B. bonaerensis*.

population viability analysis (PVA), which evaluates population size, trends in abundance, life history traits, natural variability, trends in habitat loss, and parameter uncertainty. These onerous data requirements have meant that very few marine mammal species or populations have been evaluated using PVA.

Lacking sufficient data to evaluate the risk of extinction in this manner, several surrogate variables may be measured that are highly correlated with extinction risk. Extinction is obviously correlated with declining abundance (see Section II), and the IUCN uses total declines of 80, 50, and 20% over 10 years (or three generations) to classify species as critically endangered, endangered, or vulnerable, respectively. We know that small population size is itself an extinction risk factor, and the IUCN uses population sizes of 50, 250, and 1000 mature individuals to classify species into the same three categories. Other important factors that increase extinction risk include (1) having all individuals in a single location, (2) overdispersal and the resulting loss of mating opportunities and social facilitation, (3) habitat degradation, and (4) extreme fluctuations in population size. The IUCN recognizes the compounding of risk factors

and evaluates some of these factors in tandem with population size or trends. Under domestic legislation, the United States maintains a similar endangered species list with categories of "endangered" and "threatened."

The IUCN's development and adoption of quantitative criteria for Red List classifications prompted various national efforts to take a similar approach. For example, the Mammalogical Society of Japan has applied the IUCN criteria to all marine mammal populations in Japanese waters. The status assigned to many of these populations is worse than that indicated by the IUCN's global listing for the species. There are, for example, critically endangered or endangered populations of finless porpoises (*Neophocaena phocaenoides*), striped dolphins (*Stenella coeruleoalba*), short-finned pilot whales (*Globicephala macrohynchus*), and dugongs (*Dugong dugon*) in Japan, whereas these species, overall, are listed by IUCN as either vulnerable, "data deficient" (inadequate information to assess risk of extinction), or "lower risk, conservation dependent" (out of danger but needing continued conservation measures). In Canada, the task of listing species and populations at risk falls on the Committee on the Status of Endangered Wildlife in Canada (COSEWIC). This group consists of technical experts as well as representatives of government agencies and nongovernmental organizations. Its listing decisions are based on status reports prepared by scientists familiar with the species or populations under review. COSEWIC is in the process of developing its own IUCN-style criteria for status determinations.

For species that are above the size at which extinction is a significant risk, status is usually measured relative to historical abundance or environmental carrying capacity (K). Even when the "official" definition of status is based on a percentage of K, historical abundance is often substituted because carrying capacity is so difficult to measure. Historical abundance is, itself, poorly known for many species. If there are no direct measures of historical abundance, it can be estimated by a method called "back-calculation" based on current abundance, a time series of annual human-caused mortality, and a model of population growth.

The U.S. Marine Mammal Protection Act of 1972 is probably the most far-reaching and proactive national legislation for the conservation of marine mammals. It has two main conservation goals: to keep populations at their "optimum sustainable population" (OSP) levels and to keep populations as "functioning elements of their ecosystem." OSP has been interpreted to be a range from a population's maximum net productivity level (typically thought to be between 60 and 80% of K for marine mammals) up to its carrying capacity level. Populations below OSP are considered to be "depleted." The U.S. legislation is significant for having explicit goals to maintain populations near their natural levels instead of protecting them only after they have declined to dangerously low levels.

Similarly, in Europe, the Agreement on the Conservation of Small Cetaceans in the Baltic and North Seas (ASCOBANS) has a conservation goal to restore and/or maintain stocks at a level they would reach when there is the lowest possible anthropogenic influence. ASCOBANS has interpreted this objective to mean restoring and/or maintaining populations at or above 80% of K.

II. Trends

An upward or downward trend in population size is obviously a significant component in evaluating the status of a population; however, it is also one of the more difficult components to determine. Population trends have been directly estimated for only a tiny proportion of all cetacean populations. The primary problems are that population size cannot be estimated very precisely and population growth is typically slow.

Cetacean population size is usually estimated from line-transect SURVEYS. Trends can also be based on an index of relative abundance, such as the number of whales seen per hour on standard transects with consistent survey methods. In either case, the precision of the estimates is measured as a coefficient of variation (CV = standard deviation divided by the mean); CVs of 20% are considered very good and CVs of 30–50% are considered typical. Given their life history constraints, cetacean populations can grow at a maximum rate of about 8% per year, and, for some slow-reproducing species [such as the killer whale (*Orcinus orca*) and sperm whale], maximum growth rates may be as low as 2–3%. There is no similar constraint on the rate at which populations can decline; however, there have been few instances where long-term rates of decline have been found to exceed these values.

Statistical power is a measure of the probability of detecting a significant change in a population if that population is truly growing or declining. Power increases with the actual rate of change in population size and with the sample size (both the amount of survey effort and, more importantly, the length of the monitoring period). As a rule of thumb for cetaceans, at least 10 annual surveys with good precision (CV < 20%) are required to yield a high probability (>80%) of detecting a 50% change in total population size. Thus, even a carefully monitored population can be cut in half before solid evidence of a decline becomes available. The situation is made even more difficult for endangered species [such as the baiji (*Lipotes vexillifer* and vaquita (*Phocena sinus*)], which become almost impossible to census as they become increasingly rare. Similar to cetaceans, the detection of population trends for dugongs and manatees is extremely difficult.

Our ability to detect trends in pinniped populations is considerably better. Although total population size may be difficult to estimate, a segment of the population predictably returns to land or ice to breed, give birth, or molt, and this segment can be counted accurately by ground-based observers or from aerial photographs. Growth or decline in this segment is taken as an index of trend for the entire population so this kind of count is sometimes referred to as an index count. Index counts may be based, for example, on the number of pups born or the number of total seals hauled out at the peak of the molting season. If index counts are used over a wide range of population sizes, ancillary research is typically required to ensure that the fraction of animals counted does not vary in a density-dependent manner (e.g., as per capita resources become scarce, the percentage of time spent foraging away from the beach might increase). Another factor making positive trends in pinniped populations easier to detect is that most are capable of growing at faster rates than cetaceans and sirenians.

Porpoises, Overview

ANDREW J. READ
Duke University Marine Laboratory, Beaufort, North Carolina

The porpoises are 1 of 10 families that constitute the suborder Odontoceti, or the modern toothed whales. The family Phocoenidae consists of six species, distributed in both hemispheres (Table I). For many years, and in some areas still today, there has been confusion regarding the terms "porpoise" and "dolphin." In part, this is because many early taxonomic accounts included porpoises in the family Delphinidae, although all recent accounts separate the two groups. In addition, many delphinids have been referred to as "porpoises" to distinguish them from the dolphin fish (*Coryphaena hippurus*), also known as mahi-mahi or dorado. Despite their shared vernacular names, porpoises and dolphins are phylogenetically distinct and are as different as horses and cows or dogs and cats. These differences are manifested in their morphology, ecology, and behavior, as outlined here.

TABLE I
Living Species of Porpoises

Common name	*Scientific name*	*Distribution*
Harbor porpoise	*Phocoena phocoena*	Coastal Northern Hemisphere
Burmeister's porpoise	*P. spinipinnis*	Coastal South America
Vaquita	*P. sinus*	Gulf of California
Spectacled porpoise	*P. dioptrica*	Southern Ocean
Dall's porpoise	*Phocoenoides dalli*	North Pacific
Finless porpoise	*Neophocaena phocaenoides*	Coastal south and east Asia

I. Origins

Our knowledge regarding the evolution of porpoises comes from inferences drawn from the fossil record and from the morphology and genotypes of living species. The earliest porpoise known is *Salumiphocaena stocktoni*, discovered in late Miocene strata of southern California, from approximately 11 million years ago. These early porpoises appeared at about the same time as the first dolphins. The dates of the origin of the two families are consistent with estimates of divergence between the cytochrome *b* genes of phocoenids and delphinids. Most other early fossil porpoises are known from the Pliocene in North and South America. Porpoises, dolphins, and monodontids, all members of the superfamily Delphinoidea, are likely to have descended from the Kentriodontidae, an extinct family of odontocetes. Like modern porpoises, the kentriodontids were rather small animals, approximately 2 m in length. Kentriodontids occurred in both the Atlantic and Pacific Oceans, but disappeared approximately 10 million years ago.

Analyses of the genome of living porpoises suggest that the finless porpoise is the most primitive, or basal, member of the family. This view is consistent with morphological evidence. Some researchers believe that the earliest phocoenids radiated into temperate waters of both hemispheres from the tropics, where the finless porpoise is still found today. Other researchers maintain that phocoenids originated in temperate waters of the North Pacific Ocean, where the oldest fossils are located. With our current knowledge, it is not possible to resolve which of these two scenarios are correct. Molecular evidence indicates that all modern porpoises have evolved within the past few million years.

The nature of phylogenetic relationships among porpoises has been the subject of recent debate. Researchers studying the morphology of living species have suggested that the spectacled porpoise of the Southern Ocean is closely related to the Dall's porpoise of the North Pacific and that these two species should be classified as a subfamily distinct from the remaining four species. This view has not been supported by analysis of the molecular genome, however, which suggests a close phylogenetic relationship among the vaquita, Burmeister's porpoise, and spectacled porpoise. Most researchers now separate the family into three genera: *Neophocaena*, *Phocoenoides*, and *Pho-*

coena. The first two genera are monotypic (the finless porpoise *Neophocaena phocaenoides* and Dall's porpoise *Phocoenoides dalli*) and the third contains four species (harbor porpoise *Phocoena phocoena*, vaquita *Phocoena sinus*, Burmeister's porpoise *Phocoena spinipinnis*, and spectacled porpoise *Phocoena dioptrica*). More work is required, however, on the exact phylogenetic relationships among these forms.

Periodic cycles of global cooling and warming have had profound effects on the modern biogeography of all cetaceans, and this holds true for the porpoises. For example, the distribution of the vaquita is currently restricted to the northern Gulf of California. In geographical terms, the closest relative of the vaquita is the harbor porpoise, which is found as far south as the coast of central California. Morphological and genetic evidence, however, indicate that the closest living relative of the vaquita is the Burmeister's porpoise, from the coastal waters of temperate South America. It is likely that, during a cool glacial period of the Pleistocene, ancestors of today's Burmeister's porpoises crossed the equator and were subsequently trapped in the Gulf of California by warming equatorial waters. This isolated population eventually gave rise to the vaquita.

The selective factors shaping the evolution of porpoises are poorly understood. It is unclear, for example, why all modern forms exhibit paedomorphosis and small body size (see later). Whatever these selective forces, they appear to have driven similar evolution in the delphinid genus *Cephalorhynchus* of the Southern Hemisphere. The morphology, ecology, and behavior of these dolphins are remarkably similar to porpoises in many ways and they appear to have CONVERGED with porpoises in many aspects of their biology.

II. Morphology

Porpoises share many morphological attributes that distinguish them from other small cetaceans. All six species are small, with no member of the family exceeding 250 cm in body length. Porpoises are stocky, robust animals and lack the rostrum common to most delphinids. The appendages of most species are relatively small and, in the case of the finless porpoise, the dorsal fin is missing altogether. Many of these morphological features may be related to the thermal biology of porpoises and, particularly, to the challenges posed by small body size in a cold and conductive medium.

The skulls of all porpoises exhibit pronounced paedomorphosis, the retention of juvenile characters in the adult form. In particular, the skulls of all porpoises are characterized by short rostra, large and rounded braincases, and delayed fusion of cranial sutures during ontogeny. As a result, the skulls of adult porpoises resemble those of juvenile specimens of other species. Several other cranial features are diagnostic of the family, including raised protuberances on the premaxillae and the spatulate shape of the teeth. The latter feature is an easy way to distinguish porpoises from dolphins, which have conical teeth.

An unusual morphological feature of all phocoenid species, except for the Dall's porpoise, is the presence of epidermal tubercules along the leading edge of the dorsal fin. These small, raised protuberances develop shortly after birth and usually occur in several rows. Even the finless porpoise, which lacks a dorsal fin, possesses several rows of tubercules on its dorsal ridge. Tubercules are most prominent in the Burmeister's porpoise and their presence provides the basis for the trivial name *spinipinnis*. The function of these unusual structures is unknown.

The pigmentation patterns of phocoenids vary considerably, although there are several features common to the family. Most porpoises possess patches of dark pigmentation surrounding the eye, although these patches are of varying prominence and contrast. The dark eye patch is particularly well developed in the spectacled porpoise, *Phocoena dioptrica*, where it is encircled by a narrow white line, which gives the species both its common and specific names. All porpoises (and most dolphins) exhibit a bridle, a system of stripes extending from the eye and blowhole to the apex of the melon, and most porpoises exhibit the general pattern of countershading, common to many odontocetes, of a dark dorsal cape and a lighter abdomen.

III. Ecology and Behavior

Our general knowledge of the ecology and behavior of porpoises is limited and these areas are fertile subjects for future research. The vaquita was described only as recently as 1958, for example, and few researchers have ever seen the species in the field. Burmeister's and spectacled porpoises are also very poorly known, the latter primarily from a few STRANDINGS in remote areas of the Southern Hemisphere. In contrast, our knowledge of the ecology and behavior of harbor porpoises is much more extensive.

The radiation of phocoenids over the past few million years has allowed porpoises to colonize a variety of habitats in both hemispheres. The harbor porpoise, Burmeister's porpoise, and vaquita are coastal in nature and the range of the finless porpoise extends well upstream into major river systems. The Dall's porpoise and spectacled porpoise are primarily pelagic animals.

There is little evidence of cooperative feeding in the family and it appears that individual porpoises usually forage alone. Most coastal species, such as the harbor and Burmeister's porpoise, feed on small pelagic fish, such as herring, anchovies, and capelin, and supplement this diet with demersal fishes. In contrast, Dall's porpoises feed primarily on the small mesopelagic fish and squid that comprise the deep scattering layer. To date, DIVING BEHAVIOR has been studied for only the harbor porpoise, which can dive to depths of over 200 m. Their small size makes it unlikely that any species of porpoise, even the pelagic Dall's porpoise, are exceptional divers. Dall's porpoises likely take advantage of the daily vertical migration of their prey and feed at night when these mesopelagic fish and squid are near the surface.

Porpoises are among the smallest cetaceans and this aspect of their biology is manifested in their reproductive biology. Compared to many delphinids, porpoises grow rapidly and reach sexual maturity at an early age. For example, many female harbor porpoises attain sexual maturity in their third year of life, at an age where bottlenose dolphins are still accompanying their mothers. Both Dall's and harbor porpoises are capable of

annual reproduction, and females of these species are often simultaneously lactating and pregnant. This demanding reproductive schedule is accompanied by a relatively brief life span—very few porpoises live longer than 20 years.

Although our knowledge of the social behavior of phocoenids is limited, we can say that, unlike many pelagic delphinids, porpoises usually occur alone or in small, fluid groups. This is also reflected in patterns of strandings. Porpoises generally strand singly, never in the large groups witnessed in some other odontocete species. Occasionally, hundreds of porpoises have been observed together, but these are likely temporary aggregations, rather than stable groups. In general, it appears that porpoises typically exist in fission–fusion societies in which associations among individuals are extremely dynamic. The only long-term association known to occur is between a lactating female and her dependent calf. The duration of lactation varies among species, and perhaps among populations within species, but is unlikely to surpass 2 years in any phocoenid.

With the exception of the Dall's porpoise, porpoises are generally shy, unobtrusive animals that are difficult to sight and follow at sea. Unlike many delphinids, porpoises seldom, if ever, leap clear of the water. A typical surfacing sequence is characterized by a series of gentle rolls at the surface, followed by a longer submergence. Occasionally on calm days, harbor porpoises will lie quietly at the surface for short periods. Individuals seldom approach boats or ride the bow or stern waves of vessels. In contrast, Dall's porpoises are fast swimmers that often make a characteristic splash or "rooster-tail" when they surface. Dall's porpoises are also the only phocoenid that regularly approaches boats to ride the bow wave, a behavior they may have modified from riding the pressure waves produced in front of swimming baleen whales.

IV. Conservation

Most populations of phocoenids are affected to some degree by human activities. Hunting, bycatches in commercial fisheries, and habitat degradation have had profound impacts on the health and demography of affected populations. Only the spectacled porpoise of the Southern Ocean is largely free of the effects of human influences, although even this species has been taken as bycatch in fisheries off Tierra del Fuego. The nature of human activity posing a conservation threat varies from species to species, as does the conservation status of each species.

Porpoises living in coastal areas are affected by the modification, degradation, and destruction of habitat by humans. Particularly affected in this manner is the finless porpoise, which inhabits the temperate and tropical coasts of Asia and the Indian subcontinent. Human activities, such as dredging, reclamation, pollution, and intense vessel traffic, are felt most keenly in coastal and riverine habitats where the density of humans is high. Thus, particular concern has been expressed for populations of finless porpoises in the South China Sea and adjacent waters. Other coastal species of porpoises are not immune from such effects. Harbor porpoises, for example, may be excluded from portions of their habitat in the North Atlantic and North Pacific by the use of high-intensity acoustic devices designed to keep pinnipeds away from salmon mariculture sites.

Harbor and Dall's porpoises have been hunted for their meat and blubber for many centuries. In the Danish Belt sea, an annual hunt for harbor porpoises occurred from the 14th century until the early 20th century. More than 1000 porpoises were taken annually between 1834 and 1874 in this hunt. Harbor porpoises have also been harvested from other areas, particularly the Bay of Fundy and western Greenland. A large-scale harpoon fishery for Dall's porpoises still exists off the coast of northern Japan. This hunt supplies meat for the domestic Japanese market, partially offsetting the reduction in the availability in whale meat following the moratorium in commercial whaling that began in 1986. The effects of this exploitation on populations of Dall's porpoises are not fully understood, but the magnitude of catches (more than 40,000 in 1988) is cause for concern.

Perhaps the most insidious threat to populations of phocoenids is their bycatch in commercial fisheries. Most porpoises are taken as bycatch in gill net fisheries, which use either floating nets to capture fish near the surface or nets anchored on the bottom to catch demersal species. In both cases, porpoises seldom survive entanglement in this type of fishing gear. The causes of bycatches are unclear; it is uncertain, for example, why animals with such a sophisticated system of ECHOLOCATION do not detect and avoid fishing nets. Nevertheless, all species of porpoises are taken as bycatch, sometimes in staggering numbers. The estimated annual mortality of harbor porpoises in Danish bottom gill net fisheries in the North Sea was almost 7000 between 1994 and 1998, for example. The consequences of such large bycatches for affected populations are unknown. In some areas, such as the coastal waters of Peru, porpoises taken initially as bycatch gained commercial value for human consumption so that the distinction between bycatches and directed hunting is blurred. Bycatches pose by far the most serious threat to the single population of vaquitas in the upper Gulf of California. The size of this unique population is estimated to be little more than 500 individuals and it is still subject to bycatch in several artisanal fisheries. The vaquita is one of the most endangered marine cetaceans; its uncertain future depends on conservation initiatives in Mexico.

Predation on Marine Mammals

DAVID W. WELLER
Southwest Fisheries Science Center, La Jolla, California

Although marine mammals are regarded as accomplished and sophisticated hunters, they too are preyed upon by a variety of terrestrial, avian, and aquatic predators. Predation is an ecological factor of significant influence on the behavior and organization of animal societies in general, and the need for protection from predation has likely been an important factor in the evolution of most marine mammal social systems. While the risk of predation is of little or no concern for some species, other exist under high levels of predatory pressure. A large portion of all marine mammals, ranging in size from the enormous blue whale (*Balaenoptera musculus*) to the relatively small sea otter (*Enhydra lutris*), are subjected to varying levels of predation. Responses to predators are complex and include detection and avoidance, fleeing, seeking habitat features for cover, and active defense by individuals as well as coordinated groups.

While the topic of predation is expansive and multidimensional, the focus of the following article centers on the hunting and consumption of marine mammals by their predators. The definition of predation used here excludes parasitism, FILTER FEEDING, scavenging (carrion eating), or browsing and is limited to situations in which an animal expends time and energy to locate living prey and exerts additional effort to kill and consume it. Therefore, predation is distinguished from other forms of foraging in that it concludes with the death of an animal that offers some resistance against being discovered and/or being harmed.

I. Predation on Sirenians

The relatively slow moving and rather lethargic behavior of sirenians (manatees, *Trichechus* spp., and dugongs, *Dugong dugon*) makes them seem particularly vulnerable to predation. However, manatees and dugongs actually have few known natural predators and appear to experience only occasional mortality due to predation. Although large sharks, crocodiles (*Crocodylus* spp.), and killer whales (*Orcinus orca*) are all considered to be potential predators, few records exist to confirm these suspicions. Evidence of predation, including tooth scarring indicative of unsuccessful attacks by predators, has been observed only rarely during long-term field studies on manatees (*Trichechus manatus*) in Florida and dugongs off Australia. The limited presence of marine predators in the relatively warm and shallow nearshore waters, rivers, and bays where these animals forage on marine vegetation may partially explain the paucity of observed predatory interactions. Further, the particularly thick skin and exceedingly dense bone characteristic of the sirenians may render them rather unpalatable and serve to deter potential predators.

Predation on sirenians does occur, however. For example, in South America, Amazon manatees (*T. inunguis*) are reported to be preyed on by jaguars (*Panthera onca*) and large sharks, and marine crocodiles may occasionally kill dugongs throughout their distribution. Off Western Australia, predation by killer whales on adult dugongs has been reported, including one occasion when 10 killer whales were observed attacking a group of approximately 40 dugongs in shallow water. During this incident the dugongs were huddled tightly together in an antipredator response, while pieces of flesh and integument floated nearby in blood-stained water. Local residents of Western Australia have also implicated "black porpoises" as predators of dugongs; however, what species these "porpoises" represent is entirely unclear. While some authors suggest that these porpoise attacks were likely to be by killer whales, such records may also refer to one of several other mammal-killing cetaceans such as the false killer whale (*Pseudorca crassidens*), pygmy killer whale (*Feresa attenuata*), or short-finned pilot whale (*Globicephala macrorhynchus*). It is conceivable, of course, that predation on sirenians is considerably higher than has been observed and reported. Predatory attacks on young animals, for example, may be particularly successful, and information regarding the predator-related mortality of species such as the West African (*T. senegalensis*) and Amazon manatees that mainly occur in areas inaccessible to researchers is largely unknown.

II. Predation on Mustelids

Although sharks and killer whales represent the primary predators of sea otters several terrestrial and avian predators have also been documented. Coyotes (*Canis latrans*) are known to prey on recently weaned OTTERS in parts of Alaska, and Russian brown bears (*Ursus arctos*) occasionally kill otters that haul out along the shores of the Kamchatka Peninsula. Near Amchitka Island, Alaska, sea otter pups are hunted by bald eagles (*Haliaeetus leucocephalus*). Pups are particularly vulnerable to avian predation as they float unattended at the surface while their mothers are preoccupied with searching for food. The extraordinary buoyancy of young otter pups prevents them from readily submerging and greatly reduces their chances of escaping attack by diving.

Observations of bald eagles nabbing young otter pups from the surface of nearshore waters confirm that eagles use a hunting strategy similar to that used when capturing large fish. That is, pups are gathered from the water in the talons of an eagle, flown to the nest location, and meticulously devoured. Studies conducted on Amchitka Island between the 1950s and 1970s found that up to 28% of the prey remains in eagle nests were from sea otters. Interestingly, some nests contain high levels of otter remains while other nests have none. This finding suggests that some individual eagles may actually specialize on hunting sea otter pups.

While terrestrial and avian predation account for only a small portion of sea otter mortality, sharks represent a more formidable and common predator. White shark (*Carcharodon carcharias*) attacks on sea otters along the California coast are thought to account for 8–15% of the total otter mortality recorded in this region. Curiously, there is little evidence from examination of white shark stomach contents to suggest that sea otters are actually eaten by the individuals that attack them. Instead, otters are stalked and killed by white sharks off California but are apparently abandoned prior to consumption. The absence of sea otter remains in white shark stomachs cannot be considered conclusive at this time, however, as only a small number of stomachs have been available for examination. Although other shark species are also suspected to occasionally kill sea otters, few specific details are available.

Killer whales are known predators of sea otters, but the small number of observed attacks suggests that otters are not preferred prey. Nonetheless, a substantial increase in the number of killer whale attacks on sea otters was documented between 1992 and 1996 and corresponded with a notable decline in sea otter population levels over a large part of their western Alaska distribution. It is unclear if this increase in observed killer whale attacks was due to a greater observation effort or represents a real increase in sea otter predation. If this change is merely related to increased observation effort, then killer whale predation on sea otters may not be as uncommon as previously suggested. However, if this finding represents a true increase in the rate of sea otter attacks, it may be related to the relatively recent declines of other killer whale prey, such as Steller sea lions (*Eumetopias jubatus*) and harbor seals (*Phoca vitulina*).

III. Predation on Pinnipeds

Of all the marine mammal groups, pinnipeds are probably subjected to the highest level of predation. While some pinniped species experience little or no predation pressure, others are hunted so intensively that important aspects of their natural history, including reproductive strategies, have evolved in response. Not even the largest pinnipeds such as the walrus (*Odobenus rosmarus*), bearded seal (*Erignathus barbatus*), and elephant seals (*Mirounga* spp.) are free from predation. Terrestrial predators of pinnipeds are particularly abundant in the subpolar and polar regions of the Northern Hemisphere, usually appearing in the form of polar bears (*Ursus maritimus*) and Arctic foxes (*Vulpes lagopus*). Southern Hemisphere ice seals are free from land predators, but instead have fierce aquatic predators such as the leopard seal (*Hydrurga leptonyx*) to contend with. Pinnipeds in temperate and tropical latitudes experience reduced terrestrial predation but are subjected to increased levels of attack by aquatic predators such as sharks and killer whales. When comparing Northern Hemisphere Arctic pinnipeds to Southern Hemisphere Antarctic pinnipeds, clearly divergent predator avoidance tactics are apparent. Arctic pinnipeds escape land predators by fleeing into the water whereas Antarctic pinnipeds escape aquatic predators by retreating onto ice.

All pinnipeds require a land or ice substrate for pupping, and this facet of their natural history makes them particularly vulnerable to attack in regions where terrestrial predators are present. Golden jackals (*Canis aureus*), for example, are common at a Mediterranean monk seal (*Monachus monachus*) colony on the western coast of Mauritania and have been reported to consume freshly dead monk seals and are suspected to also prey on living pups. Freshwater pinnipeds in Russia's Lake Baikal and in the Caspian Sea (*Pusa sibirica* and *P. caspica*, respectively) have no aquatic predators, but instead have an unusually high number of terrestrial adversaries. Wolves (*Canis lupus*) and eagles prey on newborn Caspian seals, and brown bears occasionally hunt Baikal seals. Ringed seal pups (*Pusa hispida*) inhabiting Finland's Lake Saimaa and Russia's Lake Ladoga are preyed upon by red foxes (*Vulpes vulpes*) and are also suspected to suffer some level of mortality due to attacks by ravens (*Corvus corax*), wolves, dogs, and wolverines (*Gulo gulo*). Similarly, brown bears, wolves, and avian predators, including eagles and ravens, sometimes also kill spotted seals (*Phoca largha*) in the Sea of Okhotsk. Glaucous gulls (*Larus hyperboreus*) and ravens may occasionally kill ringed seal pups, and gulls sometimes peck at the eyes of gray seal pups (*Halichoerus grypus*), resulting in some level of mortality.

Additional terrestrial predators also hunt pinnipeds at their haul-out sites. Coyotes, for example, prey on harbor seal pups in the Pacific Northwest and are responsible for at least 16% of the pup mortality within Puget Sound, Washington. Similarly, bears and mountain lions (*Felis concolor*) may have historically preyed on elephant seals (*Mirounga angustirostris*) along the California coast. In the Southern Hemisphere, mountain lions have been reported to prey on southern sea lion pups (*Otaria flavescens*). South African fur seals (*Arctocephalus pusillus*) that breed along the mainland coast of the southern Africa continent are preyed upon by brown hyenas (*Hyaena brunnea*) and black-backed jackals (*Canis mesomelas*), and South American sea lion pups (*Arctocephalus australis*) are probably attacked by mountain lions.

Arctic foxes have been described as hunters of small animals and birds and as a scavenger of marine mammal remains left by polar bears. However, in parts of the eastern and western expanses of the Beaufort Sea, this fox is considered an active predator of newborn ringed seal pups. In early spring, ringed seals birth and rest in "subnivean birth lairs"—ice caves complete with breathing holes constructed beneath the snow. These lairs provide both shelter from cold temperatures and protection from predators by providing a physical barrier that makes it more difficult for surface predators to detect a newborn pup. Nevertheless, foxes and polar bears enter and kill pups concealed within their subnivean homes with relative fre-

quency. Keen olfaction allows foxes to locate lairs that may be buried under as much as 150 cm of snow. In the Beaufort Sea, Arctic foxes enter about 15% of the birth lairs present within an area. Although the annual average predation rate by Arctic foxes on ringed seal pups is about 26%, rates as high as 58% have been recorded. Ringed seals are also preyed upon by polar bears and may occasionally be attacked by red foxes, wolverines, wolves, dogs, and several avian predators. As such, ringed seals are subjected to perhaps the highest level of predation experienced by any of the marine mammals.

A. Polar Bears

Throughout their circumpolar range, the major prey of polar bears consists of pinnipeds. Polar bears are versatile predators and are well adapted for catching Arctic pinnipeds. Predation is particularly heavy on pups, as they represent an easily obtained food resource. Foraging strategies employed by polar bears range from sit-and-wait tactics to active stalking and pursuit of seals on ice and in the water. When stalking seals on ice, bears "creep" along with their heads held low, often momentarily hiding behind snowdrifts and irregularities in the ice. Despite their relative stealth and excellent ability to detect prey by olfaction, bears often have little success sneaking up on seals. Observations of bears hunting, and in at least one instance capturing, free-swimming seals in ice-free waters have also been reported. One of the sit-and-wait strategies employed by polar bears occurs while hunting ringed seals. Ringed seals forage for food under ice-covered waters throughout the winter and must therefore maintain breathing holes in which to surface. Polar bears seek out such breathing holes and often patiently await the arrival of an unsuspecting seal. When a seal surfaces in the hole for a breath of air, the bear quickly grasps it and drags it from the water onto the ice.

The ringed seal is a main staple of the polar bear diet, although in the Canadian Arctic bearded seals and harp seals (*Pagophilus groenlandicus*) are taken to a lesser extent. Harp and hooded seals (*Cystophora cristata*) are particularly vulnerable to predation on the spring pupping grounds, where polar bears may kill more pups than can be consumed. In Alaska, most of the ringed seals attacked by polar bears are over 6 years of age, while in the Canadian Arctic it is mainly 1- to 2-year-old seals that are killed. Polar bears are largely unsuccessful hunting adult ringed seals due to their nearly constant antipredator vigilance. This vigilance behavior is characterized by constant head lifting and scanning of the nearby environment for the presence of predators. In late spring, polar bears enter a period of intense feeding that corresponds with the onset of the ringed seal pupping season. During this time, bears prey heavily on pups by digging into birth lairs; adult female seals attempting to protect their pups are also occasionally killed.

Walruses are occasionally preyed upon by polar bears, but this massive obobenid represents a formidable adversary quite capable of killing predatory bears. The extent of polar bear predation on walruses is not well known and is likely to vary from region to region. Walrus calves, young juveniles, and sick individuals are most vulnerable to polar bear predation. While hunting walruses, bears often cause entire hauled-out herds to "stampede" into the water by rushing toward them. Although most individuals in the stampede easily escape approaching bears, calves, or young animals may be crushed or injured in the ensuing chaos, making subsequent capture substantially easier.

B. Pinnipeds

Several pinniped species are recognized as predators of other pinnipeds and, in some locations, are responsible for a significant portion of the annual mortality incurred by regional populations. The most ferocious pinniped predators include the leopard seal in the Southern Hemisphere and the walrus in the Northern Hemisphere. In addition, several sea lion species are notorious for feeding on pinnipeds. Two types of pinniped–pinniped predation occur, one at the intraspecific level (within species) and another at the interspecific level (between species). In some cases, particular individuals (usually males) specialize in the predation of pinnipeds. For instance, young male Steller sea lions are known to prey on harbor seals off Alaska and have been noted to account for approximately 4–8% of the mortality reported for Northern fur seal pups (*Callorhinus ursinus*) at St. George Island, Alaska. Adult male Steller sea lions (*Eumetopias jubatus*) may also prey on other pinnipeds, as was recorded for one individual at Año Nuevo, California, that was observed feeding on a small California sea lion (*Zalophus californianus*). Similarly, Southern sea lions have been observed preying on South American fur seals, and at Punta San Juan, Peru, over 8% of the fur seal pups are killed by marauding sea lions during the breeding season. Off Macquarie Island in the sub-Antarctic, one young male New Zealand sea lion (*Phocarctos hookeri*) was thought to be responsible for the mortality of 43% of the fur seal pups (*Arctocephalus gazella* and *A. tropicalis*) from a particular year. At the Snares Islands, New Zealand, New Zealand sea lions have also been observed to prey on New Zealand fur seal pups (*Arctocephalus forsteri*). Finally, gray seals have been reported to consume pups of their own species, but it is unclear if this represents actual predation or merely cannibalistic scavenging of beach-cast carcasses.

1. Walruses Walruses are primarily bottom or benthic feeders whose diet consists largely of bivalve mollusks, a variety of invertebrates, and fish. In addition, they also prey on marine mammals and are known to feed on bearded seals, ringed seals, spotted seals, harp seals, and young walruses. Adult and subadult male walruses are typically responsible for pinniped kills, but females in the Chukchi Sea have also been observed eating seals. Some walruses are habitual predators of other marine mammals. Individuals that regularly attack seals develop massive chest and shoulder muscles, have long and slender tusks, and their upper torsos and normally ivory-colored tusks are stained amber from consuming the oil-rich blubber of their prey. In general, walruses kill pups and young individuals, but on occasion mature adult pinnipeds are also taken. Observations of attacks on harp seal pups and bearded seals are characterized by walruses impaling the prey with their tusks. Although very little of the skeletal muscle and bone of their mammalian prey are consumed, walruses methodically devour most, if not all, of the highly caloric hide and blubber.

Only since the 1970s have reports of seal-eating walruses become common. This relatively recent phenomenon has been linked with the almost doubling of the Pacific walrus population between the 1960s and the early 1980s. Although Pacific walrus numbers are currently thought to be in decline, the nearly 20-year increase in population size certainly elevated the probability of contact between walruses and other pinniped species and may help explain the greater use of seals as a food source in the past several decades.

2. Leopard Seals The leopard seal is known to prey on penguins, sea birds, fish, squid, krill, and pinnipeds. In certain parts of their range, pinnipeds are an important part of the leopard seal diet, whereas in other areas pinnipeds are rarely taken. Leopard seals commonly hunt a variety of pinnipeds, but young crabeater seal pups (*Lobodon carcinophaga*) are probably the most frequently attacked and form an important part of the leopard seal diet between November and January. After January, crabeater seal pups have physically developed to the point where they are better able to escape leopard seal predation, and the rate at which they are taken declines.

Parallel tooth scars resulting from unsuccessful leopard seal attacks are quite common on crabeater seals. A study of crabeater seals in 1976 reported that 78% of 85 adult seals handled for research purposes had scars resulting from interactions with leopard seals. Fresh wounds were far more common on subadults than adults, suggesting that immature animals up to the end of their first year were most likely to be attacked, and it is thought that pups younger than 6 months are probably unlikely to survive encounters with leopard seals. The relatively high level of predation on crabeater seals is believed to represent a food source potentially more important to leopard seals than either krill or penguins.

C. Sharks

Sharks represent an important predatory threat to a variety of temperate and tropically distributed pinnipeds. It is probable that all pinniped species, with the exception of inland lake seals, experience some level of shark predation. While the extent of shark attack on pinnipeds is not understood, it is nevertheless thought to play an important role in the population dynamics, life history, and behavior of some pinniped populations. For example, the high incidence of attacks by tiger (*Galeocerda cuvier*) and white-tip reef sharks (*Trianodon obesus*) on Galápagos fur seals (*Arctocephalus galapagoensis*) is thought to have contributed to their exceptionally long 3-year period of maternal investment. It has been suggested that this extended period of maternal care reduces the amount of time pups need to spend in the water foraging, which in turn significantly reduces the risk of shark predation.

White sharks are a common predator of pinnipeds, with seals, sea lions, and fur seals regarded as preferred prey in some regions of the world because of the high lipid stores contained within their blubber. Gray seals and harbor seals are commonly hunted by white sharks off eastern Canada, and northern elephant seals, Steller sea lions, harbor seals, and California sea lions represent common shark prey in the northeastern Pacific. Southern Hemisphere white sharks focus their attacks primarily on fur seals off South Africa, Australia, New Zealand, South America, and the Galápagos Islands, but also occasionally prey on New Zealand and Australian (*Neophoca cinerea*) sea lions.

Off central and northern California, the diet of white sharks consists mainly of pinnipeds. In particular, white sharks are a major predator of northern elephant seals throughout their entire breeding range, with seals of all age and sex classes vulnerable to attack. A large white shark is capable of killing and consuming elephant seals weighing as much as 2200 kg and approximately 3.5 m in length.

The hunting behavior of white sharks on northern elephant seals has been well described near the Farallon Islands off northern California. White sharks typically attack elephant seals at or near the surface and usually within several kilometers of the islands. In most cases, white sharks approach their prey from below and to the rear, grasp them in their teeth and carry them underwater, release them, and then wait for the prey to die; usually as a result of excessive blood loss. Many shark attacks are unsuccessful, as evidenced by the high incidence of shark-related lacerations and scars on the bodies and appendages of pinnipeds that escape capture (Fig. 1). The nature of these injuries suggests that when attacked from the rear, foreflipper swimming sea lions are more likely to escape than are hindflipper swimming elephant and harbor seals. Most sea lions with evidence of shark-related injuries have lower body and hindflipper injuries, whereas the majority of surviving elephant and harbor seals bear upper body injuries. While sharks sometimes inflict massively disfiguring wounds on pinnipeds, most injured seals that make it to land appear to survive. However, pregnant elephant seals that withstand shark-related injuries usually lose their pups, give birth to a stillborn, abandon the pup shortly after birth, or fail to wean the pup successfully.

In tropical regions, white sharks are less numerous and white-tip reef, gray reef (*Carcharhinus amblyrhynchos*), and especially tiger sharks represent the major pinniped predators. Tiger sharks hunt monk seals (*Monachus schauinslandi*) of all

Figure 1 *Northern elephant seal with a shark-inflicted wound near the hindflippers. Photo by Thomas A. Jefferson.*

ages off the northwestern Hawaiian Islands. Although other predators like hammerhead (*Sphyrna* sp.) and mako (*Isurus* sp.) sharks also occur off northwestern Hawaii, they apparently do not attack monk seals with any regularity. Gray reef sharks are frequently present when tiger sharks kill monk seals, but their presence is thought to represent scavenging rather that direct predation.

A high number of monk seals bear shark-inflicted wounds and scars, indicating that not all predatory attacks are successful. Adult male monk seals seem to have the highest incidence of scarring, suggesting that animals of other age classes are less likely to survive attack. Highly scarred males may also be attributed to the elevated aggressiveness in males during the breeding season and their propensity to attack or chase approaching tiger sharks. In addition to direct kills of monk seals, the severity and timing of nonfatal injuries to individual females may reduce overall reproductive success. Field observations confirm that female monk seals suffering major, but nonfatal, shark-related injuries have shorter mean lactation periods and overall lower pup survival. It has been suggested that the combination of lethal and nonlethal tiger shark attacks on Hawaiian monk seals may be hindering the recovery of this endangered population.

Pinnipeds (and cetaceans) are regularly tormented by a diminutive pest called the cookie-cutter shark (*Isistius brasiliensis*). This small squaloid shark ranges in size from 14 to 50 cm and inhabits deep tropical and subtropical waters of the Atlantic, Pacific, and Indian Oceans. By use of rasping jaws and teeth well suited to cutting, cookie-cutter sharks attach themselves to their marine mammal victims and remove small circular plugs of skin and blubber. Although these attacks are nonlethal, they represent a peculiar form of predation that falls outside the definition set forth at the beginning of this article, but is nevertheless of importance to recognize.

D. Killer Whales

The DIET of killer whales varies considerably between and within geographic regions. Some forms of killer whales, termed "transients," are mammal eaters, whereas others, termed "residents," base their diet on fish. Mammal-eating killer whales have been observed to hunt at least 14, and are suspected to take as many as 24, species of pinnipeds. With the exception of inland lake seals and monk seals (*Monachus* spp.), all pinniped species probably endure some level of killer whale predation.

Pinnipeds comprise a substantial part of the diet for some transient killer whale populations, and observations of predatory events have been witnessed in a variety of locations from around the world. In subpolar and polar areas, where killer whales are most abundant, reports of attacks on pinnipeds are particularly common. Killer whales attack pinnipeds in both offshore and nearshore regions and often in close proximity to terrestrial haul-out sites (Fig. 2).

Of all the pinniped species hunted by killer whales, southern elephant seals (*Mirounga leonina*), southern sea lions, harbor seals, Steller sea lions, walruses, and California sea lions have been recorded most commonly as prey species. Approximately 62% of the transient killer whale attacks observed since the mid-1970s off British Columbia and Washington have been

Figure 2 *Killer whale patrolling a harbor seal haul-out site. Photo by Robin W. Baird.*

on harbor seals. Harbor seals are particularly abundant in this part of the world and appear to be relatively easy prey for killer whales to capture and kill, perhaps accounting for the apparent dietary preference on this pinniped species. Steller sea lions, which account for about 7% of all observed attacks, are far more difficult to capture, and the large size obtained by adult males combined with their pronounced canines make attack potentially more dangerous. Other less frequently taken pinniped prey include California sea lions and northern elephant seals.

Pinnipeds are attacked by lone killer whales and by groups ranging in size from 2 to 30 or more, but the majority of reported attacks are by pods of 10 or less. Killer whales have often been referred to as "pack hunters" because of their tendency to often forage cooperatively and employ coordinated maneuvers to capture mammalian prey. A well-described example of this coordination was witnessed in the Antarctic, where a group of killer whales was observed to work together to generate a wave large enough to sweep a crabeater seal off an ice floe and into the water so that it could be captured.

Killer whales use a variety of strategies to kill pinnipeds, including ramming them with their rostrums or heads, flinging seals and sea lions high into the air with an abusive slap of their tail flukes, and violently shaking prey while grasped tightly in their mouths. Transient killer whales employ great stealth and remain silent while hunting so as not to announce their presence to potential prey. Although transients typically hunt for prey near to shore where they are hidden by wave action and turbulence, they are also capable open water foragers. When whales encounter potential prey in open water, one observed hunting strategy is for group members to take turns rushing the prey and striking it with their flukes or ramming it with their heads. Once killed, the pinniped prey is shared among group members, similar to the food-sharing behavior observed in social carnivores such as lions and wolves.

At Peninsula Valdés, Argentina, and on Possession Island in the Crozet Island Archipelago, killer whales intentionally strand themselves in an effort to hunt sea lions and elephant seals that are on or near the beach. Southern seal lions and southern

elephant seals are hunted off Peninsula Valdés, whereas on Possession Island, whales typically take newly weaned southern elephant seal pups. In general, pups and small adult seals are most vulnerable, but adults are also occasionally killed. Once a seal or sea lion has been captured from the beach or nearshore area, it is usually held in the mouth of a killer whale by one of the flippers or taken crossways in the mouth and shaken vigorously. Sometimes, captured pups are exchanged between members of the killer whale pod. Intentional stranding behavior also occurs in the absence of prey, suggesting that adult killer whales may actually teach their youngsters the finer aspects of this foraging strategy.

IV. Predation on Cetaceans

Although killer whales and sharks are responsible for most attacks on whales, dolphins, and porpoises, other cetaceans such as false killer whales, pygmy killer whales, and pilot whales also represent a potential predatory threat. In addition to these aquatic predators, one terrestrial predator, the polar bear, successfully hunts beluga whales (*Delphinapterus leucas*) and narwhals (*Monodon monoceros*) in Arctic areas. River dolphins appear to be the only cetacean group free from natural predation, although it has been suggested that freshwater caiman in South America may occasionally take young dolphins. Finally, killer whales are likely to experience little or no mortality related to predation.

A. Blackfish

Three members of the delphinid family, including the false killer whale, pygmy killer whale, and short-finned pilot whale, are thought to be hunters of other cetaceans. Each of these species has teeth and jaws suitable for killing and handling large mammalian prey, and all have been observed to at least occasionally prey on other dolphins. Of these three "blackfish," the false killer whale is best known for attacks on small pelagic dolphins and also has a record of harassing humpback (*Megaptera novaeangliae*) and sperm whales (*Physeter macrocephalus*). A series of observations, mainly by marine mammal observers onboard purse-seine boats fishing for yellowfin tuna in the eastern tropical Pacific, have detailed false killer whale attacks on pantropical spotted and spinner dolphins (*Stenella attenuata* and *S. longirostris*). Although nearly two dozen attacks were recorded, false killer whale predation on cetaceans outside of the eastern tropical Pacific is rare, suggesting that the high incidence of attack on the yellowfin tuna grounds may be site and circumstance specific. That is to say, false killer whales may be utilizing a prey resource related to tuna fishing operations (i.e., dolphins being released from temporary capture in fishing nets) that is unavailable outside of the eastern tropical Pacific.

Large whales, such as sperm whales and humpback whales, are also subjected to predatory advances by false killer whales. A school of false killer whales has been observed harassing a sperm whale group off the Galápagos Islands. In this event, no sperm whale mortality was recorded, but the false killer whales did inflict at least superficial injury to several individuals and elicited noticeable fear reactions. Similar, albeit uncommon, events have also been suggested for interactions between false killer whales and humpback whales.

Pygmy killer whales have also been observed in predatory attacks on small dolphins during fishery operations in the eastern tropical Pacific, although observations of this nature are less common than those recorded for false killer whales. The predatory habits of pygmy killer whales on other cetaceans are poorly understood. In captivity, this species has been implicated in the death of a young pilot whale and a dusky dolphin (*Lagenorhynchus obscurus*), but it is unclear if these events led to consumption of the victim.

Similarly, few records regarding pilot whale predation on other cetaceans are available. Although pilot whales are not generally known to prey on marine mammals, records from the eastern tropical Pacific suggest that this species does chase, attack, and may occasionally eat dolphins during fishery operations. The incidence at which these predatory events occur, however, is very low. In CAPTIVITY, pilot whales have been noted to eat stillborn and young dolphins. Short-finned pilot whales have been observed harassing sperm whales in the Gulf of Mexico and off the Galápagos Islands, and although such harassment has been observed to be nonlethal, these events nevertheless often elicit a pronounced fear response, called a "marguerite formation" by sperm whale groups. The marguerite is a defensive formation in which group members form a heads-in and tails-out circular arrangement resembling the petals of a flower. By placing the powerful flukes, a source of potential danger for predators, toward the outside and containing particularly vulnerable individuals, such as calves, on the inside of the formation, sperm whales can usually defend themselves from harm. This marguerite response has also been noted for sperm whale groups under lethal attack by killer whales and when being hunted by whalers. Therefore, the formation of a marguerite in response to pilot whale harassment suggests that sperm whales do at times appear to be threatened by this species. It remains unclear, however, if such harassment by pilot whales represents actual predatory intent or if such interactions are merely practice hunting attempts or social play.

As suggested by the accounts presented here, interactions of false killer whales, pygmy killer whales, and pilot whales with other cetaceans are not particularly common. Of the lethal attacks recorded to date for each of these three blackfish species, all have been in relatively unnatural situations. That is, attacks have occurred either in captivity where species that might normally avoid each other are maintained in the same confines or centered around the eastern tropical Pacific tuna fishing operations where smaller dolphins may become available prey due mainly to capture fatigue. Therefore, it is difficult to assess the regularity of marine mammal predation by these several species, and the scarcity of observed predatory events suggests that marine mammal prey is likely to be secondary to an otherwise fish- and squid-based diet.

B. Sharks

Sharks represent a significant predatory threat to some populations of dolphins. Crude estimations of predation rates, as determined by the proportion of dolphins within a study population possessing shark-inflicted scars and injuries, vary greatly. Shark-related scars on odontocetes are particularly notable for some populations, whereas others go seemingly untouched.

Results from several long-term photoidentification studies of bottlenose dolphins (*Tursiops truncatus* and *T. aduncus*) have documented shark bite scars rates as low as 1% off southern California, an intermediate rate of 22% in western Florida, and up to about 37% off eastern Australia. The frequency of scars may also vary for different dolphin species within the same region. For example, off South Africa, where humpbacked dolphins (*Sousa chinensis*) and bottlenose dolphins overlap in distribution and habitat use, the former species has substantially more scarring related to shark attack than the latter.

Interestingly, the proportion of individuals bearing crescent-shaped shark bite wounds is considerably higher for nearshore species than it is for their offshore counterparts. This apparent discrepancy may be attributable to a variety of factors. To date, most long-term studies on dolphin populations have been conducted nearshore, increasing the opportunity to observe shark scarring. Alternative explanations include the idea that predation on oceanic dolphin is less common overall or that shark attacks in the open ocean are generally more successful. One theory that may at least partially explain why nearshore dolphins have higher rates of scarring is related to habitat features. The habitat of nearshore cetaceans offers a variety of "cover" features, such as kelp and surf, which may make escape from a predator more successful, whereas oceanic species have no such cover and depend solely on fleeing or the protection offered by conspecifics within their social group to escape fatal attack.

Tiger sharks, dusky sharks (*Carcharhinus obscurus*), white sharks, and bull sharks (*C. leucas*) are most often implicated in attacks on nearshore dolphins and porpoises. Other sharks, including oceanic white tip and hammerhead sharks, have also been observed to occasionally attack dolphins. Tiger sharks are notorious predators of spinner dolphins off the Hawaiian Islands, whereas white sharks prey on a variety of odontocetes, ranging in size from the small harbor porpoise (*Phocoena phocoena*) to more substantial beaked whales, and perhaps even newborn mysticete whales. Evidence of shark predation on baleen whales is relatively uncommon, but a report of a tiger shark attacking a young humpback whale has been recorded. Similarly, large sharks (and killer whales) were observed circling a group of sperm whales in which one adult female was giving birth, but no direct attack was noted. Although the number of observations regarding shark attack on large whales is few, it is reasonable to assume that some predatory events probably do occur at least occasionally.

While predation by sharks is of particular concern for cetaceans in the tropics and subtropics, attacks in other regions also occur. The remains of a complete southern right whale dolphin (*Lissodelphis peronii*) fetus as well as the genital region of an adult female were found in the stomach of a sleeper shark (*Somniosus pacificus*) off coastal Chile. In addition, Greenland sharks (*S. squamulosus*) have been reported to prey upon narwhals in the eastern Canadian Arctic, and franciscana dolphins (*Ponotoporia blainvillei*) have been found in the stomachs of seven-gilled (*Heptranchias perlo*) and hammerhead sharks off Brazil. While each of these accounts is suggestive of predation, they should be considered with caution, as it is unclear if the aforementioned sharks actually attacked living dolphins or if the remains identified from stomach content analyses were attributable to scavenging.

C. Polar Bears

Although pinnipeds are the principal marine mammal prey of polar bears, they also actively hunt and occasionally consume NARWHALS and BELUGA WHALES. Polar bears off western Alaska, for example, have been observed "fishing" beluga whales and narwhals out of small openings in the ice (Fig. 3), sometimes killing numbers far greater than can possibly be eaten. In one particular event, polar bears killed and dragged onto the ice at least 40 ice-entrapped beluga whales, and in a similar episode, a single male polar bear was seen to successfully capture 13 beluga whales from a small opening in the ice over a short period of time.

Beluga whales regularly swim into extremely shallow estuary and river channel areas. On rising tides, whales penetrate far into rivers and creeks, often moving into waters so shallow that they can rest on the bottom while a considerable portion of their body remains above the surface. This behavior can sometimes result in partial stranding, but the animals are typically able to free themselves. On occasion, however, complete stranding occurs accidentally, during which time individual belugas remain beached until the return of the incoming tide. At least some beluga whale mortality results from polar bears feeding on stranded individuals. In addition to opportunistic foraging on temporarily beached whales, individual bears have been observed wading into shallow waters and chasing whales passing near to shore. Predatory polar bears also actively stalk free-swimming belugas from ice edges. In this situation, bears either roam along the ice edge or remain motionless while awaiting a group of beluga whales to move within striking range. When a whale passes near enough, a polar bear will launch itself from the ice and onto the back of the unsuspecting beluga. In one incident, a single polar bear was observed to use this hunting tactic to capture and kill two beluga whale calves within 24 hr. This hunting technique requires that bears time their jumps accurately and, more amazingly, handle and debilitate their prey in an aquatic medium. Further, once dead, the beluga must be pulled from the water and dragged onto the ice. In cases where

Figure 3 *Polar bear hunting beluga whales. Photo by Sue Flood/BBC Natural History Unit.*

this hunting technique has been observed directly, the captured belugas are generally young, smaller individuals.

Polar bears have also been observed to attempt attacks on belugas while swimming in pursuit of them. Thus far, no successful attacks have been documented for this aquatic hunting tactic, and on at least one occasion, a group of belugas was seen to chase a polar bear out of the water with group-coordinated threat behavior including tail lashing and repeated close approaches toward the swimming bear. Aquatic stalks by polar bears are largely unsuccessful due to the greater mobility and speed of whales in the water. In fact, the willingness of belugas to closely approach bears in the water, either out of curiosity or in a possible attempt to harass them, suggests that they have little fear of this predator when it is waterborne.

In contrast to the inshore habits of beluga whales, narwhals prefer deeper water and are commonly sighted in considerable numbers offshore of beluga groups in the eastern Canadian Arctic. Polar bear predation on narwhals has been observed rarely, with the few attacks reported consisting of narwhals stranded on tidal flats or entrapped by ice. In one incident, three adult female narwhals stranded on a tidal flat were consumed by a single polar bear. All three of the narwhals bore extensive claw marks and their blubber had been stripped dorsally from the head area back to the tail stock.

D. Killer Whales

In addition to pinnipeds, dugongs, and sea otters, mammal-hunting killer whales (termed transients) also prey upon a variety of dolphins and porpoises, and even occasionally attack sperm and baleen whales. Transient killer whales are relentless hunters, spending up to 90% of each daylight period searching for food. In addition to marine mammal prey, terrestrial animals such as deer (*Odocoileus hemionus*) and moose (*Alces alces*) are also taken occasionally. In these cases, killer whales opportunistically intercept individual deer and moose as they swim between coastal islands.

More than most other marine mammals, killer whales are social hunters, often working together to capture prey in a coordinated manner resembling that of pack-hunting social carnivores such as hyenas, wolves, and lions. Transients typically form slightly larger groups while hunting dolphins and porpoises, as compared to group sizes observed during pinniped attacks. Most hunts of small cetaceans have some component of chase, making more individuals necessary to prevent prey escape. Sometimes these high-speed chases result in a killer whale leaping free from the water with a dolphin or porpoise in its mouth. When dolphin prey are assembled in relatively large schools, killer whales often attempt to separate one or a few individuals from the group before commencing active pursuit. Once a prey item becomes exhausted, killer whales then attempt to kill the animal by breaching onto it, ramming it from below, tossing it into the air, or grasping it in their teeth (Fig. 4).

A variety of dolphins and porpoises are hunted by killer whales. Off New Zealand, common dolphins (*Delphinus delphis*) are attacked most commonly, but bottlenose dolphins and dusky dolphins (*Lagenorhynchus obscurus*) are also hunted. Stomach content analysis of a stranded killer whale off southern Brazil found the remains of three franciscana dolphins. In

Figure 4 *Killer whale attacking a Dall's porpoise. Photo by Robin W. Baird.*

the Gulf of Mexico, a pod of killer whales chased and killed a pantropical spotted dolphin, and Pacific white-sided dolphins (*Lagenorhynchus obliquidens*), Dall's porpoise (*Phocoenoides dalli*), and harbor porpoises are some of the more commonly hunted small cetaceans off the west coast of North America. In addition to these relatively small cetaceans, larger prey, including northern bottlenose whales (*Hyperoodon ampullatus*) and long-finned pilot whales (*Globicephala melas*), are also hunted occasionally by killer whales. In Arctic waters, killer whales sometimes herd beluga whales into shallow inlets and creek openings where they then rush into the group to capture young animals. Further, killer whales have been seen feeding on beluga whales and narwhals in open waters and on animals trapped by sea ice.

An interesting study of contrasts exists for transient killer whales off British Columbia and in Prince William Sound, Alaska. Although transients in both regions feed exclusively on marine mammals, harbor seals are the most common prey item of whales off British Columbia, whereas transients in Prince William Sound prey about equally on harbor seals and Dall's porpoises. Low harbor seal abundance in Prince William Sound may account for the apparent preference for porpoise prey in this region.

Although killer whales tend to focus their predatory attentions on pinnipeds and small odontocetes, numerous reports of attacks on sperm whales have also been recorded. In most cases, the sperm whale groups being attacked contained one or more calves. Sperm whales are likely to be difficult for killer whales to kill, as they are excellent deep divers and can escape predation by descending to depth, possess sizable teeth capable of inflicting significant injuries, and actively defend group members when threatened. Regardless of the difficulty in hunting sperm whales, field observations from the Pacific noted killer whales successfully killing at least one adult member of a sperm whale group and fatally injuring at least several others.

Killer whales have been noted to hunt all of the mysticete species except for pygmy right whales (*Caperea marginata*), but observations of attacks on baleen whales are not common. As is true for sperm whales, baleen whales are also difficult to kill, requiring extended effort and coordination between pod members. A typical strategy employed by killer whales during large whale hunts consists of first fatiguing the prey by active pursuit, followed then by delivery of a debilitating attack. It has been suggested that attacking killer whales may grasp large whales by the flukes and pectoral flippers in an attempt to slow or stop their movement or perhaps drown their prey by pulling them underwater.

In the Gulf of California, researchers watched from a small airplane as a group of 15 killer whales attacked and killed a Bryde's whale (*Balaenoptera edeni*). During this event, the killer whales repeatedly swam onto the back and head of the Bryde's whale, a behavior speculated to be useful in hindering life-sustaining respiration of the animal under attack. A similar incident was recorded off British Columbia where killer whales were observed to exhaust and kill a fleeing minke whale (*Balaenoptera acutorostrata*). Humpback whales are also attacked by killer whales, but unlike the more passive escape tactics employed by some of the other mysticetes, humpbacks defend themselves aggressively from killer whales by thrashing at them with their tail flukes and flippers.

Of all the mysticetes, gray whales (*Eschrichtius robustus*) are probably most frequently attacked by killer whales. On an almost predictable basis, gray whales are attacked by "California" killer whales in Monterey Bay each April and May (Fig. 5). Young calves making their first northward migration are particularly vulnerable, even while under the watchful eye of their mothers. Records from beach cast gray whales along the coast of the Chukchi Sea show a similar pattern to that observed off California; whales with the highest incidence of killer whale-induced injuries (i.e., tooth scarring) were generally under 10 m long, suggesting that killer whales in this region also select young gray whales as their primary predatory target.

Figure 5 *Killer whale attack on California gray whales. Photo by Sue Flood/BBC Natural History Unit.*

Figure 6 *Young western gray whale with evident killer whale tooth scarring. Photo by David W. Weller.*

Direct observations of killer whale attacks on large whales are relatively few, but several lines of evidence suggest that predatory interactions may occur more often than suspected. The presence of killer whale tooth rakes on the bodies, flippers, and flukes of many large whales can reach remarkably high proportions (Fig. 6). Photoidentification studies on humpback whales off Newfoundland and Labrador in the north Atlantic found that 33% of the individuals identified had killer whale-inflicted tooth rakes on their bodies. Scars on the flukes of 20–33% of humpback whale calves suggest that predation may be focused on young animals. A similar pattern has also been observed for western gray whales in the Sea of Okhotsk, where nearly 34% of all whales photoidentified possess killer whale tooth rakes. In this case, the western gray whale is highly endangered, making any level of killer whale predation a potentially important source of mortality. Bowhead whales (*Balaena mysticetus*) from the Bering, Chukchi, and Beaufort Sea populations have relatively low rates of killer whale tooth scarring, ranging from about 4 to 8% of the observed individuals. In contrast, 31% of bowhead whales in the Davis Strait population show evidence of scars from killer whales.

The relatively high incidence of killer whale tooth scarring on some regional populations of large whales suggests that predatory attempts are probably more regular than indicated by field observations alone and that many attacks are unsuccessful. Tooth rakes may not be truly indicative of predation attempts by killer whales, however, but may instead represent capture practice or instruction of predatory techniques for younger members of the pod. Finally, rake marks may also result from killer whales testing large whales to assess the presence of particularly vulnerable individuals that may be separated easily from a group and killed.

Although killer whales exert considerable time and energy in pursuit and capture of large whales, they consume relatively little of their victims. Reports from whaling ship logbooks and more recent field observations suggest that killer whales often preferentially consume only the tongue, lips, and portions of the ventrum of large whales before abandoning them. This phenomenon is little understood and stands in stark contrast to the behavior of terrestrial predators that consume all or most of their mammalian prey.

E. Humans

A review of predation on marine mammals would be incomplete without some mention of humans as predators. No other predator has the ability to harvest marine mammals at the same rate or intensity as humans. While killer whales or polar bears may take tens of animals over relatively short periods of time, humans are capable of sometimes killing hundreds of individuals within hours. Although the ecology of the world's oceans is in part maintained by predator–prey interactions, human exploitation of marine mammal populations can have devastating consequences.

Predator–Prey Relationships

ANDREW W. TRITES

University of British Columbia, Vancouver, Canada

Most marine mammals are predators, but some are also preyed upon by other species. Theoretically, the interaction between marine mammals and their prey influences the structure and dynamics of marine ecosystems. Similarly, predators and prey have shaped each other's behaviors, physiologies, morphologies, and life history strategies. However, there is little empirical evidence of these influences due to the relative scale and complexity of marine ecosystems and the inherent difficulties of observing and documenting marine mammal predator–prey interactions.

I. Evolutionary Time Scales

Predator–prey relationships have been likened to an evolutionary arms race—the prey become more difficult to capture and eat, while the predators perfect their abilities to catch and kill their prey. Just how strong these selective forces are probably depends on the strength of the interactions between the predators and their prey.

As predators, marine mammals feed primarily upon fish, invertebrates, or zooplankton, which in turn feed primarily upon other species of fish, invertebrates, zooplankton, and phytoplankton (Fig. 1). To capture their prey, marine mammals have evolved special sensory abilities (e.g., vision and hearing), morphologies (e.g., dentition), and physiologies (e.g., diving and breath-holding abilities). They have also evolved specialized strategies to capture prey, such as cooperation to corral fish, or the production of curtains of air bubbles used by humpback whales (*Megaptera novaeangliae*) to capture herring. Marine mammals have also evolved specialized feeding behaviors to capture prey that move diurnally up and down the water column or to capture prey that move seasonally across broad geographic ranges. This in turn has likely influenced the life history strategies of marine mammals and their prey. For example, baleen whales feed for about 6 months when plankton are abundant and concentrated in shallow water, and then fast for the remainder of the year when the plankton are too dispersed to make them worth finding.

As prey, marine mammals have had to escape aquatic and terrestrial predators. Some species of pinnipeds for example, are particularly vulnerable to predation by bears and wolves while on land, and to predation by killer whales (*Orcinus orca*) and sharks while in the water. Thus some species of pinnipeds can reduce their risk of being eaten by aquatic predators by hauling out and resting onshore. Similarly, species such as Steller sea lions (*Eumetopias jubatus*) and northern fur seals (*Callorhinus ursinus*) reduce their risk of being eaten by terrestrial predators by breeding and hauling out on offshore rocks and islands where terrestrial predators are absent. Other species, such as ringed seals (*Pusa hispida*), give birth in cav-

From McConnaughey and McRoy (1976).*

erns formed between ice and snow to avoid predation by polar bears (*Ursus maritimus*).

Fish and other cold-blooded species of prey have evolved a number of strategies to increase their chances of survival. One is cryptic countershading that enables fish to blend in with the bottom when viewed from above, and avoid detection when seen from below against a bright sea surface. Many species of fish, invertebrates, and zooplankton take refuge from predators in the deep, dark waters during the day and move toward the surface to feed under the cover of night. Another strategy evoked by the prey of marine mammals is predator swamping, such as large aggregations of spawning salmon and herring that reduce the numerical effect of predators on their prey populations. Schooling is another antipredator behavior that creates confusion through the sheer volume of stimuli from a fleeing school, making it difficult for a marine mammal to actively select and maintain pursuit of single individuals. Scattering and fleeing is yet another option to reduce predation and is used by some prey when attacked by bulk feeders such as baleen whales (e.g., humpback whales and capelin). The line between feeding and fleeing is undoubtedly fine for species of prey and must be continually evaluated by prey to minimize vulnerability to predation.

Marine mammals may also have indirectly influenced the evolution of nontargeted species in their ecosystems by consuming the predators of these species. The best example of this is the apparent influence of sea otters (*Enhydra lutris*) on kelp and other marine algae. Most species of marine algae use

secondary metabolites to defend against herbivores. However, marine algae in the North Pacific have lower levels of chemical defenses where sea otters occur compared to algae species inhabiting the southern oceans where sea otters are not present. Sea otter predation on sea urchins and other herbivores may have removed selective pressure for species of marine algae to defend themselves against herbivores. Because secondary metabolites are expensive to produce, this may have allowed algae, like kelp, to radiate and diversify without the added cost of evolving and producing antigrazer compounds.

II. Ecological Time Scales

On a shorter time scale than the evolutionary one, predators and prey can directly affect the relative abundance of each other, or they can indirectly affect the abundance of other species. Their interaction may also affect the physical complexity of the marine environment.

Predation by sea otters on sea urchins is probably the best example of how marine mammals can alter ecosystem structure and dynamics. Sea otters were hunted to near extinction in the late 1800s throughout their North Pacific range. Without predation, urchin populations grew unchecked and overgrazed the fleshy algae. Kelp did not replace the underwater barrens until reintroduced sea otters once again began preying upon sea urchins.

Primary production has been estimated to be three times higher in areas where sea otters are present compared to those areas where sea otters are absent, allowing those organisms that feed upon primary production to grow faster and attain larger sizes (e.g., mussels and BARNACLES). The increase in primary production may even alter settlement patterns of invertebrates. The kelp also provides habitat for fish and suspension-feeding invertebrates to spawn, grow, and flourish. It can also change water motion and reduce onshore erosion and may even block the shoreward movement of barnacle larvae. Thus a top predator such as the sea otter can change the structure and dynamics of marine ecosystems.

Gray whales (*Eschrichtius robustus*) and walruses (*Odobenus rosmarus*) are other species of marine mammals whose foraging behavior can also affect community structure. For example, gray whales turn over an estimated 9–27% of the bottom substrate each year in the Bering Sea. The feeding pits created by gray whales draw 2–30 times more scavengers and other invertebrates compared to adjacent sediments. The disturbed sediments may also help maintain the high abundance of gray whale prey and other early colonizing species. Similarly, walruses turn over bottom substrate in their search for clams and other bivalves. There is some evidence that they may feed selectively on certain size classes and certain species and that their defecation may result in the redistribution of sediment. Thus, the interaction of benthic feeding marine mammals with their prey can result in food for scavengers and habitat for other species.

Interactions between predators and prey also influence the shapes of their respective life tables (i.e., age-specific survival and pregnancy rates). In Quebec, Canada, for example, there are a number of freshwater lakes that are home to land-locked harbor seals (*Phoca vitulina*). Studies have found that the trout in these lakes are younger, grow faster, attain smaller sizes, and spawn at younger ages compared to adjacent lakes without seals. As for marine mammals, they typically have elevated mortality rates during their first few years of life. This is likely due to a number of factors, including their relative vulnerability to predators and their inexperience at capturing prey and securing optimum nutrition.

In the Gulf of Alaska and Bering Sea, killer whales have been implicated as a contributing factor, but not the main one, in the decline of Steller sea lions and harbor seals through the 1980s. Field observations along the Aleutian Islands indicate that these population declines were followed by a decline of sea otters in the 1990s and that this decline was caused by killer whale predation. Killer whales may have begun supplementing their diet with sea otters because they could not sustain themselves on the low numbers of remaining seals and sea lions. It is not yet clear what ultimately caused the decline of Steller sea lions and began this spiraling change of events. However, it is apparent from mathematical calculations of population sizes and energetic requirements that there are sufficient numbers of killer whales in Alaska to prevent the recovery of pinniped populations. Thus, it is conceivable that populations of pinnipeds and otters may not recover to former levels of abundance until the predation by killer whales is reduced by a reduction in killer whale numbers or by a shift in killer whale diet to other species of mammals such as dolphins and porpoises.

In addition to directly affecting the abundance of their prey, marine mammals can indirectly affect the abundance of other species by outcompeting them or by consuming species that prey upon them. A case in point are harbor seals in British Columbia whose diet was about 4% salmon and 43% hake in the 1980s. Contrary to popular opinion, the harbor seals were likely benefiting salmon because they affected the abundance of hake, a species of fish that is one of the largest predators of salmon smolts. Further north in Alaska's Copper River Delta, harbor seals were culled in the 1960s to reduce the predation on salmon. However, the immediate result of the cull was not an increased number of salmon caught, but a decrease and failure of the razor clam fishery. It turned out that the seals were primarily eating starry flounder, which fed on the razor clams. Without the seals, the predatory flounder population grew unchecked.

In the Antarctic, commercial whaling systematically removed over 84% of the baleen whales and freed an estimated 150 million tons of krill for other predators to consume each year. Species such as crabeater seals (*Lobodon carcinophaga*), Antarctic fur seals (*Arctocephalus gazella*), leopard seals (*Hydrurga leptonyx*) and penguins (chinstrap, Adelie, and macaroni) increased and moved the Antarctic marine ecosystem to new equilibrium levels. Increases were also observed in minke whales (*Balaenoptera bonaerensis*) and squid-eating king penguins due perhaps to reductions in the respective abundance of blue whales (*B. musculus*) and sperm whales (*Physeter macrocephalus*). All of these species appear to have directly benefited from an increase in prey, which was caused by the removal of whales. Penguins and seals may now be hindering the recovery of baleen whale stocks in the Antarctic.

Marine mammals are generally considered to be opportunistic foragers who select from a number of alternative prey according to availability. This is based on the relatively large number of different species that have been reported in the stomachs and feces of marine mammals. Steller sea lions, for example, are known to eat over 50 different species of fish, and even the occasional seabird. However, their diets are typically dominated by 5 or fewer species, suggesting that they may not be truly opportunistic feeders. Little is yet known about the choices that marine mammals make when foraging. Presumably what marine mammals eat is a function of nutritional value, ease of capture, and digestibility, all of which are invariably linked to the abundance of both predators and prey. These are complex biological interactions about which little is known.

Functional response curves represent rates of predation in relation to the density of prey. In most species, the rate of capture rises with the density of prey to some maximum level. These relationships between prey density and predation rates tend to be nonlinear and asymptotic, indicating that there are maximum limits to the rate that predators can capture and process prey, which are independent of prey population size. Establishing these functional relationships for different species of prey is fundamental to fully understanding the foraging ecology of marine mammals. This has not yet been done for marine mammals and will require experimentation in captivity or observational studies in the wild using electronic data collection techniques.

Ecosystem models are another technique for gaining insight into the effects of predator–prey relationships on ecosystem dynamics and structure. Using a series of mathematical equations to account for the flow of energy from one group of species to another, the models can estimate the extent of competition between species and the effect that changes in abundance of one species will have on other species in the ecosystem. One such model was constructed for the Bering Sea to understand whether the declines of Steller sea lions and forage fishes (such as herring) and the increases in pollock and flatfish between the 1970s and the 1980s were related to the commercial removal of whales. Removing historic numbers of whales from the simulated ecosystem resulted in an increase in numbers of pollock. However, the increase was only in the order of 10–20%, not the 400% increase believed to have actually occurred. The ecosystem model suggests that the Bering Sea may exist in two alternative states (consisting of two different complexes of species) and that environmental shifts (from periods of cold to warm water years) may ultimately determine when and for how long these shifts occur. The model also suggests that curtailing fishing on pollock (a major prey of Steller sea lions) may affect the Steller sea lion negatively. The explanation for this counterintuitive prediction is that commercial fisheries primarily remove larger pollock than Steller sea lions consume. Given that pollock are cannibalistic, increasing the size of the adult stock results in the increased predation of younger pollock, leaving fewer fish for Steller sea lions to consume. Thus, ecosystem models are useful tools for exploring the influence of predator–prey interactions on one another and on other components of their ecosystems.

III. Synthesis

Marine mammal predator–prey interactions occur over different spatial and temporal scales, making it difficult to empirically decipher the influences they have on one another and on their ecosystems. However, their coexistence suggests that marine mammal predators and their prey have had profound influences on each other's behaviors, physiologies, morphologies, and life history strategies. The diversity of niches filled by marine mammals makes it difficult to generalize about the evolutionary consequences of their interactions with prey, beyond stating the obvious: marine mammals have adapted to catch food, while their prey have adapted to avoid being caught.

On the shorter ecological time scale, marine mammals can affect the abundance of other species by consuming or outcompeting them. They can also indirectly affect the abundance of nontargeted species by consuming one of their predators, and can have strong impacts on the overall dynamics and structure of their ecosystems. One of the best tools for understanding marine mammal predator–prey interactions is the ecosystem model. However, more work is required through experimental manipulations and observational studies to evaluate the choices made by marine mammals and the costs of obtaining different species of prey.

Prenatal Development in Cetaceans

JOY S. REIDENBERG AND JEFFREY T. LAITMAN
Mount Sinai School of Medicine, New York, New York

Very little is known about the specifics of intrauterine growth and development in cetaceans. Indeed, the precise time intervals of such development, the basic genetic determiners, and any distinctive growth trajectories are basically unknown. What is known about cetacean prenatal development is that, as they are mammals, it is to be expected that the same basic stages of early cell division, pattern formation, organogenesis, and growth and differentiation will also be similar. For example, the "embryonic" period is usually defined as the time frame within which an animal's body plan and its organs and organ systems (i.e., integument, skeletal, muscular, nervous, circulatory, respiratory, digestive, urinary and reproductive) are established. Once all organs form, the "fetal" period of growth and distinctive development commences. Cetacean prenatal development will similarly follow this course. It is also to be expected that the absolute time of these periods will differ from terrestrial species, between odontocetes and mysticetes, and among the different species therein.

Many studies that have noted aspects of cetacean prenatal development (most in passing rather than by detailed, systemic analysis) have used terms such as "embryo" or "fetus" in a seemingly imprecise manner. It is, indeed, often difficult to determine from these whether the authors (a) are cognizant of the biological difference between an embryo and a fetus (many reporters are not anatomists or embryologists) or (b) are able to discern differences that afford the distinction to be made with any degree of accuracy. Adding to this complexity is the fact that the precise gestation periods for many cetacean species are not known. In light of these observations, our use of the terms embryo and fetus (or embryonic and fetal periods) should be taken as representing approximate guides to stages of development rather than as a precise descriptor of an absolute time frame.

It is important to remember in discussing cetacean prenatal development that most current knowledge derives from observations on embryonic or fetal specimens discovered in pregnant cetaceans either found stranded or taken aboard whaling ships. In many cases, only a length or weight is recorded (if at all) with an occasional description of external appearance. It is usually impossible to distinguish the age of the specimen, as the date of conception and length of gestation cannot be known with any certainty. As most breeding and calving seasons are known, however, some approximations are available and have been provided (Figs. 1–6).

Figures 1–6 *Fetal long-finned pilot whales (Globicephala melas) obtained postmortem from pregnant, beach-stranded whales on the shores of Cape Cod, Massachusetts. The figures are arranged numerically in order of the specimens' lengths, which should mirror the order of their gestational ages. Each black or white square equals 1 cm on the rulers in Figs. 4 and 6.*

Figure 1 *A fresh specimen of a very small, unpigmented fetus. Based upon its external appearance, this appears to be a very early fetus, probably very close to the transition between embryonic and fetal periods of development. Note the prominent rostrum and the rudimentary development of a dorsal fin, tail flukes, and genital tubercle. The dark spot above the mouth and anterior to the eye appears to be the left nostril.*

Figure 2 *An early fetus preserved in alcohol. Due to dessication, the unpigmented fetal skin (which was pink) is now discolored and shrunken against the skeleton. The fetus is curled in the fetal position, with the tail folded laterally to the left side and the dorsal fin flattened against the body. Note the attached umbilical cord and the prominent rostrum. The dorsum of the skull is depressed (from the dehydration) at the membranous fontanelle. Just anterior to this depression is the blowhole (the paired nostrils appear to have fused into one blowhole and have migrated dorsally and near the midline).*

Figure 3 *A fresh fetus is being held in a pair of gloved hands. The fetus, discovered during an autopsy, is still attached by its umbilical cord to the mother whale and is partially enveloped in its thin layer of fetal membranes (note transparent membrane and vessels at ventrum of tail stock). It has some streaks of gray pigmentation, and the melon has begun to form over the rostrum.*

Figure 4 *A frozen fetus still curled in its fetal position. The skin is pigmented black, but it is covered with whitish-gray deposits of frost from thawing. Note the developing melon over the rostrum, curled tail flukes, and the skin folds (from the folded fetal position) along the concave surface of the right lateral side. The protruding penis can be seen as a conical structure with a hook-like curl at the tip.*

Figure 5 *A thawed, full-term fetus. The lighter patches are areas where the skin has sloughed off postmortem during the freezing. The fetus is curled in the fetal position as it was found in utero, with the tail folded against the left side. The umbilical cord is evident under the tail stock. The left lateral surface of the thorax and abdomen shows a number of dorsoventral stripes, which indicate grooves between puckers where the skin is folded (the skin is particularly crimped at the beginning of the tail stock). The dorsal fin lies flat against the body and the tail flukes are curled ventrally. Note how the well-developed melon now overrides the rostrum.*

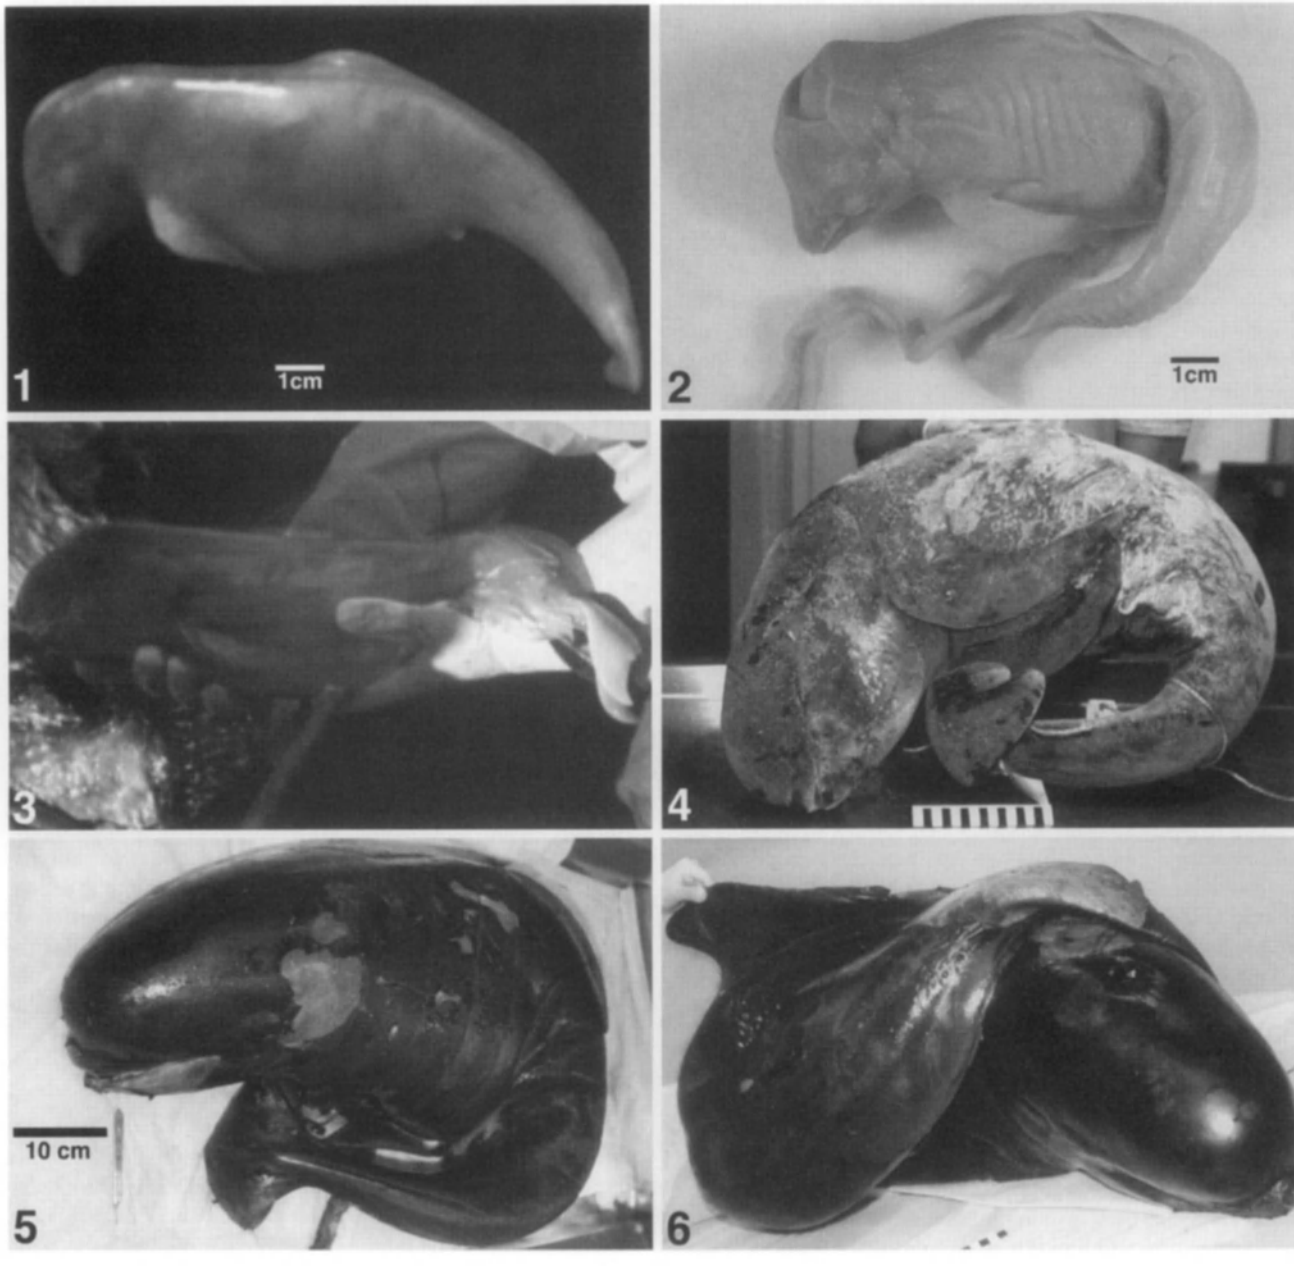

Figure 6 *Another full-term fetus (thawed) curled in a slightly different fetal position as it was found in utero. Here the tail bends to the right side and the flukes lie over the dorsum and extend to the left side. The blowhole has migrated to the top of the head, and the bulbous form of the melon can be seen clearly. The dorsal fin, which was flattened along the right side, is being held up by a gloved hand.*

I. Development of Organ Systems

A. Integument and External Characteristics

1. Skin The overall coloring of the embryo appears light pink due to the transparency of the skin (integument) allowing the underlying tissues perfused with blood to be visible. The skin consists of the epidermis (which has four layers), dermis, and hypodermis, which increase in thickness throughout the embryonic period (Meyer *et al.*, 1995). Skin coloration begins during the early fetal period. In mysticetes, dark coloration occurs initially along the rostrum bordering the opening of the oral cavity. As the mysticete fetus grows, dark patches appear along the dorsum of the thorax and abdomen and on the pectoral flippers, tail flukes, and dorsal fin. The separate and irregularly shaped patches fuse and grow into a more uniform pattern (for many species, this is usually a countershaded pattern of dark dorsum and light ventrum that resembles the adult's coloration).

2. Hair Hairs can be found along the surfaces of the upper jaw. In odontocetes, hairs appear on the lateral aspect near the tip of the rostrum, whereas in mysticetes, they are found both laterally and dorsally on the broad rostrum. In some cetacean species, these hairs can also be found on the margins of the lower jaw. These hairs appear to have some tactile properties and may derive from the vibrissae of terrestrial mammals. While most odontocetes will lose these hairs shortly after birth (except perhaps platanistoids), they are retained into adulthood in some species of mysticetes.

3. External Ears External ears (pinnae) do not develop, thus maintaining a streamlined surface contour in the ear region of cetaceans. Only a remnant of the external auditory canal is visible as a small hole present in the skin behind the eye.

4. Mammary Glands Mammary glands (mammae) are epidermal organs derived from modified sweat glands. In terrestrial mammals, and presumably cetaceans, the mammae develop along a mammary ridge (the "milk line"), which extends bilaterally from the axilla (where the forelimb joins the thorax) to the inguinal region (where the hindlimb joins the pelvis). The position of the mammae that eventually develop varies in different species: thoracic (e.g., primates, sirenians), thoracoabdominal (e.g., felids), thoracoinguinal (e.g., canids, suids), and inguinal (e.g., ungulates). Like their ungulate relatives, Cetacea only develop inguinal mammae. In females, the teats (nipples) of the mammae are internalized, being withdrawn into the mammary slits (which are positioned with one on either side of the genital slit). This internal location helps streamline the body contour and thus reduce drag during locomotion.

5. Genitoanal Slit and Contents It is difficult to sex the cetacean embryo or early fetus. As the genital tubercle develops, however, it is directed cranially in males and caudally in females (Amasaki *et al.*, 1989b). While the penis/clitoris may be totally exposed in an earlier fetus, the external genitalia are usually not completely visible in the full-term fetus as they are withdrawn into the genitoanal slit. (Note that in a postmortem specimen, the tip of the penis usually protrudes through the slit due to relaxation of the retractor penis muscle.) The genitoanal slit opens into a common vestibule occupied caudally by the anus and rostrally by the urogenital openings. In males, the urethra is contained in the penis; in females, the clitoris and urethra are separate, and there is an opening for the vagina. In males, the genitoanal slit is elongated, reaching almost to the navel. In comparison, the genitoanal slit of females is very short, appearing only between the two mammary slits. Both males and females have a streamlined external shape, as the penis or clitoris is withdrawn into the genitoanal slit and there is no scrotum (testes are intraabdominal) or labia, thus further reducing drag during swimming.

B. Musculoskeletal System

1. Extremities The forelimb extremities of whales are called pectoral flippers. Although cetaceans are derived from a quadrupedal ancestor, adult whales do not possess hind limbs. During the embryonic period, both fore and hind limb buds are present as paddle-shaped projections, with the forelimb developing before the hind limb (Amasaki *et al.*, 1989c). The rudimentary hind limb buds form skeletal element anlagens, vascular plexes, and nerves (Sedmera *et al.*, 1997a) but are completely absorbed by the fetal period. By birth, the only remaining vestige of the hind limb is a skeletal remnant of the femur embedded into the lateral body wall and a rudimentary pelvis that is not attached to the vertebrae. The forelimbs, however, continue developing during the embryonic and fetal periods. Early on, they assume the elongated shape of a typical mammalian arm and forearm, with grooves separating the digits apparent toward the distal edge. The skin overlying the flippers matures faster than the skin over the trunk (Meyer *et al.*, 1995). The stalk-like arm and forearm foreshorten into one functional unit. The skeletal elements (humerus, radius, ulna, and carpal bones) lose their mobility at the elbow and wrist joints, maintaining flexibility only at the shoulder joint.

During the fetal period, the manus of the pectoral flipper fuses into a leaf shape (the distal portion never separates into individual digits, and the interdigital grooves disappear). Odontocete flippers contain five digits—a pattern reminiscent of a terrestrial ancestry. The number of digits within the flipper varies in mysticetes: members of the Balaenidae and Eschrichtiidae families retain all five digits, whereas rorquals (members of the family Balaenopteridae) have reduced that number to four. The tip of the flipper elongates in the caudal direction as differentiation of the phalangeal cartilages progresses proximodistally. Central digits exhibit hyperphalangia (or polyphalangia), i.e., the number of phalangeal elements expands beyond the maximum of three found in most terrestrial mammals (Calzada and Aguilar, 1996). The degree of hyperphalangia varies greatly among species. For example, the second and third digits of *Globicephala melas* have 14–15 and 11 phalanges, respectively, whereas there are seven elements in each of these two digits in *Stenella attenuata* and only five for each of these digits in *Physeter macrocephalus*. Expansion in the number of phalangeal elements, rather than in the lengths of the elements, probably helps support the elongated form of the flipper while retaining some small degree of flexibility that is reminiscent of fin function in fish. Hyperphalangy and elongated pectoral flipper form may also relate functionally to the increasing/decreasing aspect ratio (i.e., relationship between length and width), hydrodynamic form (streamlining effects), or locomotor function (limited to steering, braking, and lift in most species, but can include increased maneuverability or propulsion, e.g., humpback whales).

2. Tail The tail flukes do not appear until the fetal period, after the hind limbs have regressed. The midline of the tail enlarges dorsally and ventrally in the vertical plane to form the slender and hydrodynamic tail stock. The number of caudal vertebrae may increase above that typically seen in terrestrial mammals (perhaps up to 24 in mysticetes and perhaps up to 48 in odontocetes, compared with up to 21 in ungulates). Note that the actual number of caudal vertebrae is difficult to determine with accuracy, as there are no clear anatomical landmarks to separate the caudal region from the lumbar region. The caudal tip develops two horizontal plates of tissue that do not contain any skeletal elements. These plates form the tail flukes. As the fetus nears full term, the tail flukes curl ventrally at their caudal tips so that they are directed rostromedially. This curling of the flukes makes the tail tip more compact and easier to present through the vagina during birth (see later).

3. Back, Dorsal Fin, and Ribs At about the same time that the tail flukes appear, a bulge develops along the midline of the back in the region where the dorsal fin will form. The bulge shape is then modified to a species specific shape (e.g., falcate, triangular, rounded, ridge). When sexual dimorphism in fin

height is seen (e.g., *Orcinus*), it does not occur prenatally. The vertebrae of the back unfold from the embryonic curvature (ventrally concave) to a horizontally aligned column in the early fetal period. In the late fetal period, however, the growing fetus folds again, only this time the body curves laterally. This flexibility may be possible, in part, due to the lack of a sacrum and lengthening of the vertebral column. There are additional lumbar vertebrae in most cetaceans (perhaps up to 15 in mysticetes and perhaps up to 29 in odontocetes) compared with the usual six of ungulates or five of humans. Again, this number is difficult to determine with accuracy, as there is no sacrum or pelvis, and rib articulations can vary. As the side of the fetal head approximates the tail, the dorsal fin folds flat against the concave side of the body. Dorsal fin folding facilitates vaginal delivery (see later).

The ribs of odontocetes are hinged along the lateral aspect, giving each rib two osseous elements joined by a synovial joint. Postnatally, this will facilitate thoracic cavity collapse during diving (as pressure increases with depth, the volume of air in the lungs will decrease).

4. Head (Position and Shape) and Neck The large embryonic head lies in the typical mammalian pose with the face directed ventrally at 90° to the long axis of the body. The maxillary and mandibular regions form a ventrally projecting, conical rostrum that curves slightly caudally. This projection resembles a parrot's beak, being rather thick at the base. In the early fetal period, the rostrum elongates, particularly in long-beaked species (e.g., *Stenella longirostris, Platanista gangetica*). In the midfetal period, the head and neck junction straightens into the adult position, aligned horizontally with the body. The neck region shortens and stiffens, and in many species (e.g., *Globicephala macrorhynchus*) most of all seven cervical vertebrae become compressed craniocaudally and fuse together (Ogden *et al.*, 1981). This enables a smoother transition in form between the head and the thorax, and a midline head position relative to the body's longitudinal axis. The shortened neck enhances streamlining, and fusion of cervical vertebrae improves head stability during locomotion. Vertebral fusion limits lateral or rotational head motion, leaving only dorsocaudal head movements (which help begin the propulsive body wave) at the large joint between the first cervical vertebra and the skull's enlarged occipital condyles.

5. Hyoid Apparatus The hyoid apparatus is derived from the second and third branchial arches. The single basihyal and paired thyrohyals form the large "U"-shaped plate to which the muscles of the tongue, larynx, and sternum attach, and the paired epihyals, ceratohyals, stylohyals, and tympanohyals form the osseous chains bilaterally connecting the basihyal with the skull (Reidenberg and Laitman, 1994).

6. Skull (Mandible, Ear Ossicles, and Cranium) The mandible (jaw) forms around a cartilaginous precursor (Meckel's cartilage) derived from the first branchial arch. The cetacean mandible is largely composed of a horizontal body, with very little (if any) vertical projection forming the ascending ramus. The condylar process is short, and the condylar head may appear to rest directly superior to the caudal portion of the mandibular body. In many odontocetes, the condylar head migrates with fetal development to the caudal aspect of the mandible, whereas in some mysticetes, the condylar head occupies the dorsocaudal edge of the mandible. While the ascending ramus develops most of its vertical height postnatally in many terrestrial mammals, the ascending ramus of cetaceans remains practically nonexistent through the adult stage.

The caudal portion of the first branchial arch contributes to the formation of the upper portions of the first two ear ossicles (malleus and incus). The caudal portion of the second branchial arch contributes to the lower portion of these same two ear ossicles as well as the body of the third ossicle (stapes, except for the foot plate, which derives from the otic placode).

In terrestrial mammals, and presumably cetaceans, the SKULL is derived from two types of bone: chondrocranial (that which preforms in cartilage and then ossifies) and desmocranial (that which does not form a cartilaginous stage, but rather ossifies directly in mesenchyme). The portion preformed in cartilage (the skull base) tends to be less plastic in its shape than that which ossifies from membranes (the cranial vault). Cetaceans appears to be no exception to this rule. In fact, they are an excellent example of the plasticity of the cranial vault, as this region is grossly modified compared with terrestrial mammals.

In the fetal period, the elements of the cranial vault begin to shift their relative positions so that the maxilla approximates or meets the occipital dorsally. This process of bony overlapping (called "telescoping") creates a layered appearance to the skull, where portions of bone are buried on the inner surface. In odontocetes, the parietals are depressed laterally and the premaxillary and maxillary bones overlap the frontal bone dorsally, whereas in mysticetes, the premaxilla slides over the frontal and the base of the maxilla moves under the frontal bone. The cranial vault thus changes shape from dolichocephalic (longer than wide) to brachycephalic (wider than long). The ear ossicles begin to rotate into their adult position during the early fetal period. No paranasal air sinuses (i.e., maxillary, ethmoid, sphenoid, or frontal) form within the skull either prenatally or postnatally (a diving adaptation that prevents injury from expanding/contracting the volume of an enclosed air space during depth/pressure changes). The bony nares migrate caudally to the near adult position on the dorsum of the head.

C. Respiratory Tract

1. Nasal Tract Structures of the nasal region form in the early fetal period, but asymmetry is not detected yet. Nasal conchae (bony plates that project from the nasal septum and walls in terrestrial mammals) never form. The nasal plugs (the tissues that close off the airway) are present and may derive from the tissue that forms the upper lip in terrestrial mammals. The odontocete melon, which may also derive from this same tissue, has not yet formed the characteristic bulge in the forehead region. The nasal air sacs, diverticulae of the nasal tract, begin to bud off the soft tissues of the nasal passageways.

The nasal apertures, which appear initially on the dorsum of the rostrum, begin to migrate caudally toward the adult position at the top of the head. They can be found near the junction of the rostrum and the swelling containing the forebrain.

The nasal skull grossly transforms so that the nasal floor projects ahead of the nasal passageways into the rostrum, whereas the lateral parts (which forms the walls of the nasal passages) shift from horizontal to vertical (Klima, 1999). There are two separate bony nasal passageways in all cetaceans. The soft tissues above the skull that surround the nasal passageways are maintained as two separate tubes in mysticetes. In odontocetes, however, the two soft tissue passageways fuse near their exit at the skin into one common blowhole opening. There are further differences within odontocetes in the development of the nasal skull. *Phocoena phocoena* has the most posteriorly positioned nares, whereas *Physeter macrocephalus* has the most anteriorly positioned nares. There are additional specializations in *Physeter* related to the unique forehead containing the spermaceti organ, including asymmetrically sized and positioned narial openings in the skull and soft tissue pathways through the head.

2. Larynx The larynx (voice box) forms from cartilage elements of the fourth through sixth branchial arches. Its position in cetaceans is similar to that found in terrestrial mammals. The front part (epiglottis) overlaps its ventral surface with the dorsal surface of the soft palate, creating a bridge to channel air from the nasal region into the trachea and lungs. In odontocetes, the larynx undergoes elongation of its rostral portion, forming a "goose beak" shape that inserts into the nasal region. The epiglottis elongates during the midfetal period. The posterior cartilages (corniculates) are still shorter than the epiglottis and will not reach their full proportions (i.e., exceed the epiglottis in height) until the fetus reaches full term. The laryngeal "goose beak" of odontocetes inserts into a muscular sphincter derived from the palatopharyngeal arch of the soft palate. Postnatally, this interlock will keep the rostral opening of the larynx connected with the posterior nasal cavity. This connection imparts circumferential protection from the digestive tract, allowing air to flow between the nasal region and the lungs for sound production while prey is swallowed whole underwater. Internally, the odontocete larynx develops a midline fold (which is bifurcated in *Kogia breviceps*) that appears homologous to the vocal fold of terrestrial mammals (Reidenberg and Laitman, 1988). The mysticete larynx more closely resembles that of terrestrial mammals, except that there is a large and muscular sac attached ventrally in the midline. In *Caperea marginata*, this sac lies on the right side.

3. Trachea and Lungs Tracheal rings usually develop as "O"-shaped rings, unlike the "C"-shaped rings of most terrestrial mammals. A bronchus leading to the right lung develops above the carina (tracheal bifurcation). As this bronchus emerges directly from the trachea above the primary (main stem) bronchi, it is termed a "tracheal bronchus." A right tracheal bronchus is a feature also found in the closely related artiodactyls.

The lungs mature from the embryonic glandular stage to the fetal canalicular stage (for more information on stages of lung development, see Drabek and Kooyman, 1983). Next, muscular sphincters develop around the terminal bronchioles. Because this feature is not found in terrestrial mammals, it may be an adaptation for diving. The next phase of development is the alveolar stage. By the midfetal period, cartilaginous rings develop in the terminal bronchioles. This is another feature not found in terrestrial mammals that may also be an adaptation for diving, as cartilage rings may keep the terminal airways patent under high pressures and during lung collapse at depth.

D. Digestive Tract

1. Teeth and Baleen Late in the fetal period, both odontocetes and mysticetes form tooth buds. Odontocete teeth are single cusped and usually conical in shape with species-specific variations, e.g., narwhal, *Monodon monoceros* (long spiral tusk), *Platanista gangetica* (needle-shaped), beaked whales (flattened and broad), and porpoises (flattened, spade-shaped). Postnatally, teeth are used primarily for grasping and aggression. As there are no incisors, canines, or molars (odontocetes are "homodonts"—all teeth have the same shape), the task of breaking up food is passed onto the stomach (see later). The tooth buds of fetal mysticetes are sometimes multicusped, resembling the teeth of related terrestrial mammals (Slijper, 1979). The mysticete tooth buds are more numerous in the upper jaw than in the lower jaw, but all are usually resorbed before birth. The formation of rudimentary baleen plates, which occurs concurrently with tooth bud degradation, may be induced by the process of tooth bud resorption (Ishikawa and Amasaki, 1995). As the mysticete fetus grows, longitudinal baleen ridges form in the gums of the upper jaw. These longitudinal ridges develop transverse divisions and rows of papillae composed of epidermal folds that become cornified. The cornified papillae are tubular in shape and elongate and coalesce with their neighbors to form baleen plates (Slijper, 1979).

2. Throat Grooves Throat grooves are a series of parallel, longitudinal folds found on the external, ventral surfaces of the head in rorqual mysticetes that enable expansion of the oral cavity. In other mysticetes and some odontocetes, a single pair of throat grooves can be found at the base of the jaw and may indicate expansion of this region during tongue and hyoid depression (see later). In rorqual mysticetes, throat grooves begin forming in the fetal period, appearing initially between the umbilicus and the pectoral flipper. A second set of ventral throat grooves appears next near the tip of the mandible. Toward the end of gestation, the two sets of throat grooves join to form one complete set running from the mandibular tip to the umbilicus. These throat grooves enable expansion of the floor of the mouth to engulf prey during feeding.

3. Tongue In both mysticetes and odontocetes, lingual papillae develop along the lateral border of the tongue during the fetal period. Because newborn cetaceans lack lips, these papillae probably play an important role postnatally during nursing in grasping the teat, creating a seal for suction, and forming a channel for milk to flow into the oral cavity. These papillae attain maximal size in the early postnatal period of odontocetes, but can sometimes be found persisting in adults.

The tongues of mysticetes and odontocetes differ greatly in their construction, and this difference is evident in the fetal stage. Odontocete tongues are related more closely to the tongue of terrestrial mammals, being very muscular. Their tongues have large insertions on the broad bones of the hyoid

apparatus (Reidenberg and Laitman, 1994). This arrangement helps depress the tongue into the throat like a piston, thereby creating enough negative pressure to draw in prey—a mechanism referred to as "suction feeding." The mysticete tongue (particularly in rorqual whales) is unusual in its structure because it can be flattened against the floor of the mouth and expanded laterally along with the throat pleats during prey engulfing. In addition, there is a fibrocartilage structure in the ventral throat region of rorqual whales that may be related to attachment of the mylohyoid muscle. This structure may aid jaw mechanics and support the tongue and floor of the mouth during expansion/contraction of the throat grooves.

4. Gastrointestinal Tract In mammals, gut development begins with a single, relatively straight gastrointestinal tube that is suspended in the midline of the coelom. As the embryo develops, the gut tube differentiates into the foregut and hindgut, and as each section further develops its specific shape, individual regions of the gut tube begin to rotate into different positions within the coelomic cavity. Toward the end of the embryonic period, the thoracoabdominal wall is distended. This is probably because the stomach is developing its multiple chambers and intestinal rotation is occurring. Cetaceans develop a multichambered stomach [e.g., see Tarpley *et al.* (1997) on the stomach of *Balaena mysticetus*], much like that found in closely related ruminant artiodactyls, the closest group of living land mammals to the cetaceans. The divisions of the cetacean stomach include, from proximal to distal: forestomach, main stomach, and pyloric stomach. As it does in ruminants, the cetacean forestomach arises from the stomach bud rather than the esophagus (Amasaki *et al.*, 1989a), but is not divided into the three small chambers (rumen, reticulum, psalterium) found in, for example, the cow. The size of the forestomach may be dependent on the consistency of the prey. In odontocetes, a large and muscular compartment may signify a function in breaking down whole fish or crustaceans, whereas a smaller compartment possibly relates to a diet of soft prey such as cephalopods. In mysticetes, the forestomach is smaller than the main stomach, perhaps relating to the relatively small size of their prey. The cetacean main stomach and pyloric stomach (which can have up to 12 chambers, e.g., beaked whales) are equivalent to the cow's single rennet stomach (Slijper, 1979).

The process of intestinal rotation probably resembles that of other mammals, involving temporary herniation (protrusion) into the umbilicus, rotation and folding, and then return of the contents back to the abdomen where they lie more compactly. Thus, by the early fetal period the abdomen is no longer distended by the process of intestinal rotation. The cecum and large intestines then differentiate further, developing circular folds that divide the intestines into multiple connected chambers resembling the haustra (sacculations) of terrestrial mammals (Amasaki *et al.*, 1989a).

E. Genitourinary System

1. Urinary Tract In embryos of terrestrial mammals, and presumably cetaceans, the earliest kidney is the mesonephros, composed of ducts and tubules. The embryonic metanephric duct, which buds off the mesonephric duct, becomes the ureter. As the mesonephros regresses, a second kidney structure, the metanephros, develops around the metanephric duct and is retained as the final kidney.

The fetal kidney develops as a cluster of many small and relatively independent kidney units called renicules, which will be retained in the cetacean adult. An adult kidney divided into renicules or lobes is not unusual in mammals (e.g., ox, otter) and may indicate persistence of the fetal condition. The apparent functional advantage of a kidney divided into renicules in large mammals appears to be related to a maximum size for the length of the tubules, which might otherwise be too long for proper function in a large single kidney.

The urogenital sinus (derived from the embryonic cloaca) becomes the urethra. The urinary bladder develops from the proximal portion of the allantois.

2. Reproductive Tract The remnants of the mesonephric duct become the efferent ductules, epididymis, and deferent duct for sperm transport in males. The gonads (ovaries and testes) develop from gonadal ridges, which are paired thickenings of the coelomic epithelium. In females, paramesonephric (Mullerian) ducts develop simultaneously with mesonephric ducts. Paramesonephric ducts become the bicornuate uterus and oviducts in females, but degenerate in males except for the prostatic sinus.

In males, the testes are intraabdominal, i.e., they do not descend as in most terrestrial mammals, and thus there is no scrotal sac. The internalization of these structures helps streamline the body shape, thus reducing drag during swimming. Interestingly, cetaceans develop a gubernaculum (which functions in testicular descent in terrestrial mammals), but do not develop the peritoneal outpocketing that occurs with testicular descent (the vaginal process) during the fetal period (van der Schoot, 1995). A complex vascular plexus supplies the testes (see later), functioning as a countercurrent heat exchanger to keep the testes cool despite their internal location under the insulating blubber.

The genital tubercle gives rise to the penis or clitoris (Amasaki *et al.*, 1989b). External genitalia are not usually visible externally in the full-term fetus as they are withdrawn into the genital slit (see Section I,A,5).

F. Circulatory System

1. Heart During the embryonic period, the heart is visible and has probably undergone a similar differentiation as occurs in other mammals. The heart begins as a straight tube, but during the late embryonic period, it folds and forms septa that eventually divide it into the four chambers found in all mammalian hearts. The cetacean heart, however, shows differences in shape from terrestrial mammals. In both odontocetes and mysticetes, it is laterally (transversely) broad and craniocaudally compressed, with the apex being formed by both ventricles. The cetacean heart has specializations that may be adaptive for diving, such as anastomoses between dorsal and ventral interventricular arteries, and hypertrophy of the right ventricle (Tarpley *et al.*, 1997). Diving adaptations also occur in the great vessels, such as an expandable aortic arch.

2. Blood Vessels The internal carotid artery, which is a major supplier of blood to the brain in terrestrial mammals, tapers

dramatically in the neck and terminates under the skull base at the carotid canal before reaching the brain. This reduction of the internal carotid artery probably occurs in all cetaceans that exhibit cervical rete mirabila (see later), as this is the only structure it appears to supply. Interestingly, the internal carotid artery is also reduced or absent in many artiodactyl species. The ductus arteriosus (a fetal vascular connection between the aorta and the pulmonary artery) was thought to remain patent postnatally, but a study in adult pilot whales (*Globicephala* spp.) showed that it does close (Johansen *et al.*, 1988). This is no different from terrestrial mammals and is probably the condition in other cetaceans as well.

The fetus develops complex networks of anastomosing, coiled blood vessels called retia mirabila. These vessel masses are found in regions surrounding the dorsal thoracic cage, the region near the foramen magnum, and the spinal cord. Although the function of retia mirabila is not known, it is thought that they are adaptations to diving and resurfacing. Their vessel structure may compensate for the rapid pressure changes of descent and ascent with a slow and sustained response that moderates blood flow. By dampening oscillations in blood pressure, sensitive tissue such as heart muscle or the brain and spinal cord continue to receive steady perfusion, thus avoiding oxygen debt and lactic acid buildup. As these vessels appear to store blood near vital tissue (e.g., brain, spinal cord, heart), they may thus function as a reservoir, distributing blood to these oxygen-sensitive tissues when normal circulation is affected (e.g., as pressure increases during diving, or metabolism is slowed). A less widely held hypothesis for the function of the retia mirabila is in trapping the nitrogen bubbles (emboli), which may come out of solution in the bloodstream during ascent from a prolonged dive. These bubbles are potentially fatal, as they can block smaller blood vessels and therefore interrupt blood flow in the capillary beds of organs (a condition known in human divers as decompression sickness, or caisson disease).

The fetus also develops a complex network of vessels that supply and drain the testes and uterus. These vessels are arranged in a plexus to effect a thermoregulatory countercurrent exchange. This conserves heat where needed and allows extra heat to be drawn away from these organs. Thus, the male can keep the testes cool and the pregnant female can keep the fetus in the uterus from overheating, despite the internal location under the insulating blubber (Rommel *et al.*, 1993).

G. Nervous System

1. Brain Brain development in the embryonic period resembles that of other terrestrial mammals. The brain is composed of three main sections: prosencephalon (forebrain), mesencephalon (middle brain), and rhombencephalon (hindbrain). The corticospinal tract does not develop to the same degree as terrestrial mammals, probably due to the loss of the hind limbs and the reduced role of the forelimbs in propulsion. The cochlea is enlarging, while the vestibular system is rudimentary in size—a disparity that will remain in the adult. Olfactory bulbs and nerves are present in both odontocete and mysticete embryonic brains.

The rate of brain growth and degree of encephalization differs for different species (Pirlot and Kamiya, 1975). In the early fetal period, typical cetacean features begin to develop. For example, the olfactory bulbs and nerves disappear in odontocetes. In mysticetes, however, the olfactory bulbs and nerves are retained. Because adult mysticetes retain olfactory mucosa, it is presumed that they use a sense of smell to help locate plankton, particularly swarms of krill. There is some dispute, however, as to the existence of a vomeronasal organ (a chemoreceptive organ that functions mainly in detecting sexual phermones in terrestrial mammals). Although it had been thought that adult whales had a vomeronasal organ, fetal studies of mysticetes and odontocetes show both the vomeronasal organ and nerve to be absent (Oelschläger *et al.*, 1987). The function of a cetacean vomeronasal organ is purely speculative, but may include detecting the presence and mating status of other whales and perhaps even the odor of food in the mouth. The terminal nerve (a sensory, but not chemosensory, derivative of the olfactory placode sometimes called "cranial nerve 0") persists and may function in the autonomic innervation of intracranial arteries and mucous epithelium of the nasal air sacs.

2. Spinal Cord In the midfetal period, the head and neck regions align horizontally. During this process, the cervical section of the spinal cord, which was previously flexed ventrally, must now arch under and around the cerebellum to join the thoracic spinal cord (the dorsal aspect is thus concave). As the cervical vertebrae are compressed, much of the cervical spinal cord is contained within the skull.

II. Gestational Length

Because whales are related to terrestrial ungulates, it is not surprising that their gestation is of a similar length (see Table I). Horses, for example, have a gestation of 11 months (compared to 9 months for a human's pregnancy and 22 months for an elephant's gestation). Gestation in mysticetes lasts 10–13 months. The length of gestation in odontocetes, however, is more variable, ranging from 10 to 17 months. The length of the gestation is not correlated with body size (e.g., although the sperm whale is the largest odontocete, its gestation is the same as the smaller pilot whale and less than the Baird's beaked whale, *Berardius bairdii*).

The length of gestation in cetaceans may be related to food supply and MIGRATION. Most mysticetes mate in warm waters, migrate to cold waters to feed, and then migrate back to warm waters to calve. This behavioral cycle, which takes 1 year, thus appears to be related to gestational length. Interestingly, because most feeding occurs in colder waters, a pregnant mysticete whale may well be fasting while simultaneously spending energy in migratory locomotion and nourishing a growing embryo/fetus. In this regard, it is significant that the first half of the pregnancy (largely embryo development) takes place during the migration to the feeding areas, whereas the second half of the pregnancy (largely fetal growth) takes place during the migration back to the calving areas. A whale migrating to feeding areas is not carrying a large load of stored energy compared with a whale returning to calving areas from feeding areas. In some species, pregnant whales may increase food intake by 50–60% above normal during the last 6 months of gestation.

TABLE I
Cetacean Gestations and Newborn Calf vs Adult Measurements

	Gestation (in months)	*Newborn calf (length, weight)*	*Mature adult (length, weight)*
Mysticetes			
Right whales (*Eubalaena* spp.)	12	4.5–6 m, 1000 kg	12.5–17.7 m, 30,000–80,000 kg[a]
Bowhead whale (*B. mysticetus*)	12–16	3.6–4.5 m, 1000 kg	11.5–18 m
Pygmy right whale (*Caperea marginata*)	?	2 m?	5.47–6.45 m, 3,100–3,500 kg
Gray whale (*Eschrichtius robustus*)	13–13.5	4.5–5 m, 500–800 kg	13–15.2 m, 14,000–35,000 kg
Humpback whale (*Megaptera novaeangliae*)	11–11.5	4–5 m, 900–1500 kg	11.5–19 m, 25,000–48,000 kg
Minke whales (*Balaenoptera acutorostrata* and *B. bonaerensis*)	10	2.4–3 m, 300–400 kg	6.9–10.7 m, 4000–13,500 kg
Bryde's whales (*B. brydei, B. edeni*)	11–12	3.95–4.3 m, 900 kg	11.6–15.6 m, 16,000–25,000 kg
Sei whale (*B. borealis*)	11.5–12	4.5 m, 780 kg	13–18.3 m, 20,000–25,000 kg
Fin whale (*B. physalus*)	11	6.4–6.5 m, 1750–1800 kg	17.5–27 m, 30,000–90,000 kg
Blue whale (*B. musculus*)	11–12	7–8 m, 2000–3000 kg	19–31 m, 100,000–200,000 kg
Odontocetes			
Sperm whale (*Physeter macrocephalus*)	14–16	3.5–4.5 m, 1000 kg	8.3–20.5 m, 16,000–57,000 kg
Pygmy sperm whale (*Kogia breviceps*)	11	1.2 m	2.7–3.7 m, 400 kg or less
Dwarf sperm whale (*K. sima*)	9	1 m	2.1–2.7 m, 210 kg
Cuvier's beaked whale (*Ziphius cavirostris*)	12	2.5–3 m	5.1–7.5 m, 3,000 kg
Baird's beaked whale (*Berardius bairdii*)	17	4.5–4.8 m	10–12.8 m, 11,000 kg
Northern bottlenosed whale (*Hyperoodon ampullatus*)	12	3–3.5 m	6–9.8 m
Southern bottlenosed whale (*H. planifrons*)	?	2.9 m	5.7–7.45 m
Hector's beaked whale (*Mesolodon hectori*)	?	2.1 m	4.3–4.43 m
True's beaked whale (*M. mirus*)	?	2.3 m, 136 kg	5.1–5.3 m, 1,394 kg
Gervais' beaked whale (*M. europaeus*)	?	1.6–2.1 m, 49 kg or more	3.7–5.2 m, 1,178 kg or more
Sowerby's beaked whale (*M. bidens*)	12	2.4–2.7 m, 185 kg	5.05–5.5 m
Gray's beaked whale (*M. grayi*)	?	2.42 m	4.74–5.64 m, 1,075–1,100 kg
Hubb's beaked whale (*M. carlhubbsi*)	?	2.5 m	5.3 m, 1,432 kg
Strap-toothed whale (*M. layardii*)	?	0.76–2.8 m	5.8–6.2 m
Blainville's beaked whale (*M. densirostris*)	?	1.9 m, 60 kg	4.56–4.73 m, 1,033 kg
Indian river dolphin (*Platanista gangetica*)	8–12?	0.67–0.9 m	1.7–2.5 m, 85 kg
Amazon river dolphin (boto) (*Inia geoffrensis*)	9–12	0.75–0.8 m, 7–8 kg	2–2.6 m, 100–160 kg
Chinese river dolphin (*Liptotes vexillifer*)	?	0.57–0.95 m, 10 kg or less	2.1–2.5 m, 125–16- kg
Franciscana (*Pontoporia blainvillei*)	10–11	0.75–0.8 m, 7.3–8.5 kg	1.5–1.74 m, 25–53 kg
Beluga whale (*Delphinapterus leucas*)	14–14.5	1.5–1.6 m, 79–80 kg	3–5.5 m, 400–1,500 kg
Narwhal (*Monodon monoceros*)	14–15	1.5 m	3.4–4.7 m
Commerson's dolphin (*Cephalorhynchus commersonii*)	11–12	0.65–0.75 m	1.25–1.75 m, 35–86 kg
Hector's dolphin (*C. hectori*)	?	0.5–0.7 m	1.2–1.8 m, 50–60 kg
Humpbacked dolphin (*Sousa chinensis*)	?	0.9–1 m	2.26–3 m, 195–284 kg
Tucuxi (*Sotalia fluviatilis*)	10	?	1.3–1.9 m, 35–40 kg
Common Bottlenosed dolphin (*Tursiops truncatus*)	12	0.9–1.3 m	1.9–4 m, 90–650 kg
Pantropical spotted dolphin (*Stenella attenuata*)	11–12	0.8–0.89 m	1.82–2.57 m, 119 kg or less
Atlantic spotted dolphin (*S. frontalis*)	?	0.76–1.20 m	2.3 m, 143 kg
Spinner dolphin (*S. longirostris*)	10–11	0.77–0.8 m	1.3–2.16 m, 26.5–75 kg
Striped dolphin (*S. coeruleoalba*)	12–13	1 m	2.16–2.4 m, 156 kg or less
Short-beaked common dolphin (*Delphinus delphis*)[c]	10–11	0.76–0.86 m	1.6–2.6 m, 70–135 kg
Fraser's dolphin (*Lagenodelphis hosei*)	?	0.95 m	2.25–2.65 m, 200 kg or more
White-beaked dolphin (*Lagenorhynchus albirostris*)	?	0.95–1.6 m, 40 kg or more	2–3 m
Atlantic white-sided dolphin (*L. acutus*)	10–12	1.08–1.22 m	2–2.8 m
Pacific white-sided dolphin (*L. obliquidens*)	10–12	0.8–1.24 m	1.7–2.5 m, 75–181 kg
Dusky dolphin (*L. obscurus*)	11	0.55–0.70 m[b]	1.6–2.1 m, 40–80 kg or more
Northern right whale dolphin (*Lissodelphis borealis*)	?	0.8–1 m	2–3.1 m, 115 kg
Risso's dolphin (*Grampus griseus*)	13–14	1.2–1.5 m	2.6–4.3 m, 500 kg
Melon-headed whale (*Peponocephala electra*)	?	1 m	2.2–2.75 m, 160–275 kg
Pygmy killer whale (*Feresa attenuata*)	?	0.8 m	2–2.6 m, 150–225 kg
False killer whale (*Pseudorca crassidens*)	11–15.5	1.6–1.93 m	3.96–6 m, 1,100–2,200 kg
Killer whale (*Orcinus orca*)	16–17	2.06–2.5 m	4.6–9.75 m, 2,600–10,500 kg
Long-finned pilot whale (*Globicephala melas*)	14.5–16	1.75–1.8 m, 70–85 kg	3.8–6.3 m, 280–1750 kg
Short-finned pilot whale (*G. macrorhynchus*)	15	1.4–1.85 m	3.01–7.2 m, 600–3950kg
Irrawaddy dolphin (*Orcaella brevirostris*)	14	0.9–1 m, 12.5 kg	2.15–2.75 m, 90–150 kg
Finless porpoise (*Neophocaena phocaenoides*)	11–12	0.6–0.9 m	1.8–1.9 m
Harbor porpoise (*Phocoena phocoena*)	9–11	0.7–0.9 m, 5–9 kg	1.4–2 m, 40–90 kg
Spectacled porpoise (*P. dioptrica*)	?	0.46 m	1.8–2.4 m
Dall's porpoise (*Phocoenoides dalli*)	11–12	0.95–1 m	1.7–2.2 m, 200 kg

[a]10.09-m male North Atlantic right whale was 9055 kg when weighed intact postmortem.
[b]0.98-m dusky dolphin calf weighed 22 kg; 0.67-m dusky dolphin fetus weighed 3.7 kg.
[c]May include data for *D. capensis*.

Thus, the energy demands on a whale in early pregnancy may be smaller than that of a whale in the later stages of pregnancy, when the fetus is growing at a rapid rate. In odontocetes, these energy constraints appear to have less of a temporal impact on gestational periods. This may be due, in part, to a more constant energy supply (year-round access to a food supply) for those species that migrate, or the lack of migration in other species.

Because the calf must be able to swim, see, hear, and vocalize immediately after birth, the nervous and muscular systems of the calf must be well developed. This also translates to a fairly long gestation, with as much development as possible occurring prenatally (compared with the human baby, which completes much of its neuromuscular development postnatally). The long gestation also enables calves to grow to a large size before birth, reaching approximately one-fourth to one-third of the mother's size. Once the fetus has attained a near adult form, the most dramatic changes appear to be mainly in the overall size of the fetus. As the fetal period progresses, the growth rate increases rapidly. For example, the blue whale (*Balaenoptera musculus*) gains approximately 100 kg/day in the last 2 months alone. Large newborns are also common among the whales' closest land relatives, the ungulates, which also have well-developed neural and muscular systems at birth. An additional advantage of a large calf is a smaller surface-to-volume ratio (which helps the calf conserve heat). Thus, because whales have relatively large calves, it is not surprising that multiple births are a rarity.

III. Maternal Uterus, Placenta, and Umbilical Cord

Cetaceans have a bicornuate uterus (two horns joined in a Y shape). The fetus usually develops in one horn (either horn for mysticetes, but most frequently the left horn for odontocetes), whereas the other horn is generally occupied by the allantois (one of the embryonic membranes) and placenta. The cetacean uterus has a complex vascular plexus that functions in countercurrent heat exchange (Rommel *et al.*, 1993). This keeps the fetus from overheating, despite its insulated location under the maternal blubber and adjacent to the locomotor musculature of the maternal abdomen.

The placenta is epitheliochorial (or cotyledon), which means that the maternal and fetal tissues do not fuse into one tissue, as in humans. Rather, their vascular systems remain separated by two epithelial layers with separate capillary beds. This arrangement ensures that the two layers separate relatively easily at birth, thus minimizing the inevitable loss of blood. Not surprisingly, this type of placenta is also found in the ungulates, the group of terrestrial mammals related most closely to cetaceans.

The umbilical cord is short and thick, with "amnion pearl" knobs on the outer surface that appear to regulate the development (cornification) of fetal skin. It contains two arteries and two veins, as well as an allantoic duct. When the calf is born, the umbilical cord breaks off at the fetal end, allowing the calf to swim unhindered to the surface. Because the mother does not appear to bite off the umbilical cord, it is presumed to break with little force at the moment of birth. The umbilical ring contains invaginations that probably weaken the connection between the fetal epithelium and the umbilical cord. The umbilical arteries and veins are also constricted and weak where they enter the fetal abdomen. The umbilical cord attaches midway along the length of the fetus (unlike the more caudal attachment found in fetuses of other mammals, in which the neck contributes more to fetal length than the tail). Thus, the umbilical cord will be stretched taut to the same degree regardless of whether the head or the tail is delivered first. The stretch from the delivered fetus pulling taut the umbilical cord, which is attached via the placenta to the mother's uterus, may cause its rupture at the umbilicus.

IV. Fetal Position and Birth

Birth takes place underwater. In most observed captive births in odontocetes, the fetal tail emerged first through the vaginal opening. This tail-first presentation may appear unusual, particularly when compared with the usual head-first presentations of most terrestrial mammals. Interestingly, captive manatees have also been observed to deliver their young tail-first underwater. Whereas births in the wild have been documented less frequently, they appear to be more commonly tail-first presentations in odontocetes and may be equally tail first or head first in mysticetes. As the pelvis in whales is rudimentary, it appears to have little, if any, effect on passage of the fetus during birth. In fact, the large size of the cetacean brain at birth may be possible, in part, because of the ease with which the large head of the fetus can be delivered through this rudimentary pelvis. Because there is no significant bony constriction at the pelvic outlet, there does not appear to be a physical need for a head-first delivery as in most large terrestrial mammals.

The higher frequency of tail-first presentations may also be explained by the shape and intrauterine position of the fetus. The cetacean fetus has a fusiform shape, with the rostrum and tail stock both being relatively small in diameter. The tail flukes, dorsal fin, and pectoral flippers are very pliable and are flattened against the body (fin and flippers) or curled back toward the midline to form a small knob (flukes). This folding and curling not only helps keep the fetal body within in the smallest dimensions, but it also enables the fetus to maintain a relatively smooth exterior contour with no protrusions to inhibit delivery through the vagina. In addition, the whole fetus is laterally flexed into a U shape, with the tail recurved toward the head so that the flukes are positioned adjacent to the rostrum. While this fetal folding reduces the intrauterine volume needed for carrying the fetus, it also leaves the fetus with both its rostrum and its tail flukes directed toward the maternal tail. However, because the uterine horn is also folded, only one end of the fetus can thus be directed toward the cervix. In odontocetes, it is most commonly the tail. Because the tail flukes are smaller than the cetacean head, they can therefore slip out of the vagina more easily and thus are more likely to emerge first.

The head being directed away from the cervix before parturition may be a function of either fetal shape or fetal weight. Because both the center of gravity and the largest diameter is closer to the fetal head, its "rest" position may more likely be with the heavier fetal head nearer the center of gravity of the

mother. This places the fetal head in the more distensible part of the mother's abdomen and away from the more mobile tail stock (which, due to locomotor constraints, may have less capability for expansion).

Once the fetus is settled into this birth position, continued growth appears to cause it to recurve caudally in order to fit within the mother's abdomen. Unlike terrestrial mammals, the head is not flexed ventrally in the late-term cetacean fetus because there is practically no neck and the cervical vertebrae are largely fused. Rather, the fetus folds in half laterally to conserve space. The curved midsection of the fetus takes up more room in the maternal abdomen than the fetal head and tail. Thus, the fetal abdomen is placed cranially in the mother, where there is more room for expansion, while the fetal head and tail are directed caudally near the less expandable maternal tail stock. Although the fetal head is directed caudally, it is positioned at the tip of the uterine horn (which is thus also folded to face caudally) and not adjacent to the cervix. In this folded position, it is unlikely that the fetus can reposition itself to completely switch from a tail-first to a head-first presentation. As the fetus is delivered, its body must unfold. Thus, midway through parturition, the fetal head will again face toward the maternal head as the fetal body straightens. The newborn calf bears light colored bands and shallow vertical grooves, called "fetal folds," along the skin of the lateral abdomen. These markings indicate the concave side of the fetus as it was folded *in utero*.

Pygmy and Dwarf Sperm Whales

Kogia breviceps and *K. sima*

DONALD F. MCALPINE
New Brunswick Museum, Saint John, Canada

Found throughout temperate and tropical seas, pygmy and dwarf sperm whales are small, toothed cetaceans generally assigned to the family Kogiidae. Although rarely sighted at sea, these whales commonly strand in some regions. The relatively little that is known of their biology has been gleaned from such stranded animals.

I. Diagnosis

In form, *Kogia* spp. are porpoise-like and robust with a distinctive underslung lower jaw. This latter feature has been described as giving these whales a shark-like appearance (Fig. 1). Although height and position of the dorsal fin have been reported as distinguishing the two species, they are probably not separable at sea except under exceptional circumstances. Pygmy sperm whales reach a maximum size of about 3.8 m total length and a weight of 450 kg. Dwarf sperm whales are smaller at 2.7 m and 272 kg. Adults of both species are dark bluish-gray to blackish-brown dorsally with a light venter. On the side of the head between the eye and the flipper there is often a crescent-shaped, light-colored mark referred to as a "false gill." It is only since 1966 that two species of *Kogia* have been recognized, and no subspecies have been described. Some cetologists place *Kogia* in a subfamily Kogiinae within Physeteridae with the sperm whale, *Physeter macrocephalus*. Some anatomical features suggest that the relationship between *Kogia* and other toothed whales remains poorly resolved.

II. Distribution and Status

Dwarf and pygmy sperm whales occur worldwide in temperate and tropical waters of the Atlantic, Pacific, and Indian Oceans. Evidence shows that *K. sima* may prefer warmer seas than *K. breviceps*, but currently there is little indication for seasonality in the distribution or the migration of these whales. Their precise at-sea DISTRIBUTION is unknown, as most records are based on stranded animals. Although many writers have stated that dwarf and pygmy sperm whales are rare, there is insufficient information to classify the world status of *Kogia* species, and their population sizes are unknown. The frequency with which *Kogia* strand on certain coasts, especially in southeastern United States and South Africa, suggests that they may be uncommon rather than rare in some regions.

III. Ecology

Analysis of prey in stranded animals suggests that both species of *Kogia* generally inhabit waters along the continental shelf and slope in the epi- and mesopelagic zones. Differences in the proportion of prey items in stomachs indicate that *K. sima* feeds in shallower water than *K. breviceps*. *Kogia* spp. feed mostly on mid and deep-water cephalopods but also consume fish and occasionally crustaceans, such as shrimp and crabs. Stomach contents that have been analyzed have contained cephalopod beaks from at least 13 families. Most feeding seems to takes place on or near the bottom, probably using ECHOLOCATION to find prey. Kogiid hyoid anatomy suggests powerful suction feeding.

Little is known about disease in *Kogia*. Strandings of unhealthy pygmy and dwarf sperm whales have been attributed to degenerative heart disease, as well as being linked to possible immune system problems associated with the thymus gland. Pneumonia has also been observed in stranded animals. *Kogia* specimens are frequently heavily infected with intestinal nematodes (*Anisakis* sp. and *Terranova cetecola*) and blubber-encysted larval cestodes (*Phyllobothrium delphini*). The parasitic crustacean, *Pennella balaenoptera*, has been observed embedded in the epidermal surface of both species of *Kogia*. Scarring indicates that these whales are attacked by lampreys. A white shark (*Carcharadon carcharias*) attack on a pygmy sperm whale has been documented, and pygmy sperm whale remains have been identified in killer whale (*Orcinus orca*) stomachs. Levels of PREDATION on *Kogia* are otherwise unknown. Heavy infestations with larval cestodes, which probably mature in elasmobranchs, suggest that shark attacks may be more common than the single literature report suggests.

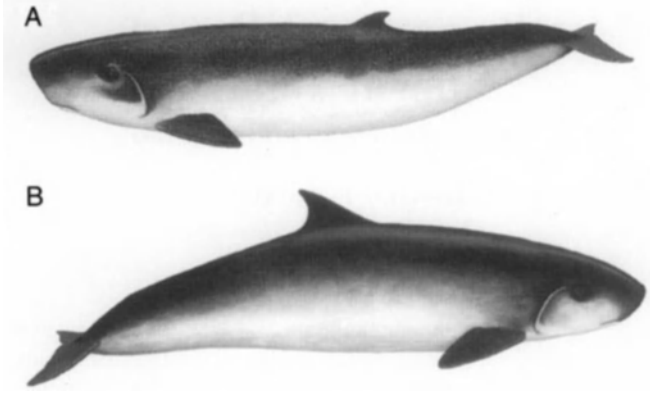

Figure 1 *(A)* Kogia breviceps. *The relatively short and more posteriorly positioned dorsal fin is useful in distinguishing this species from (B)* K. sima. *Pieter A. Folkens/Higher Porpoise DG.*

IV. Behavior

There have been no comprehensive behavioral studies of dwarf or pygmy sperm whales. Stranded animals that have been maintained in aquaria have survived no more than several months and usually only live for a few days. At sea, both species occur individually or in small groups of up to 6 (*K. breviceps*) or 10 (*K. sima*) animals of varying age and sex composition. Strandings usually involve single animals. Dwarf and pygmy sperm whales are reported to spend considerable time lying motionless at the surface with the back of the head exposed and the tail hanging down. *K. breviceps* is easily approached, but is timid and slow moving. Normal swimming speed is thought to be about 3 knots. When surfacing, both species rise slowly, produce an inconspicuous blow, and dive without showing the flukes. Neither species is known to be highly vocal.

V. Anatomy and Reproduction

The genus has the shortest rostrum among living cetaceans (Fig. 2) and the skull is markedly asymetrical. The mandibles are delicate, and the teeth are very sharp, thin, and lack enamel. *K. breviceps* lacks teeth in the upper jaw, but *K. sima* may have up to three pairs of vestigial teeth in this position. Like the Physeteridae, *Kogia* spp. have a spermaceti organ. The function of this organ is unknown, but it has been suggested that it may be involved in maintaining neutral buoyancy or function as an acoustic lens in directing sound beams during ecolocation. *K. sima* reaches sexual maturity at about 2.1 m in length. In *K. breviceps*, males are known to be sexually mature at about 2.7 m and females at a slightly smaller size. Gestation has been cited as 9 or 11 months, with the species about 1 m in length at birth.

Figure 2 *Skull of* Kogia breviceps. *The rostrum is short, the skull asymmetrical, and teeth are lacking in the upper jaw. Photo courtesy of New Brunswick Museum.*

VI. Fossil Records

Fossil forms of Kogiidae have rarely been described from fragments of teeth, cranium, and lower jaws of late Miocene to early Pliocene age. Most of these may be only distantly related to extant *Kogia* spp. However, *Praekogia cedrosensis*, described from the early Pliocene in the Almejas Formation on Isla Cedros Baja California, Mexico, is reported to be clearly ancestral to living *Kogia*.

VII. Human Interactions

The scarcity of pygmy and dwarf sperm whales and the fact that they are rarely encountered at sea mean that direct effects from humans are probably few. However, they have been reported to ingest ocean debris such as plastic bags, possibly resulting in intestinal blockage and death. Their habit of lying quietly at the surface seems to have led to occasional ship strikes. Both species are taken infrequently in commercial harpoon fisheries in the Caribbean and Indian Oceans.

Pygmy Killer Whale

Feresa attenuata

MEGHAN A. DONAHUE AND WAYNE L. PERRYMAN
Southwest Fisheries Science Center, La Jolla, California

Although called by the common name "whale," the pygmy killer whale, like its close relative, the killer whale, belongs taxonomically to the dolphin family, Delphinidae. Until 1952 this species was only known from two skulls collected in the 19th century. Since that time, a number of specimens have been collected from strandings and fishery catches around the world, yet the pygmy killer whale remains one of the least known of the small cetaceans.

I. Characters and Taxonomic Relationship

The pygmy killer whale has a moderately robust body that narrows posteriorly to the dorsal fin, hence the name *attenuata* from the Latin "to make thin or taper" (Fig. 1). The head is round and blunt and lacks a beak typical of many dolphin species. The head does not narrow or appear triangular when viewed from above as with the melon-headed whale (*Peponocephala electra*). The moderately long flippers are rounded at the tips with convex leading and concave trailing edges.

On the back and portions of the flanks and ventral surface, the pygmy killer whale is dark gray to black. A subtle, dark cape (an area of COLORATION extending from the forehead past the dorsal fin) is present, which extends the greatest distance down the side of the animal below the high, falcate dorsal fin. A paler gray area on each flank is usually present from the tail stock to the eye. On its ventral side, the pygmy killer has an irregularly shaped white patch between the flippers, around the genitals, and occasionally on the tail stock. The lips are also edged with white.

The skull is broad and robust. The upper and lower jaws have less than 15 teeth each, a character that distinguishes the pygmy killer whale from the melon-headed whale, which typically has more than 20 teeth per row.

Length measurements from several specimens average 2.31 m (range 2.14–2.59 m). Differences in lengths between males and females have not been observed in measured specimens.

II. Distribution and Ecology

Pygmy killer whales have been recorded in tropical and subtropical waters worldwide. Sightings have been relatively fre-

Figure 1 *Pygmy killer whale. Photograph by Robert Pitman.*

quent in the eastern tropical Pacific, the Hawaiian Archipelago and off Japan. The migratory status of this species cannot be determined based on available information. However, incidental catches and observations by fishermen suggest that this species is a year-round resident at least in the regions of Sri Lanka and the Lesser Antilles.

Although the feeding habits of pygmy killer whales are not well known, remnants of cephalopods and small fish have been found in specimens from STRANDINGS and incidental fishery catches.

III. Life History and Behavior

Little is known about this species' growth, reproduction, or social organization. An estimated length at sexual maturity of 2 m based on 85% of the mean length at physical maturity (Laws, 1956) is consistent with data collected from three sexually mature males ranging in length from 2.07 to 2.61 m and three pregnant females ranging in length from 2.20 to 2.27 m. Pygmy killer whales are found most commonly in small herds, ranging from 12 to 50 animals, although herds of 100 or more have been encountered. This species has been observed BOW RIDING, performing high LEAPS, and "spyhopping" (raising the head vertically out of the water).

Pygmy killer whales are suspected to be among the small whales that chase, attack, and sometimes eat dolphins (*Stenella* spp. and *Delphinus delphis*) involved in the purse seine fishery for yellowfin tuna in the eastern tropical Pacific (Perryman and Foster, 1980). AGGRESSIVE BEHAVIOR has also been observed by two pygmy killer whales in captivity in Hawaii and South Africa, but a herd captured off Japan showed no such aggression when placed in an enclosure with other dolphins.

IV. Conservation Status

Although they are not considered rare, the population size and structure of the pygmy killer whale are not known. Between 1986 and 1990, five research vessel surveys were conducted in the eastern tropical Pacific and an abundance of 38,900 (CV = 0.305) pygmy killer whales was estimated for that area (Wade and Gerrodette, 1993).

Pygmy killer whales have been caught directly and incidentally in fisheries. Small cetacean fisheries in St. Vincent and Indonesia have been known to catch pygmy killer whales, but they comprise a small proportion of the catch and these catches are thought to have little effect on the population in those areas. Monitoring of fisheries in which pygmy killer whales are caught incidentally has not been extensive. Mortality in these fisheries, such as those around Sri Lanka, could be greater than that documented and may have a significant impact on pygmy killer whale stocks in those regions. In Sri Lanka, pygmy killer whales have also been harpooned and used as bait in long-line fisheries for sharks, billfish, and other oceanic fishes (Leatherwood and Reeves, 1989).

Pygmy Right Whale

Caperea marginata

CATHERINE M. KEMPER
South Australian Museum
Adelaide

The pygmy right whale *Caperea marginata* (Gray, 1846) is the smallest baleen whale and the only member of the family Neobalaenidae (Fig. 1). Its diagnostic features include long, narrow, creamy-white BALEEN with an outer margin

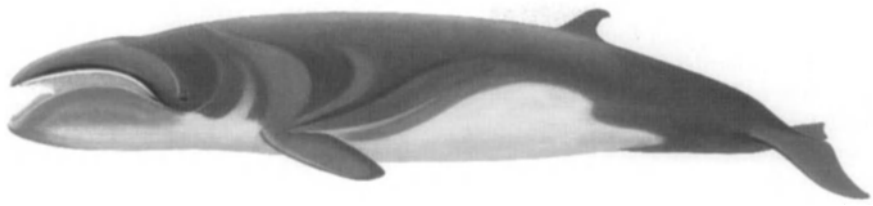

Figure 1 *Baleen whales include some of the larger whale species. The smallest baleen whale is the pygmy right whale* (Caperea marginata) *which achieves a maximum length not exceeding 6.5 m. Skeletal differences are especially distinctive and warrant the recognition of this species as the sole member of the Neobalaenidae, separate from other baleen whales. Pieter A. Folkens/Higher Porpoise DG.*

of brown or black and very fine bristles; a clearly visible band of white gum at the base of the baleen; a moderately arched rostrum that becomes more pronounced as the animal grows; a small, falcate dorsal fin placed about 25 to 30% of body length from the tail; and shallow throat creases in some animals. The overall body shape of adults is stouter than rorquals but not as broad as right and bowhead whales. From above, the head is broadest at the eyes and narrows sharply into a long and narrow rostrum on which a medial ridge may be present. The flukes are very broad and have a deep medial notch. The body is pale to dark gray above and pale gray to white below. There is a dark eyepatch and an indistinct pale gray chevron across the back behind the blowhole. The oval scars of cookie-cutter sharks *Isistius* spp. are often present. The flippers are small, narrow, and rounded at the tip and are dark gray above (contrasting sharply with the pale color of the sides of the body) and paler below. Mandibular and rostral hairs persist into adulthood but there are no callosities as in true right whales.

At sea, pygmy right whales may be confused with minke whales *Balaenoptera acutorostrata* and *B. bonaerensis*, but close inspection should reveal some of the diagnostic features noted earlier. The blunter rostrum of the pygmy right whale and its habit of swimming with its head "thrown" out of the water at an angle should also help identify it.

The SKULL and SKELETON of the pygmy right whale are unlike any other cetacean. The supraoccipital bone is very long, extending well forward on the skull. The ear bone has a distinctive wrinkle on its outer surface and is squarish in outline. The mandibles and ribs are very broad and flat. The numerous ribs (18 pairs) extend well along the body. All seven cervical vertebrae are fused and the total number of vertebrae is only 44. The flipper has only four digits.

I. Recent and Fossil Relationships

Although the pygmy right whale has sometimes been included in the family Balaenidae, recent studies of its morphology and genetic makeup have shown that its present position in Neobalaenidae is correct. It is believed to be more closely related to the gray whale (Eschrichtiidae) and rorquals (Balaenopteridae) than to right and bowhead whales (Balaenidae). Geographical variation has not been studied and no subspecies are recognized. No fossil neobalaenids have been described. A reported fossil, *Balaena simpsoni*, from Chile is believed to be related to Balaenidae.

II. Distribution and Habitat

This species is found only in the Southern Hemisphere (Fig. 2). It is circumpolar, between about 30° and 55°S, with records from southern Africa, South America, and Australia and throughout New Zealand. It has also been recorded in the vicinity of the Falkland and Crozet islands and in the open ocean of the South Atlantic and south of Australia.

The pygmy right whale lives in temperate and subantarctic regions where water temperatures are between about 5° and 20°C. It has been seen in oceanic and neritic environments where some individuals have spent up to 2 months very close

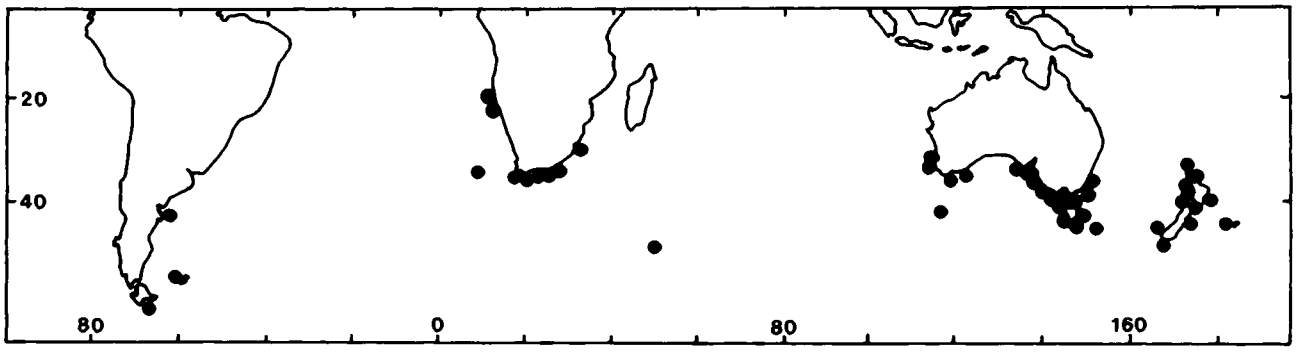

Figure 2 *Distribution of the pygmy right whale. Dots show position only, not number, of records.*

to shore, possibly feeding while there. Seasonal movements inshore may be related to the availability of food there during spring and summer. Although oceanic feeding has not been observed, animals collected there had full stomachs. The little information available on diet suggests that copepods, euphausiids, and possibly other small PLANKTON are eaten. The predators of pygmy right whales are not known.

III. Behavior

Its behavior is inconspicuous, but because so few observations have been reported, the complete repertoire may not have been recorded. Swimming speeds of 3 to 5 knots have been noted, but it is also capable of very fast acceleration and speed, leaving a conspicuous wake when doing so. One underwater observation of swimming noted that the body action was very flexed. When pygmy right whales dive they remain submerged for up to 4 min and surface briefly before diving again. The blow is inconspicuous and, when visible, is small and oval. The sounds of one solitary juvenile consisted of short, thump-like pulses or tone bursts with a downsweep in frequency and decaying in amplitude. Most energy was between 60 and 120 Hz.

Less than 20 sightings of pygmy right whales "at sea" have been recorded. They have been seen with pilot (*Globicephala melas*), sei (*Balaenoptera borealis*), and minke whales and with dolphins. Mostly these have been of 1 or 2 animals, but groups of up to 10 animals are known and one group of about 80 pygmy right whales was seen in oceanic waters. Strandings throughout the year in Australia and New Zealand suggest that the species does not migrate north–south as do most other baleen whales.

IV. Life History

Relatively little is known of the life history of pygmy right whales. Length at birth is about 2 m and at weaning is about 3.0–3.5 m. Most animals are physically mature at around 6 m, and maximum length and weight are 6.5 m and 3430 kg. Females are slightly longer than males. Sexual maturity may occur at lengths of greater than 5 m. The calving interval, mating season, and gestation period are all not known. The calving season is protracted, possibly year-round. Life expectancy is not known and no age estimates have been made.

V. Interactions with Humans

Pygmy right whales were never targeted by whalers, although they were taken opportunistically. Intentional killing by inshore fisheries and incidental captures in fishing nets are known. No animal has been kept in CAPTIVITY. Toxic contaminants are not believed to be a threat to this species because tissue levels of organochlorines and heavy metals measured in a few animals have been low.

R

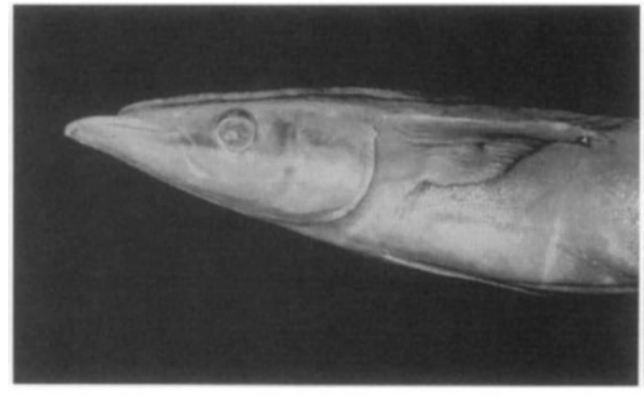
Remoras

Dagmar Fertl
Minerals Management Service, U.S. Department of the Interior, New Orleans, Louisiana

André M. Landry, Jr.
Texas A&M University, Galveston

Remora, suckerfish, diskfish, and sucker are some of the names describing eight species of marine fishes in the family Echenedidae (=Echeneidae) (Lachner, 1966; Lachner in Fischer, 1978). Remoras inhabit tropical and subtropical waters worldwide, except for the whitefin remora (*Echeneis neucratoides*), which is believed to be restricted to the western Atlantic Ocean.

I. Remora Biology



Remoras use a suction disc to attach to sharks, rays, bony fishes, sea turtles, cetaceans, sirenians, and ships and other floating objects. When attached to these hosts, remoras appear to swim upside down, but the disc is really on top of the head. The oval-shaped disc is a modified dorsal fin that has become split and flattened, forming a series of transverse, plate-like fin rays (disc lamellae) that resemble slats of a venetian blind (Fig. 1). When these fin rays are lifted, a strong vacuum is created between the remora's disc and its host.

The tenacity with which remoras attach to their hosts is best illustrated by the practice of sea turtle fishing by fishermen in the Caribbean and off China and northern Australia, and in Yemen, where it continues to this day. A fisherman ties a line around the tail of a remora and throws the fish into the water. The remora tightly attaches itself to a turtle, and the remora and its "catch" are then hauled ashore.

Suspected benefits of a remora's association with these hosts include transportation, protection from predators, increased courtship/reproduction potential, enhanced respiration, and expanded feeding opportunities. Remoras opportunistically feed on parasitic copepods (which constitute the bulk of their diet), zooplankton and smaller nekton, food scraps from meals of their hosts, and sloughing epidermal tissue and feces of the host.

II. Marine Mammal Hosts

Adult remoras typically attach to the body of a marine mammal (Fig. 2). At least three remora species utilize marine mammals as hosts: whalesucker (*Remora australis* = *Remilegia*

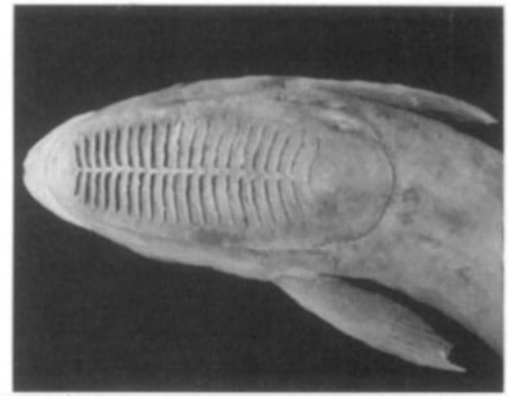


Figure 1 *Lateral and dorsal view of the head of a remora, with suction disc visible. Photographs by Bill Dailey.*

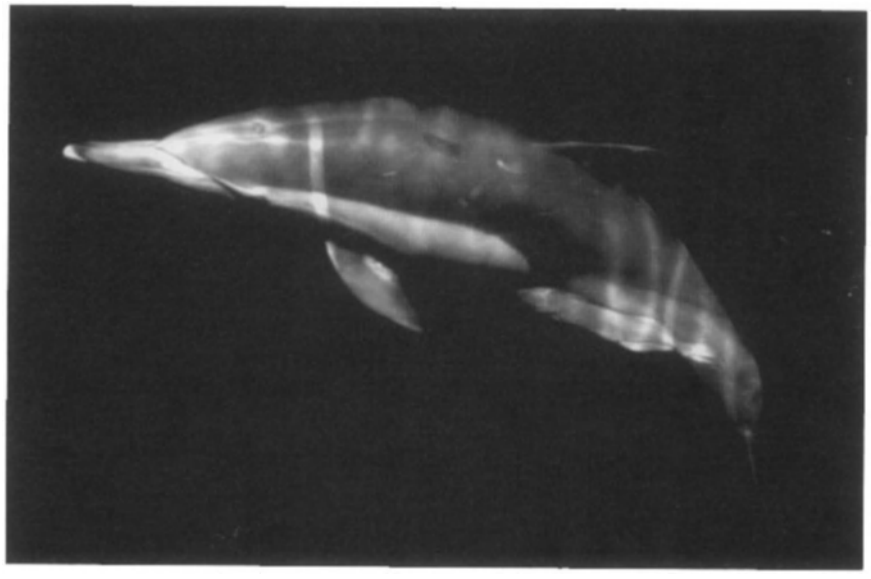

Figure 2 *Short-beaked common dolphin* (Delphinus delphis) *with remora attached. Photograph by Bernd Würsig.*

australis), sharksucker (*Echeneis naucrates*), and whitefin remora (=whitefin sharksucker, *Echeneis neucratoides*). Remoras associate with at least 20 cetaceans and 2 sirenian species (dugong and West Indian manatee). The whalesucker has been most often collected and identified from cetaceans (e.g., Rice and Caldwell, 1961; Fertl and Landry, 1999), hence its common name. A sharksucker was recently collected from a common bottlenose dolphin (Fertl and Landry, 1999). Two species of remora have been collected from West Indian manatees; these were positively identified as the whitefin remora (Mignucci-Giannoni *et al.*, 1999) and the sharksucker (Williams and Bunkley-Williams, 1996).

The remora's suction mode of attachment does not hurt the host, or leave scars, as has been suggested. However, a temporary mark resembling the disc imprint can be seen. Wounds attributed to remoras are most likely caused by cookie-cutter sharks (*Isistius brasiliensis*) or lampreys (*Entosphenus tridentatus*), which actually bite their prey or host.

Whether the remora irritates its host is uncertain. A remora may slide all over its host's body, possibly tickling the animal. Dolphins and manatees observed with remoras sliding over their bellies sometimes will jerk, and even roll over. Dolphins of various species leap with remoras attached to them, perhaps to dislodge the "hitchhiker." There also are reports of dolphins dislodging remoras from themselves or their calves and then biting them. Large-sized remoras or multiple remoras on the same host may produce a hydrodynamic drag.

III. Problems with Remora Identification

The whalesucker's preference for cetaceans leads many observers to assume that any remora spotted on a cetacean is of this species. Most remora–marine mammal associations described in the literature are based on visual or photographic observations of a remote, free-swimming host and its passenger(s) rather than specimens collected from strandings or whaling victims. Host records determined from remote observations should be considered suspect, as the identification of remoras to species is difficult without the actual specimen in hand.

The whalesucker and other host-specific remoras are typically pelagic forms with a specialized morphology consisting of large discs, short stout bodies, and reduced fin size (when compared with inshore counterparts). More commonly reported remoras are slender-bodied, inshore forms, such as the sharksucker, that are least particular about their hosts. The possibility that small, slender remoras, as well as more stocky remoras photographed on cetaceans, may represent different life history stages of one species further complicates positive identification from afar.

Reproductive Behavior

MICHAEL A. FEDAK, BEN WILSON, AND PADDY P. POMEROY
University of St. Andrews, Scotland, United Kingdom

Taking a very broad view, the "function" of marine mammals is to convert prey into offspring. Reproductive behavior is an important part of the process by which this is brought about and must serve to create a situation in which the young can safely be born and nurtured and one which facilitates mating with suitable partners. In long-lived animals, however, reproduction has to be linked to the process of gathering the resources for both reproductive effort and continued survival. Because many marine mammals do not feed where they reproduce, they must also locate breeding areas where reproduction and parental care can take place without compromising nutritional requirements. This article considers the basic problems that the animals must solve to reproduce and gives some illustrative examples of their behavior. We will take just such a broad, strategic view and look at reproductive behavior in a life history context and consider how animals balance their needs for resources and reproduction.

I. Basic Problems to Be Overcome

Although they spend most of their time in the water, seals give birth on land and most newborn pups require a period ashore before being able to cope with life at sea. The vulnerability of pinnipeds on land means that suitable breeding sites need to be isolated from potential predators, limiting the choice of suitable ones. Pinnipeds do not feed while ashore. The widely separated, patchy distribution of resources that typifies most marine ecosystems means that animals are often widely separated from one another while foraging and suitable breeding sites are often few and far between. This necessarily requires the use of stored reserves for periods of days to months. The geographical separation of feeding and breeding sites and the reliance on stored reserves are arguably the most important determinants of seal reproductive strategies and life history patterns.

Whales can give birth, nurse, and mate at sea, but conditions suitable for the birth of young may not be suitable for foraging so these two phases of their annual cycle can take place in widely separated geographical locations. Long migrations between breeding and foraging locations may still be necessary. While foraging, individuals might be widely separated from potential mates, creating difficulties for locating suitable partners. Little food may be available during the birthing and mating period, which therefore can require stored energy and materials for its success. Therefore, even though whales are not constrained to spend time ashore for breeding, in some cases, they face some of the same problems as pinnipeds.

On the whole, smaller cetaceans, including most odontocetes, opt for a different strategy. Foraging, parturition, and calf rearing overlap both spatially and temporarily. As a result, annual breeding MIGRATIONS are absent and instead nursing females and calves appear to be aided by associating with conspecifics.

Both seals and the larger whales must move to breeding areas and choose a suitable breeding site where they can safely give birth and protect and feed their young. They must choose a mate, copulate, and produce fertilized eggs. They must protect and feed their young and provide the resources and guidance needed for them to become nutritionally independent and give them a good chance of reaching maturity and recruiting into the breeding population. Then the adults must reestablish successful foraging patterns to provide resources for their own survival and reproductive success in the following year(s).

The marine habitat and the geographic and energetic constraints acting on marine mammals have shaped their life histories and reproductive behaviors to create some of the most dramatic and extreme (some might even say bizarre) reproductive patterns among mammals.

II. Importance of Size

Marine mammal groups contain some of the largest mammals in existence as well as possibly the largest animal to have ever existed. The size adopted by the various species is such an obvious characteristic that we often look past it to other features of the animals without considering its fundamental importance to BEHAVIOR. However, size stands out as being of fundamental importance as to how these animals organize their reproductive behaviors. Because of the scaled relationship between body volume or mass (M) and metabolic rate (MR), where $MR \propto M^{0.75}$, size has obvious implications for diving and foraging behavior. Larger species and individuals will require more prey each year, but they may be able to dive for longer and go longer without food and thus be able to contend with less predictable or widely distributed food distribution. It has equally fundamental implications for variations in reproductive behavior within and between species. Size in large part determines how long animals can fast during reproduction and how often they must leave their pups or the vicinity of potential mates for food. In general, bigger animals can maintain their presence on beaches for longer and can breed farther from food sources. Size also sets the relationship between the duration and the efficiency of lactation (energy used in the process divided by energy stored in the pup). It sets the weaning mass of offspring and the relative cost to the mother of achieving offspring of that mass; larger mothers can produce larger pups without putting themselves at risk. The metabolic overheads (i.e., the amount of energy required to support the metabolism

of mother and pup) are relatively lower for larger animals in relation to the stored resources available and delivered to offspring. Size can affect the capability of animals (particularly males) to secure mates and, because of its influence on attendance patterns, can determine the sort of strategies used to gain access to females; larger males can maintain residence for longer on breeding sites. In the variety of strategies and behaviors used to accomplish reproduction and the factors that determine them, size matters.

Although seals and whales face common problems, the fact that whales do not come ashore to carry out any aspects of reproduction means that we have learned about their behavior in very different ways. Behavioral observations are largely confined to activities visible from the surface, and "hands-on" techniques are much more difficult to apply. Cetaceans also have greater opportunity for complex social interactions throughout the periods of mating and PARENTAL CARE because of the extended times occupied by these activities. The different methodologies used have also led to separation in the approaches used in the study of the two groups, resulting in emphasis placed on different aspects of behavior. It is therefore expedient to treat the two groups separately for much of the remainder of this discussion, even though we will be considering the same basic strategic goals. The walrus, manatees, dugongs, and the sea otter are dealt with briefly.

III. Otariids and Phocids

We consider the strategies of reproductive behavior within the simple life history model (Fig. 1) in which the animal's mass or condition is viewed as the fundamental state variable that determines the constraints on reproductive success. It consid-

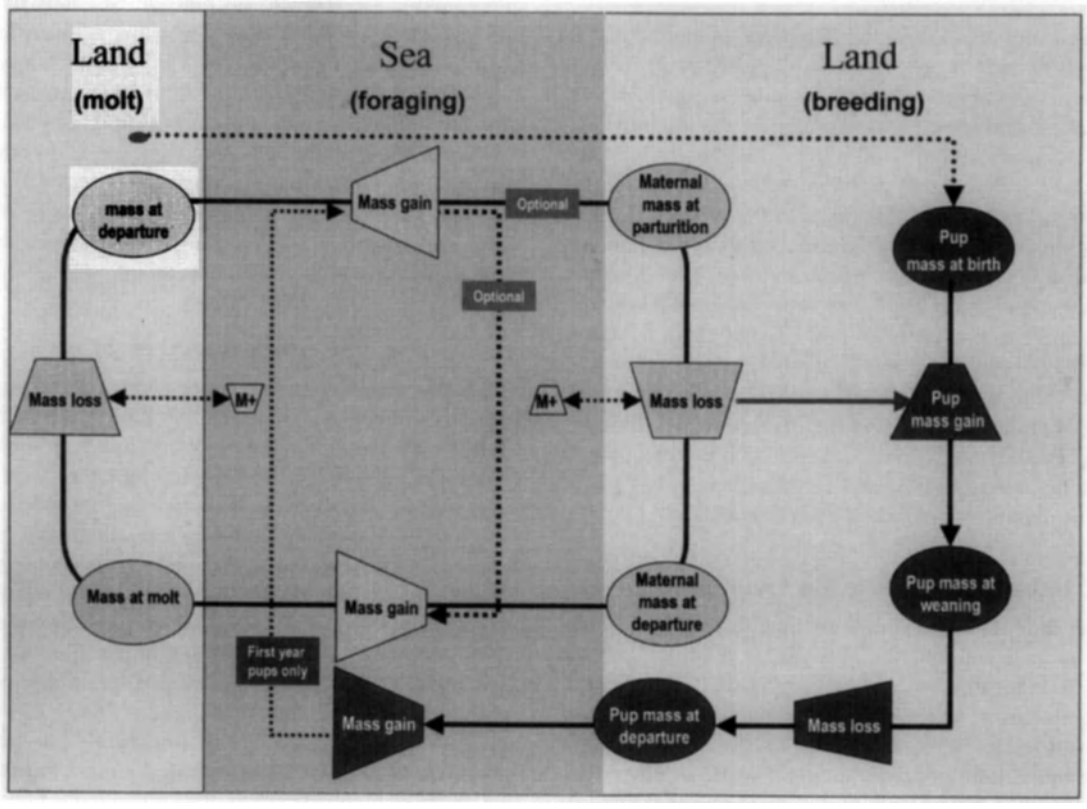

Figure 1 *A diagram of a model of female pinniped life history with mass (as a surrogate for condition) as a state variable determining reproductive success through fecundity and pup quality. Trapezoids represent mass gain and loss. Ovals denote mass at the start and end of lactation and molt. Dotted lines represent optional paths. Some species and/or individuals (particularly smaller phocids and otariid species and smaller individuals of some phocids) may top up body mass during breeding and molt by returning to the sea to feed. Pups usually bypass molt during their first year and do not breed until they have reached a certain critical mass or condition. Females may opt not to produce a pup in years when they are below a critical mass or condition. Pups that are larger or in better condition at weaning are likely to both be able to remain on the beach longer and depart in better condition. They have a better chance of surviving and to breed earlier. In this model, mass and condition determine the path taken and the resulting reproductive success rather than age per se (see Arnbom* et al., *1997). In the context of this model, reproductive behavior acts to provide access to suitable mates, influence the transfer of resources to pups and its efficiency, and protect the investment in offspring.*

ers life history as an annual cycle of terrestrial and aquatic phases split among foraging, breeding, and molt (see Fig. 1 legend for details). Virtually all species can be fit into this conceptual framework, and most aspects of reproductive behavior and their links to foraging and molting can be incorporated within it, in terms of how they affect fecundity and offspring quality. As such, it provides a useful framework within which to describe the requirements of behavior.

A. Transition from Foraging to Breeding: Locating a Suitable Place to Breed

This involves behavior that, at one extreme, may occur within a few meters, to the other extreme, movements that traverse the globe. Animals must choose a geographical area, a suitable site within that area such as a particular beach or ice flow, particular conditions within that site, and a position relative to other animals in the colony. BREEDING SITE selection must be accomplished so that parturition can occur on time and suitable mates are also available.

This transition can be considered to occur as soon as animals switch from a period of net gain of resources to net expenditure of body stores to support travel to breeding sites. It is not likely to be a sharp boundary, as animals may encounter food during their trip, but a reduction in resource acquisition is likely because animals are likely to leave prime foraging areas to make their way back to breeding sites. The critical issue is that animals arrive at the breeding site in sufficiently good condition to support the onset of breeding. In the case of many otariids, this means that females must have sufficient reserves to sustain themselves and their pups until the mother's first successful foraging bout. Condition in males will in part determine how long they can remain defending their access to females. In the case of the larger phocids, animals must have sufficient body condition to support the entire breeding effort. Smaller phocids or those with easy access to food may supplement stored reserves with foraging. It could be argued that the expenditure during this phase should be added to those of reproduction, but we know of no studies that have attempted to do this. Navigational skills and previous experience of suitable sites allow the minimum time and energy to be expended.

1. Large-Scale Movements: Choosing a Geographical Location Many species have been shown to have the navigational skills to return to previously used breeding sites from great distances, but the methods they use to accomplish this remain largely unknown. Both southern (*Mirounga leonina*) and northern (*M. angustirostris*) elephant seals have been tracked making directed trips of 1000–3000 km between breeding and foraging locations, arriving on the same beaches they used for breeding the previous season. Their great size (males may weigh over 3000 kg and females average 500 kg at parturition) is important in making such trips energetically feasible. Many other larger species are similarly capable. Smaller species may need a supply of food on route or feed closer to where they breed as the reproductive season approaches. It seems likely that the evolution of large body size in pinnipeds may have had much to do with enabling the uncoupling of geographical locations of feeding from those of breeding (for a contrary view, see Boyd, 1998).

2. The Local Scale: Choosing a Breeding Site within a Locality At the local scale, animals tend to breed where there are other seals present. This aggregative sociality is a key feature of pinniped behavior, although it is modified by the animals' state. The first animals to breed in a season tend to be the older, more experienced animals and their presence ashore encourages others to use the colony. This reinforcement means that the same rookeries tend to be used over a long term. It is possible to envisage at least two ways that new colonies may form. In a growing population, when space at an established colony has become limiting, pregnant females arriving to breed may be forced to move elsewhere if the available habitat is being used. In this scenario, the new colony should be reasonably close to the original one. Younger, primiparous females that breed later in the season may be forced to use an otherwise unoccupied location, and once there, others join them. Main criteria listed for breeding habitats are isolation (protection from land-based predators) and access to resources nearby. Few seals stray far from the sea. Otariids require a plentiful supply of food within reach of the breeding location, otherwise the breeding attempt may fail, but most phocids are functionally divorced from foraging requirements at breeding time by their ability to store resources, principally as blubber. Thus phocids may use breeding locations far removed from their foraging grounds [e.g., gray seals (*Halichoerus grypus*), northern and southern elephant seals]. Harbor seals represent an intermediate breeding and feeding strategy where mothers supplement their stored reserves with food acquired during foraging trips late in the lactation period.

3. Choosing a Position within a Site: The Individual Scale The local topography of the breeding location plays an important role in determining the particular location where pups are born. An almost flat and featureless surface with unlimited access to the sea, such as a sandbank, offers the simplest case in which animals have little to choose except their distance from the sea. Where such a location also has additional resources such as pools of water, these may act as foci for breeding animals. However, seals breeding on many islands or beaches typically arrive at the breeding area through specific access routes. Restricted access produces a radiated pattern of colonization, but also creates thoroughfares where there is continual traffic as animals arrive and leave the colony. Pup mortality in these locations can be substantial.

The degree of topographic variation on a breeding colony at a scale relevant to seals is a primary determinant of their distribution within a site. In fact, the degree of topographical variation on the breeding colony probably also defines the scale of site fidelity shown by gray seals at two Scottish colonies and may explain why fidelity is less apparent at relatively flat, open locations such as Sable Island (see later; Pomeroy *et al.*, 2000).

CONSERVATION OR MANAGEMENT considerations often require information on how animals may use available habitat, particularly where multiple use or potential conflicts occur. Habitat classification within a fine-scale geographic information system has been used to identify suitable breeding areas for gray seals, which was used to make a successful prediction of expansion of breeding areas at the Isle of May colony during the 1990s

(Twiss *et al.*, 2000, 2001). One of the main benefits of having such a detailed digital terrain model is that animals can be mapped accurately and frequently in the field, allowing examination of temporal changes in the distribution of animals. One of the products of such an approach has been the identification of the importance of pools of water on the colony for seal distribution and behavior (Twiss *et al.*, 2000).

4. Assessment of Breeding Locations and Site Choice Seals that breed on land come ashore for a variable period before parturition occurs. For southern elephant seals, this averages 4.5 days, whereas for gray seals the average time ashore before parturition is 2–3 days, although some animals are present at breeding locations for at least a month prior to parturition. This prepartum period appears to involve some assessment of the breeding location. Female gray seals emerge from the water, looking around intently and sniffing continuously, before making tentative moves inshore. Pregnant females collect together in groups near access points where they remain inactive, and any disturbance is likely to make them return to the sea. In some cases, final selection of the pupping site occurs immediately prior to parturition when females move inland; during this movement they can be seen sniffing the ground. Pomeroy *et al.* (1994) found many cases of females returning to the sea before they came ashore again to pup, sometimes in a different location to that chosen originally. Options for changing the pupping site are often limited to the prepartum period, as in most species, once the pup is born, it is not easy for mother and pup to change location together.

Once a seal has chosen a breeding site, it tends to be used again and again. This breeding site fidelity is shown by Weddell seals (*Leptonychotes weddellii*), gray seals (see later), northern elephant seals, and Antarctic fur seals (*Arctocephalus gazella*) and is probably widespread. Scottish gray seals are faithful to their previous pupping sites. Females return to pup within an average distance of 55 m on North Rona and 24 m on the Isle of May from their previous breeding sites (Pomeroy *et al.*, 1994, 2000). Males that return also show very similar spatial fidelity at both colonies (Twiss *et al.*, 1994; Pomeroy *et al.*, 2000).

Some seal species display philopatry, i.e., they return to breed at the location where they were born, e.g., fur seals (Gentry, 1997) and southern elephant seals. Gray seals also display philopatry, sometimes with remarkable accuracy (Pomeroy *et al.*, 2000).

B. Investing in Young after Birth

Parental care in pinnipeds is the exclusive domain of the mother in all but one species (see later for single exception). Males take no part in the rearing process; the only part they play in breeding is to contribute sperm during mating. In fact, the process of mating is not without risk to current offspring. Pups may become separated from their mothers or be the subject of aggressive behavior from males or females at this time, as well as running the risk of being crushed by males. Therefore, maternal care does not consist simply of feeding but includes all behaviors associated with the pup's welfare, such as maintenance of contact, vigilance, and defense against potential aggressors. A mother has finite resources available to service each breeding attempt and, once the pup is born, she has ultimate control over the feeding schedule and its duration. Mothers must gauge their reproductive effort according to the resources they have available, to do enough for the pup to have a good chance of survival without prejudicing the mother's survival or future breeding chances. The costs for mothers that expend too heavily in 1 year are reduced fecundity and lower breeding success in the next year (Pomeroy *et al.*, 1999; Trillmich, 1996). Consequently, the fundamental maternal trade-off is one of efficiency: supplying resources to the offspring at a low or acceptable expense. The single most important influence of the efficiency of the process is the "physiological time" it takes to accomplish it (Anderson and Fedak, 1987). For most phocids at least, maternal maintenance during the lactation fast must occur in parallel with the demands of feeding the pup. The shorter this time, the smaller the fraction of maternal resources that are lost as heat (generated by the combined metabolism of mother and pup) and the greater the fraction that can appear as pup growth or remain as maternal condition.

The conflict between pups' demands for resources and the requirement of mothers to limit expenditure to that which does not incur a threat to themselves is exemplified by a study of southern elephant seal pups fed as twins. In this case, mothers did not expend resources beyond the level expected for a single pup, so that the cutoff point in this case was fixed by the mother (Arnbom *et al.*, 1997).

1. Maintaining Contact with Pups Seal breeding colonies are typically sensory-rich environments. Many animals are crowded into a restricted area, with the associated sights, smells, sounds, and actions associated with such a situation. A mother must maintain contact with her pup because, in general, neighbors react aggressively to foreign pups and pups that move away from their mothers may be injured or lose contact with their mothers and starve. At birth, a mother immediately sniffs and interacts with the neonate. By the time the first feed has been completed, mothers have established a bond with their pup that becomes progressively stronger as lactation proceeds. In most species, pups vocalize almost as soon as they are born, with mothers displaying a varying degree of competence in discriminating their own pup's call (fur seals, reviewed in Gentry, 1997). In gray seals which commute from the breeding beach to the water during lactation, a returning mother looks, sniffs, and (presumably) listens when she approaches her pupping site. Often several pups are inspected before one is fed. Reunions involve the approach by the mother, sniffing and flippering of the pup, and finally presenting the nipple to feed. Other pups trying to feed at this time are often dissuaded by aggression, but may also be excluded by the mother turning away. Some gray seal mothers (particularly at the expanding colony on the Isle of May, Scotland) are poor discriminators and feed any pups that approach them. Not surprisingly, these mothers rarely wean large offspring (see earlier discussion). Otariid mothers leave their pups unattended for several days while they forage for food and must recognize their offspring

on their return. The primary mechanisms allowing this to occur successfully are smell and sound recognition.

2. Providing Protection Until the pup is born, many species of seals are tolerant of other conspecifics so that, for example, large groups of pregnant female gray seals may lie very close to each other, often touching. As soon as the pup is born this tolerance disappears and the mother becomes fiercely protective of the pup, defending a radius (typically 1.5 body lengths) around it. Any intruders into this space experience an escalating aggressive response, beginning with threats, approaches, then vocalizations, flippering, lunges, and, finally at the most extreme, contact involving biting and flippering. Tolerance of conspecifics varies between mothers, but it is not yet known whether this reflects some form of kinship recognition, familiarity based on nonrelated associations, or simply individual variation in response.

There is a single instance of possible paternal care in pinnipeds, where male Galapagos sea lions mob sharks around colonies (reviewed in Trillmich, 1996).

3. Lactation and Weaning The process of lactation is demanding for mothers. Most phocid species that fast during lactation lose 30–40% of their postpartum mass, much of it blubber, producing the highest-fat milk known in the animal world (up to 60% lipid) in the process. In most phocids the lactation period is short but intense (hooded seals, 4 days, pup growth rate 6.0 kg/day; gray seals, 18 days, pup growth rate 2.0 kg/day; southern elephant seals, 23 days, pup growth rate 4.2 kg/day). Such growth rates can only be achieved by having energy-dense milk, frequent feeds (every 4–5 hr in gray seals), and efficient conversion of maternal resources by the offspring. The concentrated milk also conserves water, which may be of short supply. Otariids have fewer absolute reserves available, although these may be relatively similar to those of phocids, and sustain their energy requirements by foraging throughout their extended but less intense lactation periods. This means that otariid pups receive feeds at intervals several days apart.

Weaning is abrupt in most phocids, as females depart from the rookery to return to the sea, leaving the pups on the beach. In most cases, mating has already occurred, and indeed observation of a successful mating is a good indication of a female's imminent departure. However, there is considerable individual variation in the time that mothers spend with pups after mating; some may remain for several days before returning to the sea. In many otariid species, a long lactation period allows offspring to develop SWIMMING, DIVING, and foraging while having the option of maternal milk as a food source. As a result, otariid mothers may have a much more prolonged weaning process, as offspring may still be with their mothers in the second year after birth.

C. Locating and Selecting a Mate

Reproduction is the single most important action that individuals of any species carry out in their lifetimes. As such, mate choice is an important consideration. Circumstances dictate the degree of choice likely in that the distribution of females at breeding time controls the mating patterns seen. For example, solitary hooded seal (*Cystophora cristata*) mothers on fast ice are unlikely to have many options in available mates and may simply mate with the male that has waited persistently beside her until she entered estrus. However, it seems likely that the successful male may have had to defend this position in encounters with others attempting to gain this opportunity. In this situation, males give the appearance of being monogamous. In contrast, large aggregations of female southern elephant seals make it possible for males to attempt to control access for mating, with the result that extreme polygyny occurs. Males in this situation compete vigorously among themselves, as the potential breeding rewards for successful males can be substantial. However, the priorities of each sex are rarely symmetrical. Female elephant seals may be considered to have exercised mate choice just after they arrive at the breeding beach. The 4.5 days spent ashore prior to parturition offer females an opportunity to assess the stability and safety of the harems they enter and the qualities of the guarding males. If pregnant females are disturbed during this preparturition period, they often change locations.

1. Female Mating Behavior Female seals are not receptive to males until they enter estrus. In gray seals, this occurs around day 15 of the average 18-day lactation period. Males that attempt to mate before the female is receptive receive a robust and clear message from the female indicating her unwillingness. Initially, a female will threaten males that approach and her subsequent vocalizations at a persistent male can alert surrounding females to his presence. Neighboring females may join in this threat display to dissuade the male, although in a very few cases, fights between male and female may develop. Because of the sexual dimorphism common to most polygynous mammals, males tend to be favored in such encounters. Females dissuade males using the same repertoire of aggressive behaviors as described earlier, but with the additional consideration that males attempting copulation are likely to have tried to mount the female. In this situation, the female's mobility and lack of cooperation, together with the aggressive display, are usually enough to make the male withdraw. Experienced males rarely attempt more than a preliminary investigation into the female status and seem particularly adept at gauging a female's receptivity.

The ability of females to resist premature advances is perhaps at its most dramatic in elephant seals, where males can be more than 10 times the mass of the females with which they mate. Even here, in a species in which males are not known for their gentility, females can repel unwanted advances. A male holding a harem frequently accesses the receptivity of females by "heading" them, i.e., he approaches and rests his head on the neck of candidate females. If the females are not receptive, they move their hind flippers rapidly from side to side in a swimming motion, slapping the side of the testing male. Most males take heed and move quickly on to test other females.

It is not clear exactly how estrus is signaled in most species. While the general behavioral indications are simply that a female's initial aggressive response to a mating attempt declines to acceptance and passivity, it is not clear what cues a male uses to judge the situation. Olfaction is probably important as males can be seen sniffing during their approach around females

(Gentry, 1997). A successful mating may also signal to other males that a female is receptive. Some females approach males and apparently solicit their attention.

Mate choice may range from having a single candidate, and therefore a passive default, or be an active process involving the assessment of, or competition between, a number of candidates. Competition may even be among sperm, in cases where multiple matings occur (e.g., gray seals, elephant seals, some fur seals). The most comprehensive studies so far come from gray seals and elephant seals. Females that occupy prime sites on gray seal breeding colonies tend to have dominant males nearby (Pomeroy *et al.*, 1994, 2000; Twiss *et al.*, 1994) and most mate with the dominant male. However, the number of pups they produce that are fathered by that male does not reflect the male's behavioral dominance or his mating success. In addition, evidence for genetically dissimilar partners has been put forward (Worthington Wilmer *et al.*, 2000). The reasons for this are not yet clear, but may lie in different attendance patterns of individual females at breeding colonies. There is some anecdotal and circumstantial evidence of mate choice in gray seals. At North Rona, where approximately 1200 pups are born each year, the father of a pup born to female J8 in 1986 was seen next to her in 1993, but both were at the other end of the island from where they had been in 1986. The pup born to J8 the following year was indeed fathered by the male seen with her in 1993. A more intriguing occurrence was first observed in 1997, when a known female left her peripheral pupping site to move about 80 m to the center of the colony where she was mated by a dominant male. She then returned to her pup and the attentions of a peripheral male at her pupping site. Females have been seen initiating copulations, but males initiate most.

2. *Male Mating Behavior* A male's reproductive success is dependent on the number of offspring he manages to sire and how many of those eventually manage to reproduce as adults. The first part of this requires successful matings, and to achieve these, males must be able to take up a place among breeding females, avoid or outcompete other males, and gain a successful copulation. Males employ a variety of strategies to achieve success (see later). The second part of his reproductive success is less straightforward, as it is possible to achieve many matings without producing any surviving offspring, let alone grandoffspring.

The first prerequisite is simply to be around breeding females. Males must coordinate their efforts with the availability of receptive females. One of the most effective ways of gaining success for males is to spend a long time on the breeding colony, but this is costly, both in energetic terms, because males usually fast, and in potential injuries inflicted by competing males (Twiss *et al.*, 1998). For these reasons, a large size tends to correlate with male success so that the largest males tend to have advantages of increased energy reserves and of greater competitive abilities.

As discussed previously, the potential for polygamy in these animals depends on the distribution of females. Although the terms monogamy and polygamy usually apply to mating patterns of species, they may be applied to the tactics that individuals employ either throughout or during phases of their lifetimes. However, without complete knowledge of the reproductive histories of individual animals, it is difficult to make generalizations. Evidence from genetic studies can provide useful insights in these areas. In general, the evidence to date from genetics supports the general observational conclusions on mating patterns, e.g., in southern elephant seals and gray seals, although some queries have been raised. One such is the failure of apparently dominant males to account for as many paternities as predicted. Male reproductive longevities are as important as their within-season success. Long-lived, reproductively active males may accrue a greater success than live-fast, die-young males whose activities are conspicuous.

As with many mammals, the risks inherent in engaging in fights over breeding have led to a formalized ritual of aggressive displays in many pinniped species. Dominance hierarchies are common so that disputes lead to fewer actual fights than might be expected. Fights occur, but usually between closely matched opponents where the preliminary assessments could not determine a clear outcome (Arnbom *et al.*, 1997; Twiss *et al.*, 1998). In gray seals, males attempt to control access to groups of females by threatening intruders with open mouth displays, hisses, and vocalizations. Intruders are chased away, but serious challengers may produce fights, which can last up to an hour and leave either or both combatants seriously injured. It is common for losers of such fights to disappear from the breeding colony.

Given the high cost of engaging in the mainstream competition for mating opportunities, it is not surprising that alternatives strategies exist. Younger, less experienced males are seen around the periphery of breeding colonies and may acquire experience gradually. Some males employ a cryptic tactic, using their similarity to females to gain a position among females, making the most of their opportunities when the dominant male is engaged elsewhere. It is becoming evident for some species that aquatic mating may occur to a greater extent than had been suspected and that the phenotypic qualities that are successful on land may not necessarily be the same for aquatically mating males.

D. Mating

In most observable species, males usually initiate copulations. Males often act to immobilize the female in some way by holding or biting the back of the neck. On land, the male's weight applied via his body or flippers can help position the female. In the water, because animals are near neutrally buoyant, the male's weight is less important in restraint. In gray seals breeding on land, a male attempts to mount the female by maneuvering alongside and then throwing his head and shoulders over the female's back. Her response is almost always aggressive, but a female in estrus will accept the male's advances if he persists and manages to grasp the skin of her neck in his jaws. This act is the single best predictor of a female's acquiescence. At the same time, the male tries to achieve intromission by repeated pelvic thrusts, while the female either cooperates by lying still or resists by moving her rear as much as possible. Gray seals also mate underwater. There too, males grasp the females by the back of the neck in their jaws. Because the male cannot restrain the female as easily, she has greater opportunity to avoid the mating. Obviously, both must breathe and both move

together to the surface when necessary. It is not clear how the need to breathe is communicated to the other partner, but cooperation is evident. In both situations, when a successful mating is achieved, the pair remains relatively motionless, for anything as brief as 5 min or as long as 40 min (gray seals; Twiss *et al.*, 1998). The function of such long copulations is not known, as males indulging in long copulations are leaving other females unguarded. It is thought that ejaculation occurs toward the end of the copulatory period; certainly females have been observed to have rhythmic contractions of the lower abdomen in the later stages of copulations. Remating of a female may take place soon after a copulation, either by the same or a different male.

E. The Transition to Foraging

1. Postweaning Behavior of Mothers The mothers of most otariids leave their pups repeatedly to feed and gather the resources to support continued lactation. For them, weaning does not therefore represent a dramatic change in behavior. They simply fail to return. Some species, such as the Galapagos fur seal (*Arctocephalus galapogoensis*) may give birth to the subsequent pup before the prior pup is weaned, but this pattern is unusual. For most, animals may shift to nonbreeding haul-out locations and engage in longer and more distant foraging trips. For phocid mothers, however, weaning occasions an abrupt change in behavior. Typically, soon after mating occurs one or a few times, mothers abandon their pups, leave their position in the colony, and quickly enter the sea. In some species (particularly among otariids), animals may be seen traveling away from breeding sites in groups, but in many phocids, departure appears solitary. Pups are normally left behind. The "decision" to leave is a critical one in relation to the state of body energy reserves. Good foraging areas may be distant from breeding locations and have changed in position and value while animals were breeding. Mothers must have sufficient stored reserves to enable them to reach these without putting themselves at unacceptable risk.

2. Postweaning Behavior of Pups Weaning prompts dramatic changes in behavior for pups as well. Once pups are weaned, they no longer have the protection of their mothers. They no longer nurse and begin to fast for a time before the transition to nutritional independence. Otariid pups undergo what may be thought of as temporary weaning, when their mothers depart to sea to feed in between bouts of lactation. They have the experience of being left unattended prior to true weaning and show some of the behaviors of weaned pups early in development. In either case, pups typically move to areas where they can avoid contact with adults and may often congregate in large groups. In many cases, this movement is stimulated by aggressive encounters with other mothers and adult males within the colony. In elephant seals, mothers leave the weaned pup behind in the harem, possibly at a central location within it. Other mothers will act aggressively to the approach of pups other than their own, which tends to move unattended pups around, with a net movement to the periphery of the harem. Within a day of weaning, pups are usually out of the harems and then move around the beaches in an apparently undirected way. When they encounter other pups, they tend to remain with them. The end result of this mobility is that large numbers of pups end up in "crèches" at places on beaches where no harems are present.

Phocid pups often remain in such groups, associated with breeding sites, for periods from days to months after weaning. The function of the time spent in these "postweaning fasts" is not understood, but is thought to involve a period of physiological, behavioral, and/or social development. Pups may interact with one another, exhibiting some variants of adult behavior. For example, male elephant seal pups often engage in mock fights that involve the rearing up and head strikes seen in battles between breeding males. Pups of both sexes tend to move into shallow inshore water or freshwater ponds during the night and swim and dive. Dive depths as great as 271 m have been observed in pups from Macquarie Island during this time (Hindell *et al.*, 1999), but in general dives are short and shallow. An increasing fraction of the day is spent in the water until departure on the first foraging trip, typically after about 30–45 days and after about 35% of the mass attained by weaning has been lost.

For pups too, the decision on when to leave is potentially difficult and critical. Phocid pups have no prior, independent experience of foraging locations. They tend to leave as individuals, not forming into groups to avoid predators, and in any case, any other pups departing after weaning are similarly naïve. The way they choose to locate foraging sites and the cues they use to help them remain largely unknown. Even otariids and phocids with unusually precocious young do not appear to use the opportunity for mothers to lead pups to food. Walruses (*Odobenus rosmarus*) seem to be the only exception to this. Pups travel with mothers prior to weaning and nurse at sea, giving them the opportunity to get geographical information on where to feed. It seems likely that if mothers could direct pups to food, they could obviate the need for a fraction of the material resources given to pups with this information. It seems surprising that this occurs rarely.

IV. Walruses, Sirenians, Sea Otters, and Polar Bears

While facing the same fundamental problems as seals in accomplishing successful reproduction, these groups show some unique variations in reproductive behavior and other life history features. Detailed accounts can be found in Fay (1982) for walruses and Riedman and Estes (1990) for sea otters (*Enhydra lutris*). This section discusses only those features peculiar to these groups, emphasizing the unusual features of reproductive behavior.

A. Walruses

Walruses share many features of their breeding behavior with phocid and otariid seals but differ in that much of the important behavior takes place underwater. Like many species of seals, they are polygynous. Males display and interact aggressively to gain access to females, but unlike some phocid and otariid species, this activity tends to take place exclusively in the water, where mating also occurs. Both sexes are often highly gregarious when hauled out on ice or land, and animals are

often seen in closely packed groups. While the activities performed out of water may have important physiological and social functions, with the important exception of parturition, they do not seem to relate directly to reproduction. Pups are born on ice or land but unlike seals, nurse at sea. Nursing is often seen when a mother orients herself vertically with her head above water while the pup nurses upside down, hindflippers at the surface and head down at the nipples. Walruses are the only pinniped group where offspring are known to accompany mothers during maternal foraging and this is made possibly by the ability to feed pups at sea. Because walrus offspring move about with their mothers when they feed, young have the opportunity to learn about foraging locations and techniques from their mothers, which probably has important implications for the demands placed on mothers by lactation.

B. Sirenians

The manatees (*Trichechus* spp.) and dugong (*Dugong dugon*), are unique in being the only group of mammalian marine herbivores. This lifestyle has led to unusual distribution patterns as well as unusual breeding and social behavior. They are not colonial breeders. Individuals of both sexes move in response to the availability of resources such as food and fresh water but they do not to move in herds while foraging. The only apparent long-term social link seems to be between mothers and calves (see later). Florida manatees (*T. manatus latirostris*) living at the northern edge of their range congregate in large groups around warm water sources, such as power plant effluents and warm springs. Although they seem dependent on warm water sites at times of exceptionally cold weather, this opportunistic proximity is not utilized to bring the sexes together for mating. Males and females can range widely at other times. Locating mates seems to be the result of chance encounters between males and estrous females. Little is known about how males locate estrous females, but the increased mobility of estrous females may increase chances of encounters. When a female comes into estrus (lasting up to 3–4 weeks), "mating herds" of hopeful males surround her. The generally quiet and gentle appearance of the species is belied at this time with aggressive behavior between males trying to secure mating opportunities. During estrus, females may mate with several males. Calves are born underwater and nurse there, accompanying their mothers for 1–4 years. Contact between mothers and young is maintained in part acoustically. The extended period of contact between mother and calves while animals forage offers ample opportunity for information to be passed from a mother to her young. This is in marked contrast to the situation described earlier for most pinnipeds and probably has played a role in setting up what has been termed "learned traditional patterns of distribution." The seasonal aggregations of Florida manatees at cold weather refuges such as the springs and power plants mentioned earlier often contain individuals from several generations. Small groups often also congregate briefly at so-called "rendezvous sites" (often places where watercourses intersect) where animals may interact, rubbing and swimming around one another. The social role of these interactions is not understood fully.

C. Sea Otters

Sea otters probably arose from a different evolutionary lineage than the groups discussed earlier from whom they show some important differences in reproductive behavior. Like sirenians, they are not colonial breeders. Although they have a polygynous breeding organization, males occupy and defend a territory that is used for foraging and reproduction. Even though they seem less specialized for a marine existence than seals, sea otters spend virtually all their time at sea, foraging, mating, giving birth, and rearing their young in the shallow coastal zone. However, they are limited to relatively short, shallow dives and spend a greater proportion of time at the water surface than most seals and whales. Most of their reproductive behaviors occur there. Females tend to have partially overlapping home ranges along the coastal zone. Adult males have ranges that overlap with those of one or more females but not of other males. Higher quality male territories (e.g., those rich in food or other resources) tend to overlap with those of more females. Males defend their ranges, but this is often accomplished without obvious aggression, possibly via cues that allow individual recognition and the use of knowledge of past encounters to settle disputes. Males may leave their territories from time to time and may compete elsewhere with other males for access to females.

Mating takes place at the water surface and can involve precopulatory touching and playing. During copulation, males may grasp females by the muzzle while the pair tumble about vigorously. The grip of the males often causes injury and permanent scarring. Pups are born and nurse at sea and may spend 5 months or more with their mothers. Information exchange between mothers and pups is likely to play a role in determining the survival of the young. Pups are often provided with prey by their mothers and may show preference for the same prey types. Sea otters are well known as "tool users" (using hard objects to break up prey) and these skills may also be passed from mothers to pups. Mothers and pups can be quite vocal, calling to each other at the surface using a variety of sounds. Again, males play no role in the care of young.

We are left with the intriguing question: if the ability to give birth at sea, nurse in the water, and lead pups to food is possible in the walrus, sirenians, and sea otter, why do these patterns not occur more often in the "mainstream" pinnipeds? It is true that most extant pinnipeds produce young that are not equipped with the insulation to enter cold water directly from the womb, but in a few species (e.g., harbor seals), pups do enter the water within hours of birth. Aquatic parturition and nursing therefore seem to be possible evolutionary options for the pinnipeds as they are for these others groups and, as discussed later, cetaceans.

D. Polar Bears

Polar bears (*Ursus maritimus*) are considered marine mammals because they range widely over sea ice foraging on seals and often enter the sea to swim relatively short distances to and from ice floes and land. They tend to fast during the summer months when sea ice is absent. Their reproductive patterns are similar to those of brown bears (*U. arctos*). After a period of

delayed implantation and a relatively short 3- to 4-month gestation period, the small (approximately 0.5 kg), altricial young are born in dens on land near shore or occasionally on stable sea ice. At this stage both mother and young exist on the mother's stored reserves, acquired from the previous winter's foraging out on the frozen sea. Cubs remain in the den with the mother until they grow to about 10 kg and then may spend some additional time in the den area before mother and cub move away onto the sea ice to look for food. Cubs spend around 2 years with their mother, presumably learning and gaining hunting experience, so there is ample opportunity for information to be transferred from mother to cub.

Male bears will kill and eat cubs if their mother does not defend them, and mothers will not associate with males or mate until cubs are independent. It is not clear how males find and recognize receptive females, although olfaction probably plays an important role.

V. Cetaceans

Unlike pinnipeds, cetaceans have evolved a behavioral and anatomical suite of adaptations allowing them to mate, give birth, suckle, and nurture their young entirely in water. Freed of the spatial and temporal constraints imposed by reliance on land or ice to breed, cetaceans have developed a wide diversity of social systems and life history strategies quite unlike those of the pinnipeds. While some cetaceans, principally the mysticetes, compartmentalize breeding to a temporally and spatially discrete component in their lives, the majority breed and acquire resources simultaneously. Further, consecutive breeding attempts themselves may be superimposed upon each other, with females concurrently rearing calves from different breeding attempts and even contributing directly to the survival of their offspring's own offspring.

Having no need of land to reproduce has assuredly led to the success and ubiquitous nature of the cetaceans, but for the same reason has also severely hampered our abilities to understand them. At the most basic level, discrete acts, such as copulation and birth in most species, have never been observed, let alone quantified, while comparing the success of different tactics employed by individuals within populations is simply impossible as yet. What is known is pieced together from anatomical studies, whaling operations, live captures, individual identification, genetic analyses, and interspecies comparisons. From these fragments, it is clear that the cetaceans have much to teach us about the ecological determinants of reproductive and social behavior and even offer the potential to broaden our understanding of mammalian reproductive behavior as a whole.

A. Seasonality of Reproduction

For the majority of cetaceans, reproduction has a seasonal component. For mysticetes (with the possible exception of Bryde's whales, *Balaenoptera edeni/brydei*), breeding occurs as a discrete phase of each year with other aspects, principally feeding, often being either reduced or halted entirely. The best-known species shuttle on an annual basis between productive feeding regions and areas associated with parturition, early nursing, courtship, and mating. The reproductive behavior of gray whales (*Eschrichtius robustus*) is a prime example. Existing populations survive in the northern Pacific and migrate from high-latitude temperate or polar waters after a summer of feeding, southward along North American and Asian coasts to breed in sheltered coastal waters. Although almost all gray whales migrate, whether reproducing or not, pregnant females move south earlier than males and then 80 or so days later return north again following behind the males and newly mated. Humpback and right whales follow similar patterns, but the behavior of rorquals, such as the blue (*Balaenoptera musculus*), fin (*B. physalus*), and minke (*B. acutorostrata* and *B. bonaerensis*) whales, is more poorly known and, though seasonal, it is as yet unclear for many populations when and where breeding actually occurs.

The lives of odontocete cetaceans are less obviously compartmentalized and breeding takes place simultaneously with other activities. Detecting breeding seasons is consequently harder and is usually estimated from parameters such as the first appearance of neonates at sea, fetal maturity in stranded or captured animals, and seasonal changes in testes. From such studies, it appears that the majority of odontocetes extend their breeding activities over protracted seasons. Interestingly, those that remain in high-latitude areas tend to reproduce at the opposite time of year to neighboring mysticetes. Harbor porpoises (*Phocoena phocoena*) in the North Atlantic, for example, ovulate, mate, and give birth in spring and early summer, whereas seasonally sympatric humpback whales migrate south to breed in winter. Furthermore, within species, the specific timing of reproduction may vary by region or population. Common bottlenose dolphins (*Tursiops truncatus*), for example, show diffuse seasonal peaks in reproduction but these vary in their timing with location.

The reasons why mysticetes and odontocetes adopt such differing behavioral and physiological strategies toward the seasonality of reproduction remain poorly understood. Body size clearly allows the larger mysticetes and sperm whales to store sufficient reserves to forego feeding and dedicate time to breeding. Because most odontocetes are smaller, it is tempting to assume that they have less capacity to fast during a discrete breeding season; however, they are of similar body size or larger than the highly seasonally breeding pinnipeds. It therefore remains a possibility that odontocetes, and females in particular, have protracted breeding seasons, simply because other aspects of their lives allow it. For all cetaceans, it is likely that food availability, risk of predation, water temperature, and sea or river conditions are important in dictating which season is actually selected to breed.

B. Gathering Resources to Invest in Reproduction

At times outside of specific breeding seasons, mysticetes gravitate toward areas that maximize their potential for prey consumption. Migrations into productive, often high-latitude, areas are therefore common. The duration and rate of energy acquisition appear to be important in determining subsequent

reproductive interval, ovulation rate, and fecundity. For odontocetes, particularly the smaller species, such migrations are less evident and suggest that their reproductive capabilities allow them to remain in their foraging areas year-round. A different strategy is found in the much larger sperm whales (*Physeter macrocephalus*). Females remain in tropical or subtropical waters year-round, whereas the sexually dimorphic males migrate from productive high-latitude feeding areas toward the equator and their mates to breed. The extreme sexual dimorphism (with males weighing up to three times as much as females) may necessitate such migrations to regions especially rich in prey.

C. Locating a Suitable Place to Breed

Breeding in cetaceans can be broken down into three phases: giving birth, suckling young, and mating. Because gestation in most cetaceans is close to 12 months, these three activities generally occur at a similar time of year and are therefore often considered as if they were one event. However, the factors that influence each differ and thus the choice of breeding habitats may well represent a compromise for the individuals concerned. The processes of giving birth and suckling young may benefit from waters with low predator abundance while these characteristics will be of less importance for mating. Examples of differences in locations for these activities are rare, especially in odontocetes, where little is known about breeding site selection as a whole. One study of harbor porpoises in the North Sea found significantly higher proportions of calves in a specific coastal area relative to neighboring waters, although the reasons why this area was favored are as yet unknown. Mysticetes offer more concrete examples of breeding areas. Those most studied include humpback (*Megaptera novaeangliae*), gray, and right whales (*Eubalaena* spp.), which typically breed near coasts, with the latter species favoring sheltered shallow waters. As might be expected, they also offer some evidence of the differing requirements of raising young and mating, with females with newborn calves favoring slightly different areas to the other breeding individuals. It is unknown if breeding site availability is a significant factor limiting the size of behavior of cetacean populations.

Underlying all of the issues associated with mysticete migrations to breeding sites is the controversy over why the mysticetes migrate at all. Sheltered shallow waters are not unique to the tropics, and some mysticetes, such as the bowhead whale (*Balaena mysticetus*), appear capable of breeding in the same polar waters in which they feed. Factors that pose direct benefits to adults do not appear to withstand scrutiny whereas the thermal constraints on calves do not seem likely when neonate mysticetes are larger than most adult odontocetes and are probably already thermoneutral in colder waters. Instead, the possibility of calf PREDATION by killer whales (*Orcinus orca*) might lie as the root cause of such enormous migrations for at least some of those species large enough to be capable of making them.

Gray whales appear to navigate to and from their breeding areas by following the coastal margins of their respective continents. In contrast, the north–south migrations of humpback whales seem to be deflected by coastlines, currents, and underwater topography rather than guided by them. How these whales find locations such as the Hawaiian Islands each year in waters as large as the Pacific is still unknown. Use of celestial, acoustic, or magnetic markers are distinct possibilities.

D. Giving Birth

Few cetaceans births have been observed in the wild, but in captive odontocetes, most births are accomplished rapidly without direct assistance from conspecifics. However, there are several reports of animals seemingly helping in the birth process, either pulling the fetus or placenta clear of the birth canal. The frequency of such activities, if they occur at all in wild populations, is unknown. Because wild births have been observed so rarely, little is known about how females might reduce the risks of predation and separation in the moments after birth. The proficient swimming abilities of newborn calves permit mother and neonate to vacate an area rapidly where the birth occurred and so minimize the attentions of predators, while the social nature of cetaceans may permit increased predator detection and defense. Newborn calves adopt a swimming posture alongside their mothers permitting tactile communication, camouflage, and slipstreaming.

E. Investing in Young after Birth

Parental care in cetaceans is predominantly the responsibility of the mother, although male and female kin as well as unrelated females may provide additional care. The levels of nonmaternal care vary considerably among species, being generally rare in mysticetes and more common in odontocetes. Pilot (*Globicephala* spp.) and killer whales offer some remarkable examples of care and nutritional investment that are notable not just within marine mammals but for all mammals.

1. Maintaining Contact and Providing Protection All cetaceans are born nutritionally dependent on their mothers, but with births occurring without the spatial certainties of land or ice, there is potential for calves to become separated from their mothers and therefore starve rapidly or become prey. For those species that suspend foraging during breeding, females can devote almost continuous attention to their calves. Species that continue to forage face a problem, as the diving abilities of calves may be insufficient to follow their foraging mothers. Babysitting among this latter group appears to be a common solution, with an apparent continuum among odontocetes. This can range from females of similar breeding status schooling with one another and presumably taking turns guarding calves or at least acting as a spatial point of reference, through to related females and their adolescent young accompanying mothers and their neonates in sperm whales. It may even extend to a system demonstrated by killer and pilot whales (apparently unique among mammals) of stable kin groups with neither male nor female dispersal but instead investment in raising their own (females only) and related offspring (females and males). Despite such behavioral safeguards, however, cetacean mobility makes separations between mother and calf inevitable. Individually specific calls are thought to be important in reuniting individuals in species such as the common bottlenose dolphin. However, such mechanisms take time to develop, and neonate mortality, although low compared with other mammals, is substantial.

Our understanding of cetacean reproductive behavior is undoubtedly hampered by the potential ambiguity of the behavior that can be observed. This is particularly prevalent in aspects involving the spatial proximity of individuals and apparently altruistic or cooperative behavior. The social complexities of cetacean societies and the considerable component that appears to be learned and practiced make context an essential component of any behavioral observation. Babysitting is an attractive and logical concept that has been described frequently, but the appearance of a calf with an adult animal other than its mother may result from other motives. Young inexperienced female Indian Ocean bottlenose dolphins (*T. aduncus*), for example, may temporarily kidnap calves and thereby improve their own maternal skills (Mann *et al.*, 2000), whereas males and females of social mammals in general may benefit from capturing and killing another's young.

2. Lactation and Weaning Cetacean calves do not suffer the constraints experienced by phocid seals, which need to rapidly transfer resources to the pup in order to resume feeding, nor do they endure the periods of maternal absence experienced by otariid pups. Instead female cetaceans take their mobile calves with them and are generally only separated for the length of a foraging dive. Thus calves have the opportunity to suckle frequently and match milk intake with energy expenditure and growth. Milk is transferred via two mammary teats, which are located in slits to either side of the genital opening about two-thirds of the way down the mother's body on her ventral side. The presence of bristles on the rostra of neonate cetaceans is thought to help calves orient during suckling while a frilled margin to the tongue and muscular control of milk ejection likely aid efficient milk transfer.

Mysticete calves are generally weaned within a year of birth and, in migratory species, coincides with the pair reaching high-latitude feeding grounds. Weaning may precipitate separation of cow and calf but in its timing offers opportunities for the mother to train a calf in migration routes and the location of feeding areas, and potentially facilitate membership of feeding assemblages. Lactation in the majority of odontocetes is longer, and in some cases far longer, with weaning appearing to be gradual and occurring over a period of months or years. Lactose, for example, has been detected in the stomachs of sperm whales up to 13 years of age. Such long-term maternal investment suggests that many components of odontocete development require a considerable period of learning and training. Foraging tactics in odontocetes are often performed in groups and, while it is unknown what proportion are cooperative or exploitative, their complexity is clear, as is the need for a high degree of interindividual coordination and practice. Calves may learn through observations or dedicated tutoring. The prolonged lactation and consequent investment in young allow calves to develop before facing nutritional independence. Bottlenose dolphins probably wean around 18 months after birth but remain closely associated with their mothers for at least 4 years. Young killer and pilot whales may never separate from their mothers, drawing comparison with elephant matriarchal societies where the eldest animals may function as long-term information stores and guardians for their offspring and offspring's offspring.

F. Locating and Selecting a Mate

1. Female Mating Behavior The number of offspring that female cetaceans produce in a lifetime varies. Groups such as the porpoises and baleen whales may give birth on an annual or biennial cycle and have the potential to produce between 12 and 20 offspring in a lifetime. Others produce much fewer. Some female killer whales, for example, may produce as few as 5 to 6 young in their entire lives. Whether 20 or 5, these numbers are small given the huge investment in time and resources that each calf receives, and therefore the choice of an appropriate mate to father them is a major component of the reproductive fitness for individual females.

In short, we have little solid information on how female cetaceans choose mates. In any species or population there are many potential junctures where a female may be making behavioral or physiological decisions, both before conception and afterward. In some instances, females may have the opportunity to simply select a particular male with which to copulate from a range of alternatives. Such a case has been proposed for humpback whales, where males may engage in communal display behaviors on the breeding grounds without showing any defense of resources. Females would have opportunities to approach males based on the quality of their displays. Female bottlenose dolphins are frequently seen being attended by single or alliances of males. While males may have opportunities to herd a female against her will, the females may also have the opportunity to reject or maintain that contact. Females have been observed rebutting the copulation attempts of males by fleeing or rolling upside down at the surface so that males do not have access to the female's genital opening.

After copulation, females may have a range of behavioral and physiological options to influence the probability of conception. The number of subsequent males with which she mates would influence the probability of a particular male being the father. The large volumes of sperm produced by males of several cetacean species (see later) suggest that females mate with several males and that competition between the sperm themselves may be a frequent occurrence in such species. Mating repeatedly with a particular male would also bias the odds significantly. Whether an egg is available for fertilization is also critical and it appears that ovulation itself may be related to mating and therefore has the potential to be under the female's control.

Even after fertilization has occurred there are opportunities to select whether to continue investment in a particular partner's offspring. These may range from selection abortion, energetic investment in the fetus, and the subsequent level of parental care expended in the calf. At present we have little information to determine whether such behavioral and physiological decisions are made, but because evidence for such has been found in birds and terrestrial mammals, it is possible that such options are open to female cetaceans.

2. Male Mating Behavior The reproductive behavior displayed by males is a function of the social and physical environments in which they live and compete. As with the diversity of habitats and lifestyles exhibited by cetaceans, males of different species and populations show a huge range of tactics to

maximize their reproductive potential. At a basic level, males should behave to optimize the number of their own sperm competing to fertilize a female's egg and limit the number of those of competitors. Thus males may increase the probability of obtaining copulations by signaling their quality to females and competing males through physical or acoustic displays (e.g., postural displays in bottlenose dolphins, songs of humpback whales, sperm whale vocalizations), ornamentation or body scarring (teeth and scars in beaked whales), intermale combat (humpback whales), extreme body size (sperm whales), or simply tracking the long-distance migrations of females (humpback, gray, and right whales). Males may attempt to guard receptive or potentially receptive mates to reduce the probability of competitors mating and increase the number of copulations they can obtain themselves. The alliances formed between male bottlenose dolphins may be an example of such behavior where pairs or trios of males may trade off their exclusive access to a female in order to ensure that other males cannot gain mating opportunities. The potential absence of such alliances in some other populations of common bottlenose dolphins (Wilson *et al.*, 1993) suggests that such tactics are context specific and influenced by factors such as the relative abundance of receptive females and potential for males to monopolize them.

Even once copulation has occurred, competition between males need not be over. Gray, bowhead, and right whales and harbor porpoises all have testes substantially larger than their body size would predict. Large quantities of sperm and the ability to copulate frequently may allow males to flush away or dilute the sperm and consequent reproductive chances of other males.

Males may also be able to increase the effective pool of receptive females by influencing the fate of other males' calves. Infanticide is common among terrestrial mammals and is often carried out by males in order to force females to switch from investing resources into a previous calf not sired by themselves and to become reproductively receptive again. It is unknown if such behavior occurs in cetacean societies, but the violent deaths of young bottlenose dolphins in some populations suggest that males may exploit such options.

The long lives and intricate social organization of cetaceans, particularly odontocetes, also offer males the opportunity to increase their fitness, not by maximizing their potential to father offspring, but by investing in their kin. The lack of male dispersal in killer and pilot whales and the absence of interbreeding within pod members suggest that males may remain with their maternally derived relatives to provide care or protection and thus to increase their own inclusive fitness.

G. Mating

Cetaceans live in a three-dimensional environment that facilitates copulation from a variety of orientations. Common positions include ventrum to ventrum with the pair oriented in the same directions, or the male may mount the female from a nonparallel position. Intromission may last only a few seconds or far longer and involve vigorous thrusting or a more passive attitude. Mating may be preceded and followed by prolonged periods of courtship and petting. Mating episodes may be repeated over periods of minutes, hours, or days.

H. The Transition to the Nonbreeding Season

While copulation and parturition are generally seasonal in cetaceans, the investment in reproduction for females is an almost continuous process after reaching sexual maturity. Baleen whales that migrate from breeding grounds with neonate calves wean them on the feeding grounds. They may have several months of intensive feeding before returning to the breeding grounds to mate or be already pregnant following copulation the previous year. Female odontocetes frequently superimpose reproductive events by being both pregnant and lactating or suckling more than one generation of calf at the same time. Perhaps the most intriguing situation is demonstrated by female pilot whales, which appear to cease ovulating after age 40 and yet continue to lactate for well over another decade. In doing so, they have the potential to not only extend long-term care to their own offspring, but also influence the fate of their offspring's own offspring.

Ribbon Seal

Histriophoca fasciata

GENNADIY FEDOSEEV
Marine Mammals Council
Moscow, Russia

I. Diagnostic Characteristics and Taxonomy

The ribbon seal is an endemic species of the North Pacific. Although it used to be grouped together with the Greenland seal into the same genus, Pagophora (Naumov and Smirnov, 1936), it is now considered to belong to the monotypic genus *Histriophoca* (Scheffer, 1958; Geptner *et al.*, 1976).

The ribbon seal's coloring is bright and unusual (Fig. 1). There are four light stripes against a black or brown background: one stripe goes round the neck, another encircles the body at the bottom of the flippers and two more symmetrically underline the base of the pectoral flippers. During the first year the color is fairly dull and becomes brighter only when the seal is 2 years old. The skull of the ribbon seal is short, the cranium braincase and cheekbones are wide, and the face is short and narrow. The teeth are small; their number varies from 32 to 36 (Geptner *et al.*, 1976).

II. Anatomical and Physiological Features

The ribbon seal differs from the rest of the seals by its respiratory anatomy. There are no lobes in the lungs; the trachea in its middle part consists of semirings at the top and a membrane at the bottom. Through a narrow fissure the membrane is connected with a thin-walled air sac that is quite well developed in a mature male. Females have smaller air sacs, whereas immature animals have nondeveloped ones. The air sac also functions as a hydrostatic organ used in phonation (Sokolov *et al.*, 1968).

The ribbon seal has several features that show the degree of its adaptation to deep diving and fast SWIMMING, with well-developed internal organs among them. Their weight as a proportion of body weight is high: heart on average, 8‰, lungs 17‰, diaphragm 7‰, liver 22‰, and kidneys 2.7‰. These indices are higher than those of other seals (Fedoseev, 2000).

The ribbon seal is physiologically well adapted to a pelagic lifestyle and deep diving (up to 600 m): it has the highest number (3.9–4.7 million) and volume (50–72%) of erythrocytes and the highest blood hemoglobin contents (18–26 g%) among all seals (Sokolov, 1966).

III. Distribution and Population Size

The ribbon seal inhabits that area between the southern part of the Chukchi Sea and Japan and Korea. There are three populations of this particular species: two in the Okhotsk Sea and one in the Bering Sea (Fig. 2). A part of the latter in spring and summer migrates to the southern region of the Chuckchi Sea. Single ribbon seals have been seen close to the California coastline (Morro Bay). The range of the migration is little known.

In 1961 the population size of the ribbon seal in the Bering Sea was estimated at 115,000 to 120,000. By 1969, because of sealing, the population was reduced to 60,000 to 70,000. After sealing had been limited to 2000 to 3000 animals a year (vs 9500), the population size by 1987 reached 120,000 to 140,000. In the Okhotsk Sea, according to data collected for many years, the population size fluctuated between 200,000 (1968–1974) and 630,000 (1988–1990). For many years the average number was 370,000 with the central northwestern population being 320,000 and the southern 50,000 (Fedoseev, 2000).

IV. Ecology

The ribbon seal belongs to the ice seals, whose life is closely connected with ice. However, if the ice is thicker than 10–15 cm, the ribbon seal is unable to make holes in it. This is why it dwells in areas with stable white ice broken into huge chunks and avoids areas of solid ice fields. Broken ice usually appears in regions of an abrupt continental shelf, where due to high water circulation this form of ice dominates; moreover, it constantly gets moved around. In such areas there are a lot of fish and squid, which are the main foods for ribbon seals. In the Bering Sea, these areas coincide with

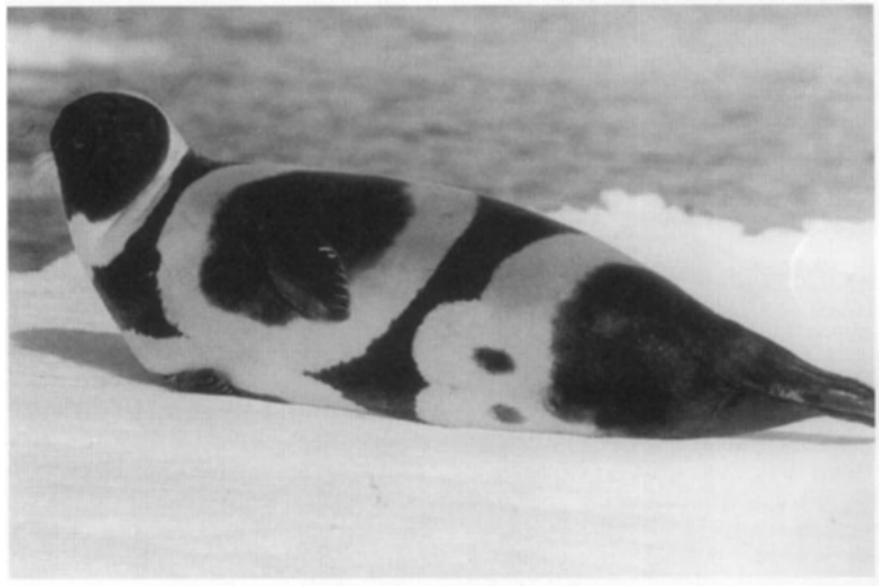

Figure 1 *Male ribbon seal.*

the sea ice edge. In the Okhotsk Sea, where the climate is more severe and ice covers up to 80–90% of the sea surface, reproductive rookeries are located deep in the ice, whereas in the southern part of the sea they can also be found where there is a deep sea bed with cyclic water turnover that facilitates spacing the ice out.

The period of mating and pup rearing is adjusted to spring ice breakup. When it shifts together with the beginning of ice breakup, this results in the reproductive isolation of different populations. It is in the southern part of the Okhotsk Sea where ribbon seals start delivering the pups the earliest, i.e., in the second part of March. In the northwestern part of the Okhotsk Sea and in the Bering Sea it takes place in April, with the peak in the middle of the month.

There are four reproductive ecotypes related to ice formation (Fig. 2). What is special about the reproductive ecotypes is that the variety of breeding conditions defined by different types of ice, its thickness, shape, the hummocks, the amount of snow on it, its location, and the speed of its decomposition determine the time of rearing and pup growth, which is reinforced by natural selection. Due to the existence of ecotypes, the populations of the ribbon seal are adapted to both short-term (within 1 year) and long-term (several years long) modifications of ice conditions: it has a wide range of features adapted to breeding in various conditions and can keep population size relatively stable.

The spatial structure of the populations, their morphological characteristics, and the maturation of animals in different populations are determined by the proportion of the ecotypes in different regions. Ribbon seals that breed on the ice above the deep sea bed in the southern part of the Okhotsk Sea are most specific—both the conditions of reproduction and the foraging situation are different from those in shelf zones and abrupt continental shelf zones in the northwest and in the Bering Sea.

V. Forage

Thirty-five species inhabiting the Okhotsk and the Bering Sea constitute the ribbon seal's food. During the first year it feeds mostly on euphausiids. At the age of 1–2 it feeds mostly on shrimp, whereas adult animals eat cephalopods and fish. In the Okhotsk Sea, adult animals eat mostly Alaskan pollack (65%), whereas in the Bering Sea they mostly feed on squid and octopus (67%). The ribbon seal's daily consumption is 8–10 kg, including invertebrates and fish; the annual consumption of the whole ribbon seal population is more than 300,000 tons in the Bering Sea and about 1,160,000 tons in the Okhotsk Sea (Fedoseev, 2000).

VI. Life Cycle and Behavior

The length of a newborn seal's body is from 73 to 98 cm and it weighs 6–10 kg; specific features of different populations are taken into account. After the first year of life, the length of animals belonging to different populations becomes 128–134 cm and the weight 40–50 kg. During the period of maturation when the animals are 2–3 years old, the average body size is 145–155 cm and the weight is 55–70 kg, whereas mature animals' (who are more than 10 years old) body length is 165–175 cm and weight 72–90 kg. Ribbon seals inhabiting the southern part of the Okhotsk Sea are bigger and heavier than those from the northwestern part and from the Bering Sea.

During the breeding season (March–April), animals do not segregate by age and sex; adult animals dwell on the ice to give birth to pups and immature seals are there for molting. In May and June when adult animals start molting, gathering of ribbon seals on the ice increases because of melting and decomposition of the ice. In June, when there is little ice left, one can see a mass of ribbon seals consisting of different populations. The latter should be taken into consideration when

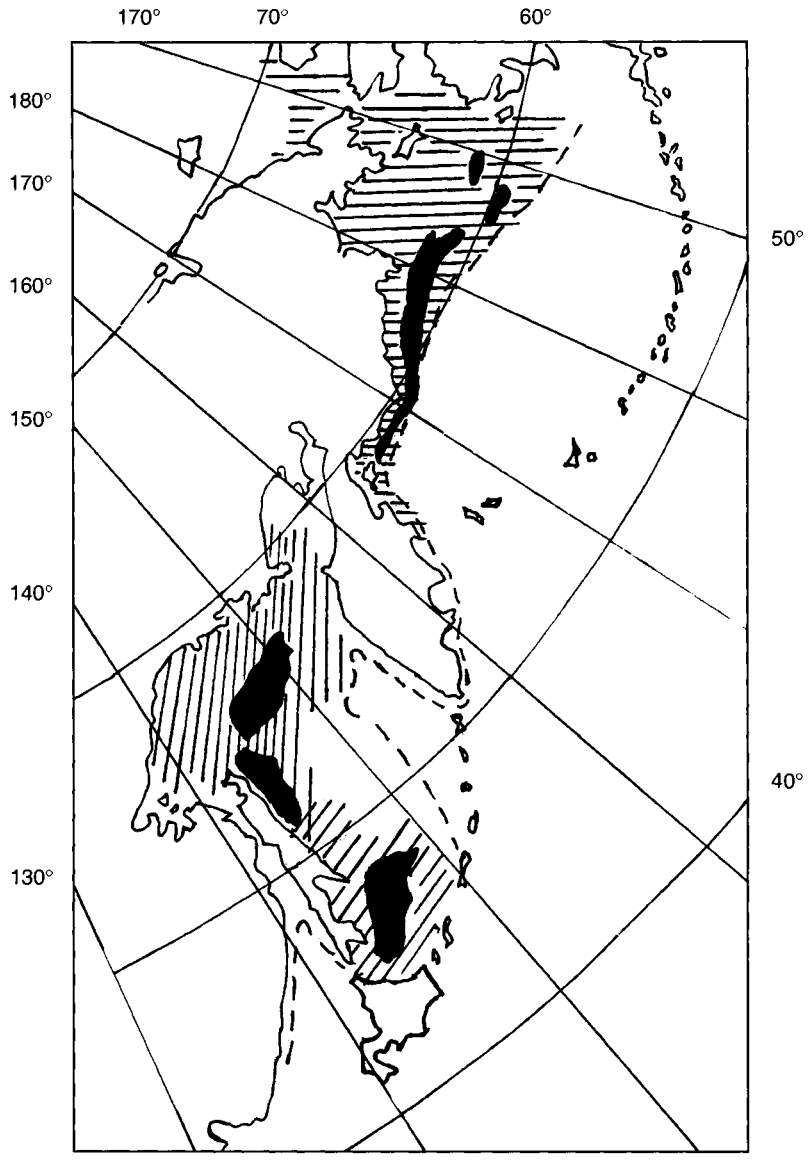

Figure 2 *Different populations and breeding sites of the ribbon seal in North Pacific seas. Broken line, ice edge; solid areas, breeding sites; horizontal stripes, the Bering Sea population; vertical stripes, the northwestern part of the Okhotsk Sea population; and diagonal stripes, the southern part of the Okhotsk Sea population.*

a population approach to data analysis is used. Where the ribbon seal dwells when there is no ice left has been little studied.

Due to the pelagic way of life and dwelling far from the sea coast, the ribbon seal has not developed a fear of humans. This seal is very trusting and hardly reacts at all when a ship approaches and people come out on the ice. It makes the ribbon seal a perfect object for ecological tourists who can take pictures of the animals on the ice. In the open water the ribbon seal is hardly noticed at all as it disappears from the sea surface noiselessly: it sticks its black head out vertically and takes it back like a periscope.

VII. Demographic Parameters of Populations

The ribbon seal's age is defined by horn covers on the claws and the layers of cement on the tusk apexes; analysis shows that it can reach the age of 30 and beyond.

Analysis of age data and the female contingent in the breeding process showed that the proportion of newborns in populations can be 24–31%, and the proportion of females having pups for the first time (recruits) 4–6% (Fedoseev, 2000). During the period of study (1982–1985) the potential of population

growth in the Bering Sea was lower than in the Okhotsk Sea because the range of reproductive ecotypes and the distribution in the Okhotsk Sea were wider than in the Bering Sea (Fedoseev and Volokhov, 1991; Fedoseev, 2000).

VIII. Relations with Humans

Between 1956 and 1992, seals living on ice, ribbon seals among them, were the subject of commercial hunting. Up until 1969 the hunt was not limited, with the average annual yield being 11,000 animals in the Okhotsk Sea and 9000 in the Bering Sea. Between 1969 and 1992 the annual yield was reduced to 5000 to 6000 animals in the Okhotsk Sea and 3000 to 4000 in the Bering Sea.

Right Whale Dolphins

Lissodelphis borealis and *L. peronii*

Jessica D. Lipsky

Southwest Fisheries Science Center, La Jolla, California

Right whale dolphins are known for their distinctive black and white color patterns and lack of a dorsal fin. These characteristics make these species easy to identify at sea. Although these species were first described in the first half of the 19th century, their overall biology, life history, taxonomy, and behavior are poorly known.

I. Characters and Taxonomic Relationships

While both species of right whale dolphins lack a dorsal fin, they have very different pigmentation patterns. The northern right whale dolphin (*Lissodelphis borealis* Peale, 1848) is mainly black with a white ventral patch that runs from the fluke notch to the throat region (see Fig. 1). This band widens slightly at the urogenital area in males and to a greater extent in females (Leatherwood and Walker, 1979). There is another small white patch on the ventral tip of the rostrum and on the underside of the flippers. The southern right whale dolphin [*L. borealis* (Lacépède, 1804)] has a similar white ventral patch; however, it extends higher on the posterior flanks (see Fig. 2). The back of the dolphin is black, and the white area reaches a high point midway along the body, dipping down at the flipper insertion and covering most of the head and rostrum. Newborn calves are usually dark gray or brown, attaining adult coloration after the first year of life.

Right whale dolphins can grow to lengths of 3 m; males tend to grow larger than females (Leatherwood and Walker, 1979). Weights have been recorded up to 116 kg (Jefferson *et al.*, 1994). The flippers are slender and pointed at the tips. Flukes have a median notch that is moderately deep with concave trailing edges. The teeth are small and sharp, ranging in numbers from 37 to 54 per row in the northern species and 39 to 50 in the southern species, with more teeth in the lower jaw (Jefferson *et al.*, 1994).

Recent classifications have placed the right whale dolphins in a monogeneric delphinid subfamily Lissodelphinae or in the subfamily Delphininae. However, based on an analysis of cytochrome *b* (mtDNA) sequences, LeDuc *et al.* (1999) tentatively placed them in the subfamily Lissodelphinae with *Lagenorhynchus* spp. and *Cephalorhynchus* spp.

II. Distribution and Ecology

Right whale dolphins are found in cool-temperate and sub-Arctic waters in the North Pacific and circumpolar sub-Antarctic and cool-temperate waters in the Southern Ocean (see Fig. 3). In the North Pacific, northern right whale dolphins range from Kuril Islands, Russia, south to Sanriku, Honshu, Japan, extending eastward to the Gulf of Alaska and south to southern California (Rice,

Figure 1 Lissodelphis borealis *off the coast of California. Photo courtesy of Robert L. Pitman.*

Figure 2 Lissodelphis peronii *off the coast of Chile. Photo courtesy of Robert L. Pitman.*

1998). They are distributed approximately from 34°N to 55°N and 145°W to 118°E. Occasional movements south of 30°N are associated with anomalous cold-water temperatures. In the Southern Hemisphere, southern right whale dolphins are found most commonly between 25°S to 55°S in the eastern South Pacific and about 30°S to 65°S. They are found most often between the subtropical and Antarctic convergences, with distributions reflecting the variability in these oceanographic features (Gaskin, 1968). It has also been observed that the range of the southern right whale dolphins often extend northward along eastern cold-water boundary currents.

Migration of both *Lissodelphis* species is not entirely known or understood. In northern right whale dolphins, there appears to be an inshore shift in winter and spring off California, which coincides with peak abundance of their primary food source (squid) (Leatherwood and Walker, 1979). Forney and Barlow (1998) found that northern right whale dolphin abundance was greatest off the Southern California Bight in winter, while in the summer there were no sightings made in this area. In addition, they observed a greater abundance of *L. borealis* offshore in summer and a greater abundance inshore on the Southern California Bight continental shelf in winter (Forney and Barlow, 1998). Southern right whale dolphins tend to occur year-round in a localized area off Namibia, Africa, where high-productivity waters prevail (Newcomer *et al.*, 1996). Off the coast of Chile, southern right whale dolphins are present year-round and have been discovered to migrate northward during winter and spring. Food sources. which are affected by changing water temperatures, appear to be a factor in this species' migration. In addition, these two species are commonly found in oceanic, deep waters. on highly productive continental shelves, or sometimes where deep waters approach the coast.

Northern right whale dolphins have been observed to associate with 14 other species of marine mammals in the North Pacific Ocean. They are mainly observed with Pacific white-sided dolphins, *Lagenorhynchus obliquidens*. which share a similar distribution and habitat (Klumov, 1959; Leatherwood and Walker, 1979). They are also commonly found with pilot whales (*Globicephala macrorhynchus*) and Risso's dolphins, *Grampus griseus* (Leatherwood and Walker, 1979). Southern right whale dolphins are associated most often with pilot whales (*Globicephala melas*) and dolphins of the genus *Lagenorhynchus* (Jefferson *et al.*, 1994).

PREDATION on right whale dolphins is poorly known; however, killer whales and large shark species are occasional predators. There are two records of predation on southern right whale dolphins: a 0.87-m southern right whale dolphin fetus was found in a 3.6-m sleeper shark (*Somniosus* cf. *pacificus*) off the coast of Valdivia, Chile in 1990 (Crovetto *et al.*, 1992) and a 1.7-m Patagonian toothfish taken off central Chile in 1983 had a 0.86-m southern right whale dolphin neonate in its stomach (Van Waerebeek *et al.*, 1991).

The northern right whale dolphin has been observed to feed primarily on squid and lanternfish; however, other prey species include Pacific hake, saury, and mesopelagic fishes (Leatherwood and Walker, 1979). The southern right whale dolphin feeds primarily on various squid and fish species.

Strandings of northern and southern right whale dolphins are uncommon. An apparent increase in strandings of *L. peronii* is possibly the result of discarded animals from a rapidly developing swordfish gillnet fishery off northern Chile (Van Waerebeek *et al.*, 1991).

III. Behavior and Life History

Right whale dolphins tend to be gregarious animals, often traveling in groups of up to 2000–3000 in the North Pacific (Leatherwood and Walker, 1979) and up to 1000 in the southern species (Gaskin, 1968). Herds are characterized by four main configurations, including V-shaped herds, "chorus line" formation herds, tightly packed herds with no identifiable subgroups, and herds with subgroups within the main group (Leatherwood and Walker, 1979). Both forms have been observed to travel slowly or quickly; this is associated with surfacing modes, BREATHING intervals, and travel speeds. Right whale dolphins can travel up to 40 km per hour (Leatherwood and Reeves, 1983). In some instances, right whale dolphins will bow ride on vessels, especially in the presence of other species, although sometimes they will actively avoid approaching vessels. Aerial behavior such as BREACHING, belly flops, and side and fluke slaps are not uncommon, especially in the fast swimming mode.

Information on growth and reproduction for right whale dolphins is limited. Twenty-three specimens have been examined in the eastern North Pacific, and their data suggest that males attain sexual maturity between 212 and 220 cm and females at about 200 cm (Leatherwood and Walker. 1979). In November 1990 and 1991, 229 northern right whale dolphins were obtained from the Japanese squid drift net fishery and examined for total length, age, and sex (Ferrero and Walker, 1993). Ferrero and Walker (1993) found that the average length for sexually mature males is 214.7 cm and 199.8 cm for females in the northern species. In addition, they calculated that the age at the onset of sexual maturity for males is approximately 9.9 years and for females it is approximately 9.7 years (Ferrero and Walker, 1993). In the western North Pacific, other reports indicate that females attain sexual maturity between 206 and 212 cm (Jefferson *et al.*, 1994). Northern right whale dolphin neonates range between 80 and 100 cm at birth (Jefferson *et al.*, 1994). Ferrero and Walker (1993) found that for northern right whale dolphins length at birth ranged be-

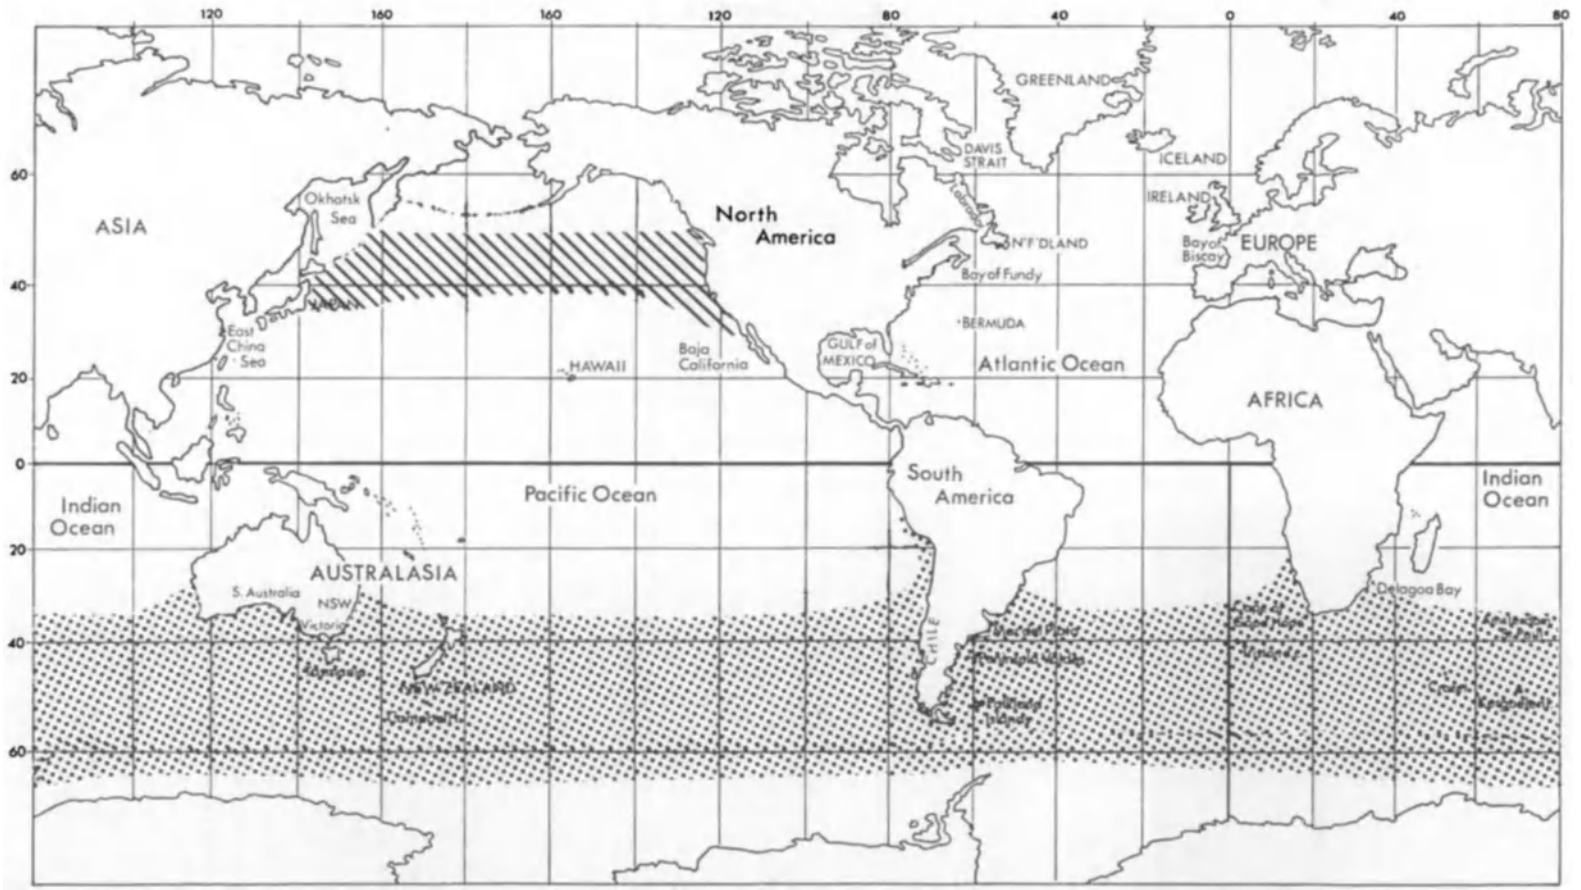

Figure 3 *Approximate ranges of* Lissodelphis borealis *(hatched) and* L. peronii *(stippled).*

tween an average of 99.7 and 103.8 cm using three different methods of length estimation. The calving season is unknown; however, small calves are often seen in winter or early spring. In the Southern Ocean, right whale dolphin reproductive biology is largely unknown. Two females measuring 218 and 229 cm and one male measuring 251 cm have been examined and were all sexually mature (Jefferson *et al.*, 1994).

Sound production in northern right whale dolphins has been recorded (Fish and Turl, 1976). Clicks with high repetition rates were recorded, with few whistles. Sound production in southern right whale dolphins has not been described.

There have been few attempts to capture live animals due to the difficulty in maintaining these oceanic species. A northern right whale dolphin was captured live and held for 15 months; however, most live captures have not survived more than 3 weeks (Walker, 1975). There have been no reported attempts to capture live southern right whale dolphins.

IV. Conservation Status

In the 19th century, whalers occasionally took northern right whale dolphins. Although there is currently no direct fishery for right whale dolphins, the northern species is occasionally taken in Japan's harpoon fishery and in the Japanese and Russian purse-seine fisheries (Klumov, 1959). In addition, a few individuals were taken in Japan's salmon gillnet fishery (International Whaling Commission, 1983) and in California's shark and swordfish driftnet fishery. The majority of right whale dolphin bycatches in recent years occurred in the North Pacific squid driftnet fisheries operated by Japan, Korea, and Taiwan (Jefferson *et al.*, 1994). The squid fisheries began in 1978 with small incidental takes of 300–400 dolphins until the mid-1980s when incidental takes were on the order of 15,000–24,000 dolphins per year (Mangel, 1993). It is thought that the stock in this area has been depleted to 24–73% of its pre-exploitation level (Mangel, 1993). In the past few years, southern right whale dolphins have been taken off Chile and Peru for use of their meat and blubber for human consumption or use as crab bait (Newcomer *et al.*, 1996). Since 1989 there has been an increase in southern right whale dolphin bycatches in the developing swordfish gillnet fishery off Chile (Van Waerebeek *et al.*, 1991).

The effects of POLLUTION and contaminants on right whale dolphins are currently unknown. Given the nature of the pelagic habitat of the northern species, the effects of pollution are probably minimal. However, seasonal shifts in migration and distribution could possibly have a negative impact on these species.

Ringed, Caspian, and Baikal Seals

Pusa hispida, P. caspica, and *P. sibirica*

NOBUYUKI MIYAZAKI
Otsuchi Marine Research Center, University of Tokyo, Japan

I. Distribution and Taxonomy

The ringed seal (*Pusa hispida*), Baikal seal (*P. sibirica*), and Caspian seal (*P. caspica*) have features in common, such as small size, delicate skull, and affinity for ice.

Baikal seals and Caspian seals are found in Lake Baikal and the Caspian Sea, respectively. The ringed seal is a species of circumpolar Arctic coasts with a broad geographic distribution and is found wherever there is open water in fast ice, even as far as the North Pole, and in fjords and bays, but rarely in the open sea or on floating pack ices (King, 1964). Although numerous populations and/or subspecies have been reported for the ringed seal, at present five distinct subspecies are usually recognized: *P. h. hispida* from the Arctic Ocean and the confluent Bering Sea, *P. h. ochotensis* from the Sea of Okhotsk, *P. h. saimensis* from Lake Saimaa, *P. h. ladogensis* from Lake Ladoga, and *P. h. botnica* from the Baltic Sea (Fig. 1).

II. Morphology

A. External Appearance

Baikal seals, which do not have distinct spots, are uniform dark silver gray dorsally and light yellowish gray ventrally (Fig. 2). Caspian seals are irregularly spotted with brown or black against a light grayish yellow background (Fig. 3). The spots are light-colored rings. In the ringed seal, gray–white rings are found on the generally gray backs, and the belly is usually silver and lacking dark spots (Fig. 4). The rings are separate or somewhat fused together. The pups of these three species are born with a white woolly natal lanugo. This lanugo is considerably finer and longer than that of the two other northern phocids, the spotted seal (*Phoca largha*) and ribbon seal (*Histriophoca fasciata*) (Frost and Lowry, 1981).

B. Skull Morphology

Comparison of skull morphology indicates that Baikal seals have a greater length of jugal, and narrower least interorbital width and width of nasals at the maxillo-frontal suture than Caspian seals. However, in the ringed seal, characters relating to skull width, width of bulla, and greatest length of bulla show larger values, whereas characters relating to condylobasal length and width of snout at canines show smaller ones compared to the other two species. A canonical discriminant analysis was performed using 14 characters lacking sexual differences. Subspecies of the ringed seal are clearly distinguished from Baikal and Caspian seals. Cluster analyses by the neighbor-joining method and the UPGMA (unweighted pair-group method using arithmetic averages) method based on Mahalanobis dis-

Figure 1 *Distribution of the ringed seal (dark), Caspian seal (dots), and Baikal seal (stripes) (redrawn from King, 1964). Numbers indicate subspecies of the ringed seal; 1,* P. h. hispida; *2,* P. h. ochotensis; *3,* P. h. saimensis; *4,* P. h. ladogensis; *and 5,* P. h. botnica.

Figure 2 *Adult Baikal seal on ice, Lake Baikal. Photo by S. Tanabe.*

tance suggest that Baikal seals have closer affinity with the ringed seal than the Caspian. This relationship coincides well with sequence analysis using mitochondria DNA.

III. Age and Growth

The maximum known age in both sexes in Baikal seals is 56 years for females and 52 for males (Pastukhov, 1993). According to Amano *et al.* (2000), the oldest age of Baikal seals in samples (N = 73) collected in 1992 was 24.5 years for females and 35.5 years for males. In Caspian seals collected from Pearl Island in the western North Caspian Sea (N = 118), the oldest age was 43.5 years for females and 33.5 years for males. The maximum known age for the ringed seal is 43 (McLaren, 1958).

Growth in body length of Baikal seals appears to cease around the age of 15 years (Amano *et al.*, 2000). The seals may continue to grow for 8–9 years after the age of sexual maturity (6 years for females and 7 years for males). Asymptotic body length is 140 cm in males and 130 cm in females. In Caspian seals, body length growth appears to cease around the age of 10 years, which is the age of sexual maturity in both sexes. Asymptotic body length is 118 cm in males and 111 cm in females. McLaren (1958) reported that the growth of ringed seals continues throughout the first 8–10 years of life. About 86% of final body length is attained by sexual maturity of 6–8 years. Average adult lengths for the ringed seal vary from 121 cm in the Chukchi Sea to 128.5 cm in the Bering Sea (Fedoseev, 1975) and 135 cm in the Canadian Arctic (McLaren, 1958).

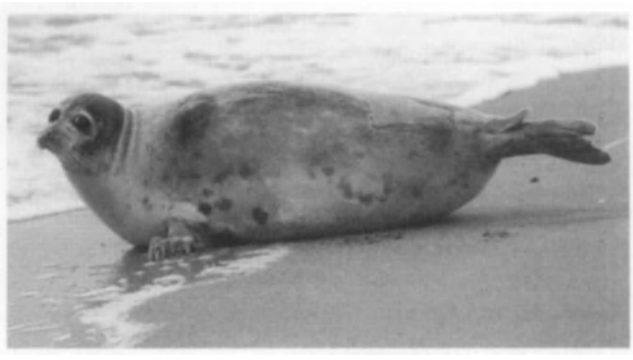

Figure 3 *Caspian seal on Pearl Island, northwestern North Caspian Sea.*

Figure 4 *Ringed seal at Dikson, the Arctic Ocean.*

IV. Behavior

Movements and dive patterns of Baikal seals appear to be associated primarily with seasonal movements of their primary prey, golomyanka and sculpins, and correlated secondarily with patterns of ice formation and thaw. Most dives are to depths of 10–50 m, although a few exceed 300 m (Stewart *et al.*, 1996). Dives may last between 2 and 6 min but a few dives exceed 40 min.

For two adult male Caspian seals, most dives were less than 50 m in depth while a few exceeded 200 m. Dives were mostly less than 50 sec long but some exceeded 200 sec.

V. Reproduction

Most Baikal seals breed by 6 years for females and 7 years for males (Thomas, 1982). Pups are 65 cm in body length and 4.1 kg in body weight on average. A rather high rate of twinning (4% of annual births) is exhibited compared to other seals (Pastukhov, 1968). Mating may occur underwater in March at about the time mothers wean their pups. Mothers nurse the pups in a birthing lair. The lactation period is estimated at 2–3 months. The MATING SYSTEM is assumed to be polygamous with little or no pair bonding. In winter, when Lake Baikal is covered with ice averaging 80–90 cm in thickness with a maximum of 1.5 m, seals are sighted throughout the lake and adjacent to breathing holes in the ice. In Baikal seals of 7 years or more, 84% of females gave birth to pup yearly (Patstukhov, 1993).

Caspian seal pups are born on the ice from the middle of January to the end of February and are about 60 cm in body length. Mating takes place between the end of February and the middle of March. Sexual maturity is attained at 4–6 years in females and 6 years in males (Ognev, 1935; Fedoseev, 1975). The pregnancy rate of Caspian seals over 9 years was 31.3% (N = 16) in 1993 and 20% (N = 30) in 1997 and 1998.

Ringed seal pups, which are born between the middle of March and the middle of April, are on average 65 cm in body length and about 4.5 kg in body weight. They are always born on shore-fast ice, either in a lair under the snow, excavated by

the mother, or in a natural hollow in the ice. Ringed seals attain sexual maturity at 6–7 years old in both sexes with wide geographic variation from 3–5 years for *P. hispida botnica* to 6–10 years for *P. hispida hispida* (Frost and Lowry, 1981). The peak of mating activity probably occurs in mid-April, shortly after parturition and while the female is still lactating (King, 1964). The lactation period is nearly 2 months. In ringed seals, pregnancy rates of sexually mature females vary geographically: 91–92% in the Baffin Island area (McLaren, 1958; Smith, 1973), 86% in the southern Chukchi Sea (Johnson *et al.*, 1966), and 53% in Alaska waters in 1975–1977 (Frost and Lowry, 1981).

VI. Food

Baikal seals feed mainly on four fish species: the greater golomyanka (*Comephorus baicalensis*), the lesser golomyanka (*C. dybowskii*), the Baikal yellowfin sculpin (*Cottocomephorus grewingki*), and the longfin sculpin (*C. inermis*), all of which are not of commercial value. In captivity, an adult Baikal seal consumed up to 5.6 kg of fish per day (Pastukhov, 1969).

Caspian seals in the northern Caspian Sea feed on *Clupeonella engrauliformis, C. grimmi, C. delicata caspia*, Gobiidae, *Rutilus rutilus caspicus, Atherina mochon pontica, Lucioperca lucioperca*, other fish species, and crustaceans (Khuraskin and Pochtoyeva, 1997). It is estimated that an adult Caspian seal appears to take 2–3 kg fish per day, or approximately 1 ton of fish per year.

Ringed seals feed on small fish and also on a wide variety of small pelagic amphipods, euphausiids, and other crustaceans. Seventy-two food species were identified in the stomachs of seals from the eastern Canadian Arctic. In shallow, inshore waters, the seals feed near the bottom, chiefly on polar cod (*Boreogadus saida*) and on the small crustacean *Mysis*, whereas those in the deeper offshore waters catch the planktonic amphipod *Themisto libellula* (King, 1964).

VII. Population

The population of Baikal seals from 1971 to 1978 was estimated to be between 68,000 and 70,000 animals (Pastukhov, 1978a). The number of seals taken annually has varied: before 1917 about 2000 to 9000; in 1930 about 6000; and currently between 5000 and 6000 (Pastukhov, 1978b). In 1987–1988, an outbreak of morbillivirus infection resulted in a large mass mortality of Baikal seals (Grachev *et al.*, 1989). A mass death of Baikal seals also occurred in 1998.

The Caspian seal population declined from about 1 million animals early in the 20th century to 360,000–400,000 by the end of the 1980s (Krylov, 1990). According to Khuraskin and Pochtoyeva (1997), 115,000–174,000 animals have been hunted annually since the early 19th century. A total of 86,000 animals were killed in 1966. From 1970, seal hunting on the northern ice was limited to a catch of 20,000–25,000 pups. In the spring of 1997, a mass death of several thousand seals occurred.

A minimum population estimate for *P. hispida hispida* is 2.5 million (Bychkov, 1971), although there are many uncertainties in the estimation method, survey season, survey design, data analysis, and so on. Population size was estimated at 800,000–1,000,000 for *P. hispida ochotensis* (Bychkov, 1971), 10,000–50,000 for *P. hispida botnica* (Scheffer, 1958), 2000–5000 for *P. hispida saimensis* (Scheffer, 1958), and 5000–10,000 for *P. hispida ladogensis* (Scheffer, 1958). Many thousands of ringed seals are caught annually from all areas where they occur, mostly for their skins, which are used for leather or for their decorative fur, and also for blubber (King, 1964). A mass death of ringed seals was recorded in 1960 in the Baltic Sea and the North Sea.

Risso's Dolphin

Grampus griseus

Robin W. Baird
Dalhousie University, Halifax, Nova Scotia, Canada

The Risso's dolphin (*Grampus griseus*) is the fifth largest member of the family Delphinidae, with adults of both sexes reaching up to about 4 m in length. The common name comes from the person (Risso), who described the type specimen to G. Cuvier in 1812. Risso's dolphins are unusual looking for a variety of reasons. Their anterior body is extremely robust, tapering to a relatively narrow tail stock, and they have one of the tallest dorsal fins in proportion to body length of any cetacean (Fig. 1). The bulbous head has a distinct vertical crease or cleft along the anterior surface of the melon. Color patterns change dramatically with age. Infants are gray to brown dorsally and creamy-white ventrally, with a white anchor-shaped patch between the pectoral flippers, and white around the mouth. Calves then darken to nearly black, while retaining the ventral white patch. As they mature they lighten (except for the dorsal fin, which remains dark even in adults), and the majority of the dorsal and lateral surfaces of the body become covered with distinctive linear scars, most of which are presumably caused by intraspecific interactions. Older animals can appear almost completely white on the dorsal surface (Fig. 2). No evidence of SEXUAL DIMORPHISM exists. Dentition is unusual, with most individuals having no teeth in the upper jaw and only a small number (two to seven pairs) in the lower jaw. Some researchers have suggested that population division exists both between and within ocean basins (based on morphological data), though sample sizes are small, and no subspecies are currently recognized.

Figure 1 *The Risso's dolphin is one of the largest dolphins, characterized by a large dorsal fin, a bulbous head which possesses a distinct cleft on the anterior melon, and a robust body that nevertheless possesses a narrow tail stock. Photo by R. L. Pitman.*

Figure 2 *Color changes in Risso's dolphin. As adults they become lighter and lighter, as illustrated in this relatively light animal, especially as compared to the animal illustrated in Fig. 1. Photo by R. L. Pitman.*

Risso's dolphins are distributed worldwide in temperate and tropical oceans, with an apparent preference for steep shelf-edge habitats between about 400 and 1000 m deep (Fig. 3). Mass strandings of this species are very rare, and because they have not been taken in any numbers in whaling operations, relatively few specimens are available. Because of their typically offshore habits, relatively little is known about the biology or behavior of this species. The inshore presence of Risso's dolphins has been documented in several areas, and such movements have facilitated behavioral and population research. The range of Risso's dolphins seems to be limited by water temperature, with animals most common in waters between 15 and 20°C and rarely found in waters below 10°C. No worldwide population estimates exist, although a number of regional estimates are available.

Risso's dolphins are relatively gregarious in nature, typically traveling in groups of 10–50 individuals, with the largest group observed estimated to contain over 4000 individuals. They frequently travel with other cetaceans. Off southern California they have been documented to "bow ride" on and apparently harass gray whales (*Eschrichtius robustus*), and aggressive behavior directed toward short-finned pilot whales (*Globicephala macrorhynchus*) has also been observed. No evidence of predation by either killer whales (*Orcinus orca*) or large sharks is

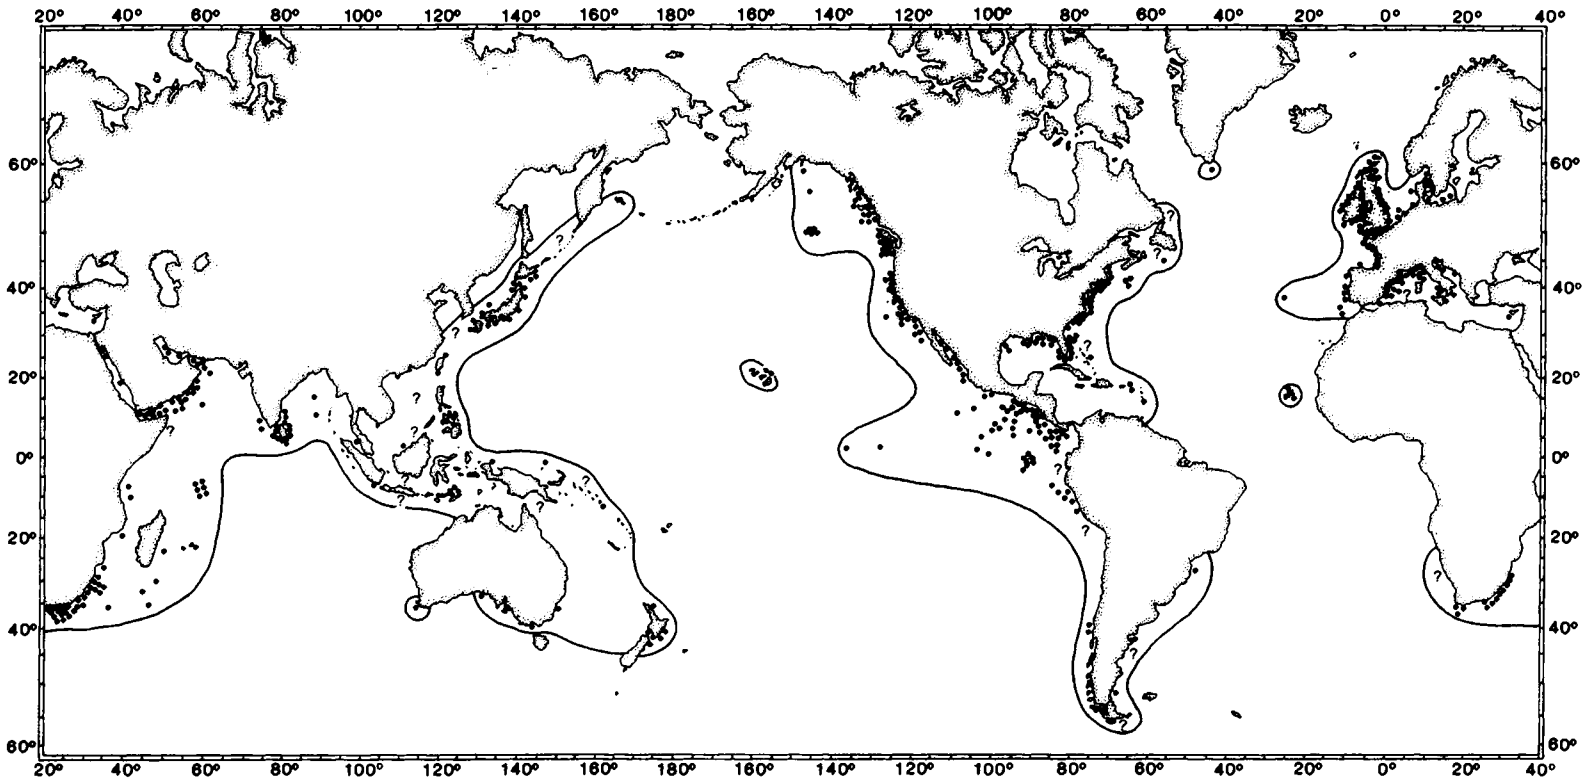

Figure 3 *The known distribution of Risso's dolphins. Dots represent actual sighting and stranding records. Question marks indicate records where the accurate geographical location was not given. From Kruse, Caldwell, and Caldwell (1999).*

available, although both likely prey on Risso's dolphins at least occasionally. Risso's dolphins are thought to feed almost entirely on squid (both neritic and oceanic species), and limited behavioral research suggests that they feed primarily at night. No studies on diving behavior have been undertaken.

Life history information for this species is relatively sparse. The maximum longevity of Risso's dolphins is likely over 30 years, although few aging studies have been undertaken, and growth layer deposition rates in teeth have not been calibrated. Age at sexual maturity and the calving interval are not known. There appears to be a peak in calving seasonality during the winter months.

Interactions with humans are diverse. While they occasionally BOW RIDE on vessels, in most cases Risso's seem to avoid boats. At least one strong exception exists: one Risso's dolphin, nicknamed "Pelorus Jack," escorted boats into Admiralty Bay in New Zealand for over 20 years. Risso's dolphins have been recorded stealing fish from long lines in a number of areas, and these interactions have often resulted in deliberate killing. Small numbers of Risso's dolphins have been killed in small-scale WHALING operations around the world, and off Sri Lanka, these takes may seriously jeopardize the local population. Risso's dolphins are also killed accidentally in fishing gear around the world. Risso's dolphins have been held in aquaria in both Japan and the United States, although they are relatively uncommon in CAPTIVITY compared to other species of cetaceans. A number of hybrids with bottlenose dolphins (*Tursiops truncatus*) have been documented in Japanese aquaria.

River Dolphins

RANDALL R. REEVES
Okapi Wildlife Associates, Hudson, Quebec, Canada

Most people are surprised to learn that some species of dolphins, and one porpoise species, live either entirely or partly in freshwater rivers and lakes. These animals are obviously exceptional, and they are the result of geologic processes that allowed (or forced) marine-adapted species to become established in inland waters. River dolphins exhibit some extreme characteristics in their morphology and sensory systems. They are also among the most seriously threatened cetaceans because their habitat and resources must be shared with many millions of people.

I. Definition and Distribution

The term "river dolphin" is not unambiguous. In Rice's (1998) evaluation of marine mammal SYSTEMATICS, for example, he assigned the term to the "peculiar long-snouted" dolphins in four single-species genera: *Platanista* (the Indian river dolphin), *Lipotes* (the Chinese or Yangtze river dolphin), *Inia* (the Amazon river dolphin), and *Pontoporia* (the La Plata dolphin). He also contends that each of these genera belongs to a separate family and that *Platanista* is the only living representative of the primitive superfamily Platanistoidea. The previous convention had been to consider the four morphologically similar species, or species groups, as all falling within the Platanistoidea. Although the genera *Lipotes* and *Pontoporia* are clearly monospecific, it has been customary to recognize two species of *Platanista*—the Indus dolphin (*P. minor*) and the Ganges dolphin (*P. gangetica*). Rice (1998) found no solid morphological evidence to distinguish them and thus proposed that they be considered subspecies: *P. gangetica minor* and *P. g. gangetica*. There is no question that the two populations have been totally isolated for a considerable time (at least hundreds of years). *P. g. minor* is confined to the Indus drainage in Pakistan, whereas *P. g. gangetica* occurs in the Ganges, Brahmaputra, Megna, Karnaphuli, and Sangu drainage systems of India, Bangladesh, and Nepal. There are three separate populations of the boto (*Inia geoffrensis*): the Bolivian subspecies *I. geoffrensis boliviensis* in the Madeira River drainage above the Teotonio Rapids at Porto Velho, the Amazonian subspecies *I. g. geoffrensis* distributed throughout the Amazon drainage basin except the upper Madeira system, and the Orinoco subspecies *I. g. humboldtiana* distributed throughout the Orinoco drainage basin (Fig. 1). The Yangtze River dolphin or baiji (*Lipotes vexillifer*) is endemic to China's Yangtze River system. In the past, it also occurred at least seasonally in the two large lakes, Dongting and Poyang, appended to the middle reaches of the Yangtze.

However tortuous the arguments may be with regard to the number of species or subspecies, and their systematic relationships, a more immediately practical way to define "river dolphins"

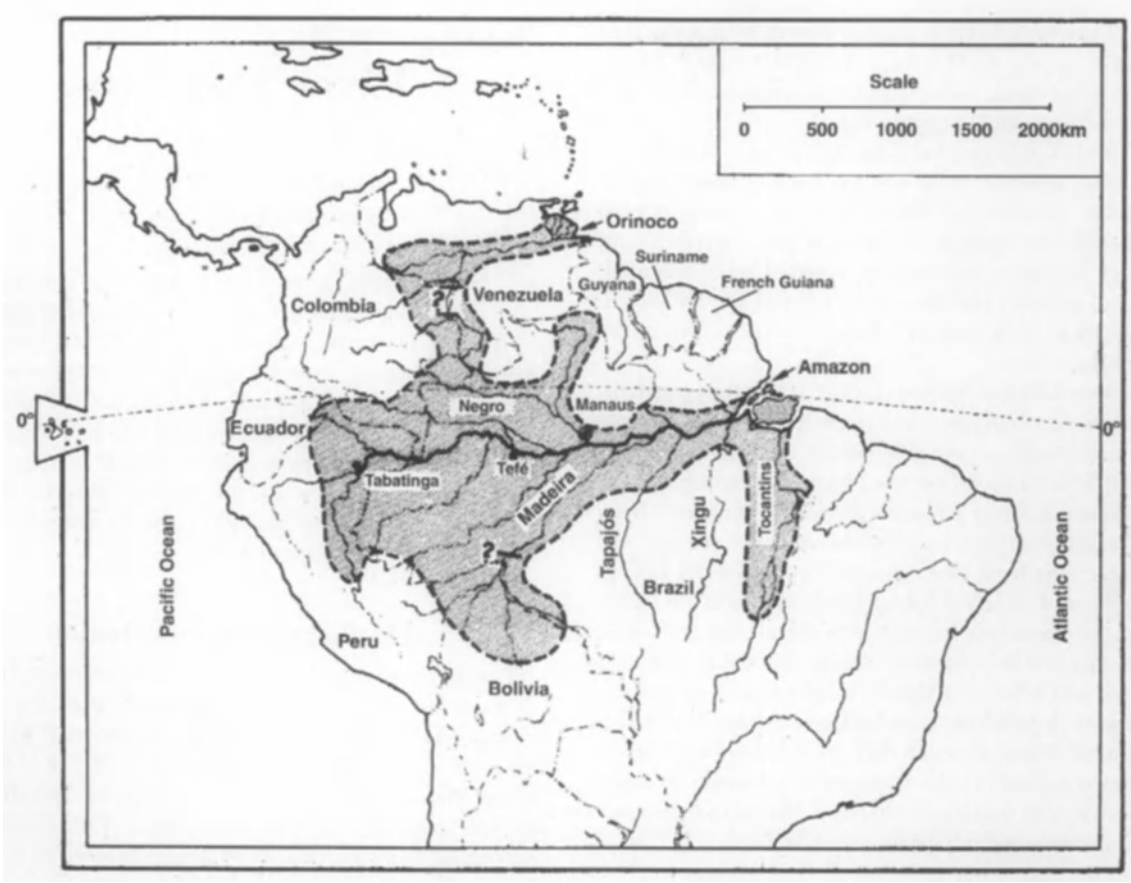

Figure 1 *Distribution of the boto, showing three main river systems inhabited. Upper "?" indicates likely barrier between Orinoco and Amazon subspecies; lower "?" indicates likely barrier between Amazon and Bolivian subspecies.*

is according to their present-day distribution and ecological position in nature. If river dolphins are defined only as those cetaceans that live solely or primarily in rivers, then the La Plata dolphin or franciscana (*Pontoporia blainvillei*) must be excluded because it lives in coastal marine waters of eastern South America, including the estuary of the Rio de la Plata (River Plate) between Argentina and Uruguay. At the same time, several species can be added to the list. The tucuxi (*Sotalia fluviatilis*) inhabits tropical coastal marine waters of eastern South and Central America but also lives far up the Amazon to the Andean foothills, frequently entering lakes and side channels as well as being abundant in the large, fast-flowing main rivers. The species also occurs in the lower Orinoco River and in the lower reaches of rivers in Guyana and Surinam. Rice (1998) recognizes two subspecies: the freshwater *S. f. fluviatilis* and the marine *S. f. guianensis*. The Irrawaddy dolphin (*Orcaella brevirostris*) similarly occurs in nearshore marine and estuarine waters of Southeast Asia, portions of Indonesia, and northern Australia, but it is also present far up several large rivers, including the Irrawaddy, Mekong, and Mahakam. With further study, there will almost certainly be grounds for recognizing subspecies and geographically separate populations of *Orcaella*. The finless porpoise (*Neophocaena phocaenoides*) also fits the category of a facultative freshwater cetacean. Although it occurs primarily in shallow marine and deltaic waters from the northern Arabian Sea, coastwise, to Japan, one population inhabits the Yangtze River and its adjoining lake systems to as far as 1670 km upriver from Shanghai. This population is classified as a separate subspecies (*N. p. asiaeorientalis*). Finless porpoises also have been known to occur at least several tens of kilometers up the Indus and Yalu rivers.

Regardless of how one defines them, the modern river cetaceans occur in only two continents: South America and Asia. Most questions regarding their origins and how they evolved remain unresolved. In the case of *Inia*, for example, one hypothesis is that their ancestors entered the Amazon basin from the Pacific Ocean approximately 15 million years ago, while another is that they entered from the Atlantic Ocean only 1.8–5 million years ago.

II. Behavior and Ecology

Little, in fact almost nothing, is known about river dolphin societies: how they are structured, how individuals coalesce and disperse to form associations, or whether bonds between individuals are long-lasting or transient. In general, these animals seem not to be highly social, with observed group sizes rarely exceeding 10 or 15 individuals. Yet the densities at which they exist, expressed in terms of individuals per unit area of water surface, sometimes far

Figure 2 *Despite the impression in this photo from Marineland of Florida that botos are sociable, a major problem with captive groups has been the extremely aggressive behavior of mature males. (Photograph from Caldwell, Caldwell, and Brill, 1989.)*

exceed those of marine cetaceans. For example, botos and tucuxis in portions of the upper Amazon system typically occur in densities of 1 to 10 individuals/km^2 (Vidal *et al.*, 1997).

The distribution of river cetaceans is far from random. They tend to congregate at particular points in a river, especially at confluences (where rivers or streams converge), sharp bends, and sandbanks, and near the downstream ends of islands. In a detailed study of the distribution of Ganges dolphins in Nepal's Karnali River, Smith (1993) found the animals primarily in eddy countercurrent systems of the main river channel. Such areas of interrupted flow occur when fine sand or silt is deposited as a result of stream convergence. It is not entirely clear why the dolphins are attracted to these sites, but it likely has some relation to prey availability and energy saving. As Smith (1993) points out, positions within eddies "require minimal energy to maintain but are near high-velocity currents where the dolphins can take advantage of passing fish." Large confluences may contain tens of dolphins at a given time, but such concentrations appear to be adventitious rather than formed for social reasons. In other words, noninteracting individuals are found in close proximity due to the clumped nature of resources and refugia in the river systems where they are found. There are, of course, differences in degrees of sociability among the species. The author has seen as many as 12–15 tucuxis actively herding prey fish against a riverbank in concert, whereas botos appear to be solitary hunters most of the time, even when they are chasing the same school of fish. This applies equally to Indus and Ganges dolphins, which always seem to be acting individually or in very small groups.

In addition to their freshwater habitat, river dolphins have a number of characteristics that set them apart from other cetaceans. The eyes of Indus and Ganges dolphins lack a crystalline lens, rendering the animals functionally blind. At most, they may be able to perceive gross differences between light and dark. Because most of their habitat is highly turbid, underwater VISION would be of little use. These dolphins usually swim on their side, with one flipper (most often the right one) trailing near the river bottom and the body oriented so that the tail end is somewhat higher in the water column than the head end. Their head nods constantly as they scan acoustically for prey and obstacles. Indus and Ganges dolphins remain active day and night. All river dolphins are endowed with a sophisticated biosonar system, but those other than the Indus and Ganges dolphins also have good vision.

All river dolphins have adapted to living in a highly dynamic environment. Although much of their habitat is silty, they also occur in areas where the water is clear, as in the upper reaches of the Ganges, or "black" (stained by tannic acid), as in many Amazon and Orinoco tributaries. Water levels in the lower Amazon can vary seasonally by as much as 10–12 m. During the dry season, the dolphins (and other fauna) are restricted to the deep channels of lakes and rivers, while during the flood season they can range widely. Amazon dolphins penetrate into rain forests and venture onto grasslands during the floods. Their DIET seems diverse, with at least 45 fish species from 18 families, plus crabs and river turtles, represented in examined stomach contents (Best, 1984). Both schooling and nonschooling fish species are eaten. Amazon dolphins are the only modern cetaceans with a differentiated dentition. The teeth in the front half of the jaw are conical, whereas those in the latter half have a flange on the inside portion of the crown, more reminiscent of molars (for crushing) than canines or incisors (for biting and holding). Presumably, this feature is related to the hard-bodied or spiny character of some of their prey (e.g., armored catfishes, even turtles); large catfish are often torn into smaller pieces before being eaten.

Irrawaddy dolphins engage in "cooperative fishing" with throw-net fishermen in Burma's Irrawaddy River (Smith *et al.*, 1997). The fishermen call the dolphins by repeatedly striking the sides of their canoes with a wooden pin. Then they slap the water surface with a paddle, utter a turkey-like call, and make several practice throws of the net. When conditions are favorable, the dolphins slap the surface with their flukes and begin herding the fish school toward the fishermen. With a signal from one of the dolphins (its partially submerged flukes waving laterally toward the fishermen), the net is thrown. According to the fishermen, catches made with the help of dolphins are consistently better that those made without their assistance. Not surprisingly, the animals are revered and protected by the residents of local fishing communities along the Irrawaddy.

III. Threats and Conservation Concerns

Any description of the river cetaceans must include a section on their conservation status. They are among the most endangered marine mammals (see Smith and Smith, 1998; Reeves *et al.*, 2000). The Yangtze River dolphin is probably the most critically endangered cetacean species. Discovered by Western science as recently as 1918, it apparently was still common and widely distributed along the entire Yangtze River, from Three Gorges to Shanghai, when China's Great Leap Forward began in the autumn of 1958. From that time, the baiji was hunted intensively for meat, oil, and leather. Although legally protected, Yangtze dolphins continue to die accidentally in fishing

gear, from collisions with powered vessels, and from exposure to underwater blasting during harbor construction. This mortality, combined with the effects of overfishing, pollution, industrial and vessel noise, and the damming of Yangtze tributaries, has driven the baiji population to the brink of EXTINCTION. Only a few tens of individuals are thought to survive. The finless porpoise that share much of this river dolphin's historical range have also been declining rapidly in recent years, presumably for the same reasons. Efforts to protect both species have been far from adequate. As the controversy surrounding construction of the Three Gorges Dam in the upper Yangtze River has eloquently demonstrated, China is committed to a course that places further industrial development of the Yangtze basin far ahead of preserving the natural environment (Zhou *et al.*, 1998).

The Indus and Ganges dolphins are also classified as endangered, with the former numbering about a thousand and the latter possibly in the low thousands. Indus dolphins occur today only in the main channel of the river, although historically they inhabited several large tributaries as well (Sutlej, Ravi, Chenab, and Jhelum). Their population has been fragmented by irrigation dams, and the subpopulations trapped upriver of these dams have progressively gone extinct. Now, only three subpopulations of Indus dolphins are large enough to be considered potentially viable. The Ganges dolphin has also lost large segments of upstream habitat as a result of dam construction, but its generally broader distribution has meant that it is less immediately threatened with extinction. Like the baiji and Yangtze finless porpoise, the Indus and Ganges dolphins are subjected to incidental capture in fishing gear, especially gill nets. An additional concern for the Ganges dolphin is that fishermen in some parts of India and Bangladesh use dolphin oil as an attractant while fishing for a highly esteemed species of catfish. This means that there is a demand for carcasses and a disincentive for releasing live dolphins found in nets. Some tribal people in remote reaches of the Ganges and Brahmaputra still hunt dolphins for food.

Ultimately, all river cetaceans are threatened by the transformation of their habitat to serve human needs. In addition to impeding the natural movements of dolphins and other aquatic organisms, dams in southern Asia divert water to irrigate farm fields and supply homes and businesses in an arid landscape, reducing directly the amount of habitat available to the dolphins. As water becomes an increasingly strategic resource in a warming world with burgeoning human populations, the prospects for river cetaceans are certain to deteriorate even further.

River Dolphins, Evolutionary History

CHRISTIAN DE MUIZON
National Museum of Natural History, Paris, France

The term "river dolphins" has been used traditionally to include the Recent odontocetes living in fresh waters and of which affinities to other groups of odontocetes were unclear. They have been generally included in the superfamily Platanistoidea, mainly because of their freshwater habitat and because they present many plesiomorphic characters relative to other groups such as delphinoids, physeteroids, or ziphiids (e.g., Slijper, 1936; Simpson, 1945). The four genera of living "river dolphins" (*Platanista, Lipotes, Inia,* and *Pontoporia*) were, therefore, regarded as belonging to a monophyletic group of primitive odontocetes. Other freshwater (but also partly marine) odontocetes, such as *Orcaella* (Irrawaddy River dolphin) and *Sotalia fluviatilis* (tucuxi), were not included in Platanistoidea because of their unanimously accepted close affinities to Delphinoidea. While there was a widespread assumption of their monophyly, the affinities of recent Platanistoids (i.e., "river dolphins") and referred fossil genera to other living and fossil groups of odontocetes have long been very confused and interpretations diverse. The "platanistoids" or some of their included taxa have been regarded as closely related to several groups of fossil odontocetes, e.g., Squalodontidae, Eurhinodelphinidae, and "Acrodelphinidae."

A possible para- or polyphyly of the traditional concept of Platanistoidea was first considered by Muizon (1984) and was confirmed by further studies (e.g., Muizon, 1987, 1988, 1991, 1994; Heyning, 1989; Fordyce, 1994; Messenger and McGuire, 1998). As expressed in these studies, there now seems to be a consensus on the nonmonophyly of the "river dolphins" and their fossil relatives (Fig. 1). The genus *Platanista* appears to belong to an early diverging group of odontocetes, and the three other genera (*Lipotes, Pontoporia,* and *Inia*) are regarded as closely related to Delphinoidea. *Platanista* is the Recent representative of a monophyletic group of odontocetes, the Platanistoidea, which was well diversified and widely distributed during the Oligocene and the Miocene. This group, in addition to Platanistidae, includes the fossil families Prosqualodontidae, Squalodontidae, Waipatiidae, Squalodelphinidae, and possibly Dalpiazinidae. The other "river dolphins" are included with Delphinoidea within the monophyletic infraorder Delphinida (Muizon, 1988). There is no consensus on their position within Delphinida, although they are generally regarded as basal taxa.

I. Platanistoidea

This monophyletic superfamily of odontocetes includes one Recent genus (*Platanista*) and approximately 15 fossil taxa (according to interpretations) (see Fordyce and Muizon, 2001). As recommended by Muizon (1987) and Fordyce and Muizon (2001), only the genera based, at least, on reasonably complete cranial remains, including ear bones are considered. The monophyly of Platanistoidea is supported by several synapomorphies such as the reduction or loss of the coracoid process of the scapula, the development of an articular ridge or peg on the periotic, and the ventral deflection of the anterior process of the periotic

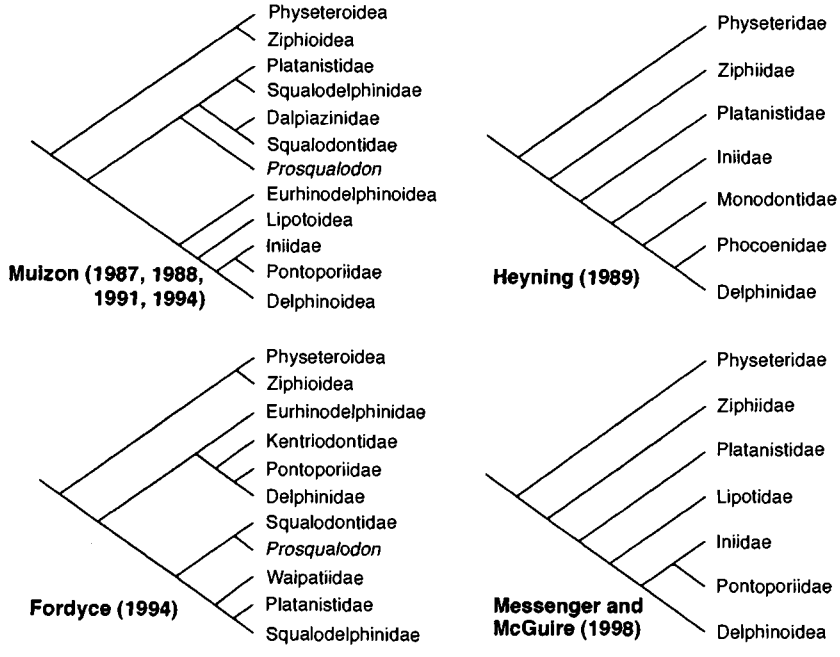

Figure 1 *Cladograms of recent hypotheses on the affinities of "river dolphins."*

(Muizon, 1994; Fordyce, 1994). This superfamily includes five (possibly six) families: Squalodontidae, Prosqualodontidae, Dalpiazinidae, Waipatiidae, Squalodelphinidae, and Platanistidae. In contrast to their Recent representative, all the fossil platanistoids are marine, which would indicate that adaptation to a freshwater environment is probably a derived condition.

A. Squalodontidae

Squalodonts are the most common fossil platanistoids. They are also called "shark-toothed" dolphins because of their heterodont dentition, with the posterior teeth being triangular with roughly or finely serrated edges resembling shark teeth. This plesiomorphic condition has often been one of the major arguments to refer many fossil taxa to this family. As a consequence, until recently, the Squalodontidae represented a waste basket of fossil odontocetes with heterodont dentition. Squalodontid genera based on partial or complete skulls are *Squalodon*, *Kelloggia* (a possible synonym of *Squalodon*), *Eosqualodon*, and *Phoberodon*. Synapomorphies of Squalodontidae as defined by Fordyce (1994) are essentially based on the morphology of the periotic, a bone unknown in *Phoberodon*, *Eosqualodon*, and *Kelloggia*. Muizon (1991, 1994) has proposed some cranial synapomorphies of the Squalodontidae, some of which, as mentioned by Fordyce (1994), are probably not securely established. Therefore, it is clear that the monophyly of Squalodontidae still has to be confirmed by a more thorough study of their auditory region. Furthermore, a better knowledge of the anatomy of the enigmatic genus *Patriocetus* could confirm its introduction into the Squalodontidae, as proposed by Rothausen (1968).

Squalodontidae present the scapula synapomorphies of Platanistoidea (however, this bone is unknown in *Eosqualodon* and incomplete in *Phoberodon*). Some other synapomorphies, present in all the Platanistoids except *Prosqualodon*, are incipiently developed in Squalodontidae; such as the overlap of the palatine by the maxilla and the presence of a shallow subcircular fossa in the squamosal dorsolateral to the periotic (see Muizon, 1987, 1991, 1994).

Squalodontidae are cosmopolitan basal platanistoids. All their remains were found in marine coastal environments. *Squalodon* is present in the Miocene of Europe, Asia, and North America; *Eosqualodon* is present in the Miocene of Europe; *Kelloggia* is present in the late Oligocene of Asia; and *Phoberodon* is from the early Miocene of South America. Undescribed squalodontids have also been found in Australia and New Zealand (Fordyce and Muizon, 2001). Squalodontids are relatively large odontocetes approaching the size of the living *Mesoplodon* spp. (beaked whales). They had a long rostrum with strongly procumbent anterior teeth (Fig. 2). In fact, the medial incisors were almost horizontal. The teeth were strongly heterodont. The vertex was low and the skull was symmetrical. As in all platanistoids, Squalodontidae have enlarged and slightly concave premaxillary fossae anterolateral to the nares. These fossae received premaxillary sacs of the nasal tract. Premaxillary sacs are tightly related to the presence of nasal plugs and melon, and their presence in Squalodontidae is an indication of efficient echolocation ability.

B. Prosqualodontidae

The single genus *Prosqualodon* is included in this family. Initially placed in Squalodontidae (e.g., Simpson, 1945; Rothausen, 1968), *Prosqualodon* has been removed from this family by Muizon (1991) because it does not possess the synapomorphies of the auditory region observed in other platanistoids; however, it was maintained in the superfamily because it bears the scapula synapomorphies of the group. Therefore, *Prosqualodon* would be the sister group of all the other platanistoids. However, *Prosqualodon* has also been regarded as member of the the infraorder Delphinida on the basis of the presence of the same apomorphic character of the palatine [presence of a lateral lam-

ina as defined by Muizon (1988)] in the two groups. In fact, as stated by Muizon (1994), the palatine-derived character in Delphinida. Fordyce (1994) regarded *Prosqualodon* as the sister taxon of *Squalodon*, whereas Fordyce and Muizon (2000) retained the taxon Prosqualodontidae, which they regard as a platanistoid family, although they state that *Prosqualodon* could also be a squalodontid.

Prosqualodon is an austral genus that has been found so far in the early Miocene of Argentina, Australia, and New Zealand. It is a medium-sized odontocete, and its size ranges from a small *Globicephala* (pilot whale) to a large *Tursiops* (bottlenose dolphin). As squalodontids, *Prosqualodon* had heterodont teeth. The anterior teeth are elongated conically and project anteroventally; the posterior teeth are triangular, low, transversely compressed with a rugose enamel, and bear several denticles on their anterior and posterior crests. The rostrum is short, the vertex is symmetrical, and the braincase is lower than in *Squalodon*. Premaxillary fossae are clearly present but they are less developed and shallower than in *Squalodon* (Fig. 3).

C. Dalpiazinidae

The single known genus of the family, *Dalpiazina*, has been related to the Platanistoidea on the presence of several similarities that it shares with *Squalodon* (see Muizon, 1991, 1994). However, it is noteworthy that none of the platanistoid synapomorphies are observable on the specimens available and, therefore, the affinities of this family still have to be confirmed. *Dalpiazina* is a medium-sized odontocete (like a small *Tursiops*). The rostrum is relatively long and bears homodont dentition. It is known from the early Miocene of Italy, and some possible dalpiazinids have been discovered in New Zealand (Fordyce *et al.*, 1994).

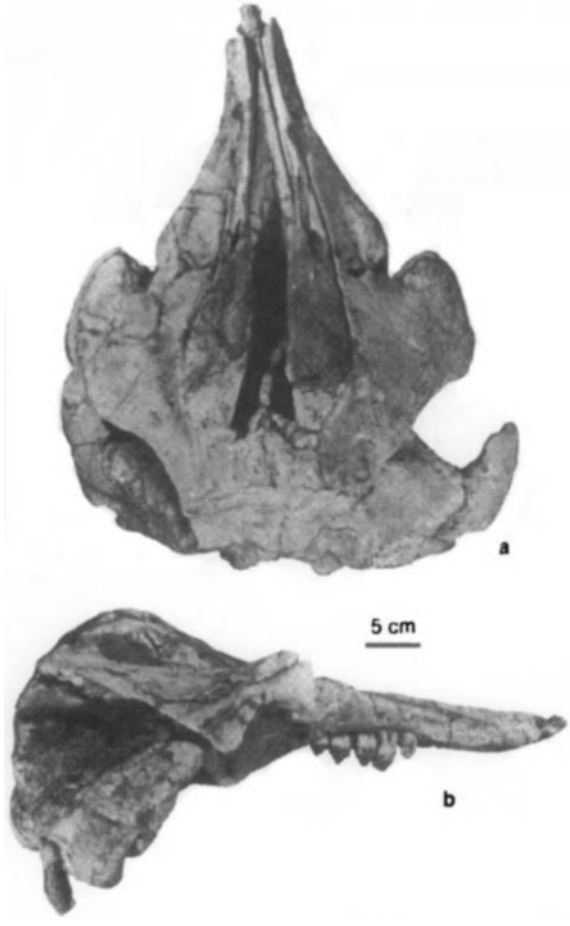

Figure 3 *Skull of* Prosqualodon australis *(early Miocene, Argentina) in dorsal (a) and lateral (b) views.*

D. Waipatiidae

Waipatia is known from a nearly complete skull with ear bones and partial skeleton. This genus presents the auditory region synapomorphies of the platanistoids and, although its scapula is unknown, is better placed in this superfamily than in any other group of odontocete (Fordyce, 1994; Fordyce and Muizon, 2001). It is a medium-sized platanistoid similar in size to *Tursiops*. The rostrum is long and slender (Fig. 4). It bears heterodont teeth but the posterior triangular and double-rooted teeth are smaller than in Squalodontidae. The incisors are conical and strongly procumbent. The skull roof is very low as in squalodontids. The skull of *Waipatia* shows clear directional asymmetry of the bones. The premaxillary fossae are well developed, and the premaxillae extend posteriorly to the nasals and contact the frontals on the vertex as in the other platanistoids. *Waipatia maerewhenua*, the single species clearly referred to this family, is from the late Oligocene of New Zealand.

Sulakocetus is a primitive odontocete from the late Oligocene of Asia (Caucasus). It bears heterodont dentition but its posterior double-rooted teeth are small as in *Waipatia*. Apparently the periotic of the single known skull is unknown (or unprepared) but its tympanic is squalodont-like. The scapula bears a small coracoid process. Because of this character, *Sulakocetus* should be excluded from Platanistoidea. However, it is probable that the small (reduced) size of the process represents an incipient development of the platanistoid condition. This genus has been classified by Fordyce and Muizon (2001) as a possible waipatiid. However, it is clear that more information on its auditory region is needed to clarify the systematic position of *Sulakocetus*.

E. Squalodelphinidae

This family includes the genera *Notocetus*, *Medocinia*, *Phocageneus*, and *Squalodelphis*. The four taxa are based on reasonably well-preserved skulls and/or ear bones. Squalodelphinidae present the platanistoid synapomorphies of the scapula (loss of the coracoid process, anterior position of the acromion) and of the ear region (e.g., subcircular fossa, articular ridge of the periotic, morphology of the apex of the tympanic) (see Muizon, 1987, 1994). Squalodelphinidae are cosmopolitan and marine. *Notocetus* is from the early Miocene of South America and New Zealand; *Squalodelphis* and *Medocinia* are from the early to middle Miocene of Europe; and *Phocageneus* is from the early Miocene of North America. Squalodelphinidae are medium-sized odontocetes similar in size to (to slightly smaller than) the living *Tursiops*. The rostrum is of moderate length and slender (Fig. 5). The teeth are more or less homodont: the posterior teeth are single rooted but they are clearly lower and

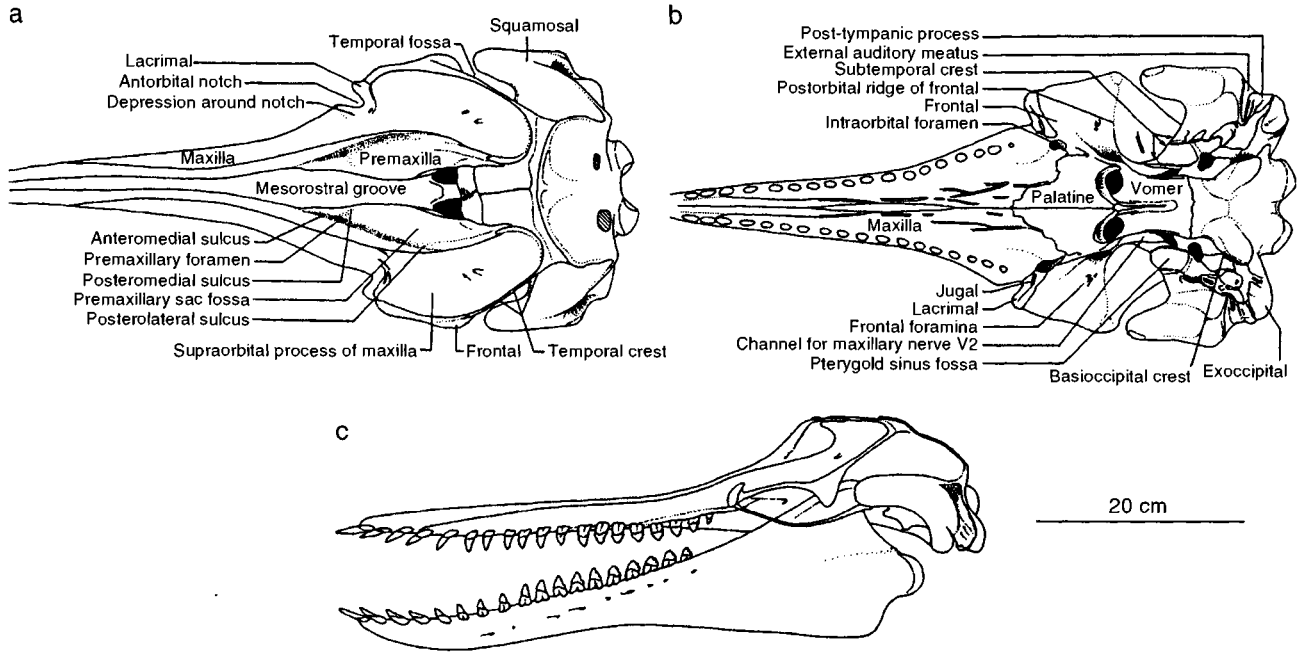

Figure 4 *Reconstruction of the skull of* Waipatia maerewhenua *(late Oligocene, New Zealand): (a) dorsal, (b) ventral, (c) lateral views [from Fordyce (1994), modified]. Reproduced with permission of the San Diego Society of Natural History.*

more triangular than the anterior. An interesting characteristic of Squalodelphinidae is the thickening of the supraorbital region of the skull (maxilla and/or frontal) (Figs. 5b and 5d). This condition seems to foreshadow the extreme morphology observed in Platanistidae (see later and Fig. 6).

F. Platanistidae

Platanistidae are represented in the fossil record by two genera: *Zarhachis* and *Pomatodelphis* (Fig. 6). They both show all the Platanistoid synapomorphies of the ear region, palatine, and scapula. The main characteristic of Platanistidae is the development of large maxillary (*Platanista*) or maxillofrontal (*Zarhachis, Pomatodelphis*) crests, which are already incipiently developed in Squalodelphinidae (see earlier discussion). A peculiarity of *Platanista* is the fact that the palatine is entirely covered by the maxilla and the pterygoid. In *Zarhachis* and *Pomatodelphis* this condition is incipiently developed, as the palatine is partially covered (Muizon, 1987, 1994) and the visible

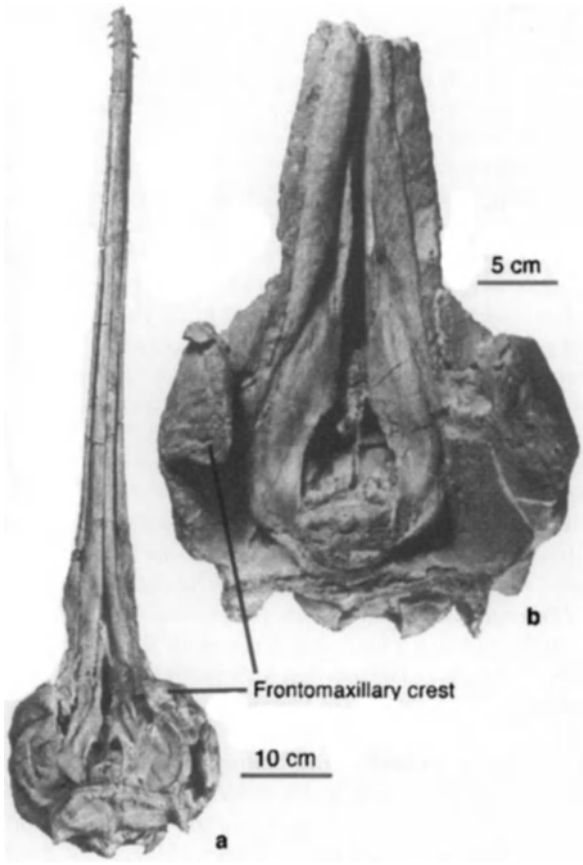

Figure 6 *Skulls of Platanistidae: (a)* Pomatodelphis *cf.* inaequalis *(middle Miocene, Maryland) skull in dorsal view and (b)* Zarhachis flagellator *(middle Miocene, Maryland) skull (most of the rostrum missing) in dorsal view.*

portion of the bone is displaced laterally. Both genera have a very long and slender rostrum bearing homodont teeth. *Zarhachis* is slightly larger than *Pomatodelphis* and approaches the size of a small *Mesoplodon*. *Allodelphis* has been regarded as a platanistid; however, this genus is still too poorly known to be clearly referred to this family. It is provisionally considered to be a platanistoid, pending discovery of more complete specimens. The two undoubted fossil palatanistids, *Zarhachis* and *Pomatodelphis*, were found in a marine environment. They are from the middle Miocene of North America and Europe (*Pomatodelphis* only). No fossil platanistids have been found so far, neither in the Southern Hemisphere nor in Asia, and it is possible that the family had a Tethyan distribution.

II. Nonplatanistoid "River Dolphins"

These are represented by the Recent families Lipotidae (*Lipotes*), Iniidae (*Inia*), and Pontoporiidae (*Pontoporia blainvillei*, the franciscana). Most authors recognize the three families, however, some authors place the three genera in the same family, Iniidae (Heyning, 1989), whereas others (Fordyce *et al.*, 1994) recognize only two families: Pontoporiidae (*Pontoporia* and *Lipotes*) and Iniidae (*Inia*).

Fordyce and Muizon (2001) recognized three families because the three groups probably do not represent a monophyletic unit. They are included in the infraorder Delphinida on the basis of several synapomorphies (Muizon, 1988), such as the development of a lateral lamina of the palatine, the sigmoid morphology of the involucrum of the tympanic and its posterior excavation, the development of a ventral rim on the ventromedial face of the anterior process of the periotic, and the increase in size of the processus muscularis of the malleus. Lipotidae are the earliest divergent Delphinida. The other Delphinida [Inioidea (Iniidae+Pontoporiidae) and Delphinoidea] differ from Lipotidae in the following synapomorphies: reduction of the anterior process of the periotic, which loses the bullar facet; increase in size of the processus muscularis of the malleus, which is distinctly more developed than the manubrium; and presence of a pair of ventral processes on the anterior region of the sternal manubrium (Muizon, 1988). The second diverging clade is Inioidea. The third clade, Delphinoidea, presents an apomorphic thickening of the apex of the anterior process of the periotic and a great reduction of the dorsal portion of the transverse process of the atlas. Therefore, Delphinida include three superfamilies of odontocetes: Lipotoidea, Inoidea, and Delphinoidea (Muizon, 1988). These phylogenetic hypotheses on the nonplatanistoid "river dolphin" have been partly confirmed by Messenger and McGuire (1998).

A. Lipotoidea

This monofamilial superfamily includes two genera: *Lipotes* (Recent, China) and *Parapontoporia* (Neogene, west coast of North America). *Prolipotes* from the Miocene of China is based on a nondiagnostic mandible fragment and is regarded as incertae sedis (Fordyce and Muizon, 2001).

Parapontoporia (Fig. 7) is regarded here as a lipotid, although classified by its author (Barnes, 1985) in Pontoporiidae. However, as noted by Barnes (1985) and Muizon (1988), the periotic of *Parapontoporia* is extremely similar to that of *Lipotes vexillifer*, the baiji, and bears no resemblance to that of pontoporiids. In fact, Barnes (1985) noted that *Parapontoporia* was more similar in many aspects of its skull to *Lipotes* than to *Pontoporia*. The skull of *Parapontoporia* displays a distinct narrowing at the base of the rostrum, which is always present in *Lipotes* and generally absent in pontoporiids (when present in *Pontoporia* it is weak); *Parapontoporia* does not bear the premaxillary eminences that are present in all pontoporiids and iniids; the nasals of *Parapontoporia* tend to be approximately vertical and not horizontal as in pontoporiids.

Parapontoporia is the only fossil lipotid based on good cranial material. Whereas its braincase is only slightly larger than that of *Lipotes*, its rostrum is almost twice as long. The asymmetry is less pronounced than in *Lipotes* but distinct. The teeth are small, single cusped, and numerous (ca. 80 on each side). In *Lipotes* the number of teeth varies from 30 to 36. Lipotids are known in the Northern Hemisphere only (China and California) and it is possible that the evolutionary history of the family took place in the North Pacific.

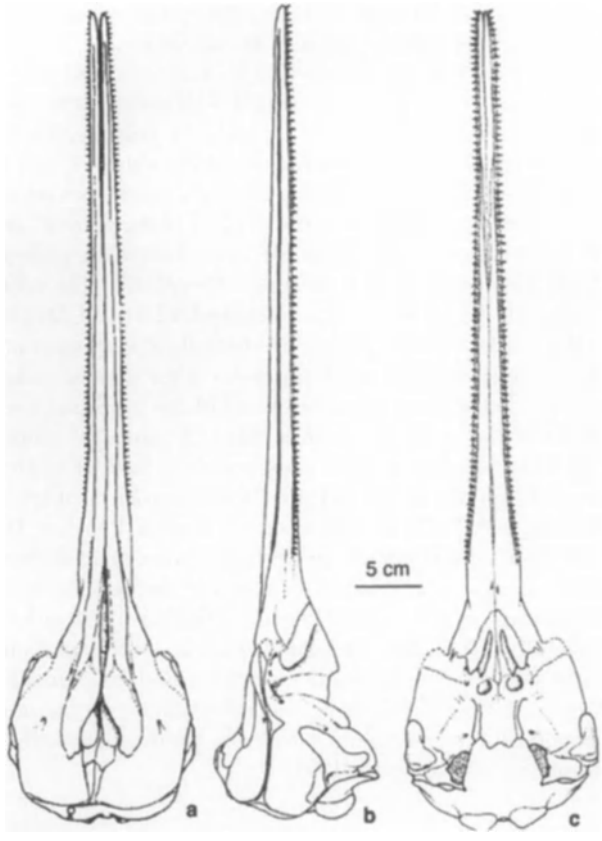

Figure 7 *Reconstruction of the skull of* Parapontoporia sternbergi *(early Pliocene, California): dorsal (a), ventral (b), and lateral (c) views [from Barnes (1985), modified]. Reproduced with permission of the Contributions to Science, Los Angeles County Museum of Natural History.*

B. Inioidea

This superfamily includes Iniidae and Pontoporiidae. The two families share synapomorphies of the periotic (great reduction of the anterior and posterior processes), malleus (unique extreme development of the processus muscularis), premaxilla (presence of premaxillary eminences), and maxilla (frontomaxillary crests: dorsal inflexion of the postorbital edges of the maxilla and frontal). The superfamily is documented by a few well-established fossil genera mostly from South America.

Iniidae are represented in the fossil record by a single genus known by relatively well-preserved cranial remains: *Ischyrorhynchus*. Genera *Saurocetes*, *Plicodontinia*, *Hesperocetus*, *Hesperoinia*, and *Lonchodelphis*, which have been related to Iniidae, are based on nondiagnostic rostra, mandible fragments, or isolated teeth. Although they could be referrable to this family, these genera should be regarded as incertae sedis pending further cranial discoveries. *Goniodelphis* is based on a partial skull, which probably belongs to an iniid. However, because of its incompleteness, this specimen has been only tentatively referred to the family by Fordyce and Muizon (2001).

One of the major characteristics of Iniidae (*Ischyrorhynchus* and *Inia geoffrensis*, the Amazon river dolphin or boto) is the development of a frontal hump on the vertex, which is expanded at its apex. Iniidae also present an extreme reduction of the posterior process of the periotic.

Ischyrorhynchus is approximately 30% larger than *Inia* and its rostrum is proportionally longer. In addition to these features, *Ischyrorhynchus* is very similar to the Recent iniid. It is from the late Miocene of the Paraná Basin (Argentina) and, therefore, was living in a freshwater environment.

Pontoporiidae are known by two fossil genera based on well-preserved cranial remains (with associated ear bones): *Pliopontos* and *Brachydelphis* (Fig. 8). *Pontistes* is another pontoporiid and is based on a single partial skull with a well-preserved vertex. *Pontivaga* has been referred to the pontoporiids; however, this genus, which is based on a partial mandible, is regarded as incertae sedis.

Pontoporiidae share synapomorphies such as a low vertex with flat subhorizontal nasals and the posterior extension of the posterior process of the periotic, which becomes blade-like.

Pliopontos is 50% larger than *Pontoporia*. As in the recent taxon, the rostrum is long and slender with sharp small teeth. Except for its size, *Pliopontos* is very similar to *Pontoporia*. It is from the early Pliocene of Peru and was marine. *Brachydelphis* is a much less classical pontoporiid. It has a very short rostrum, which is as long as the braincase. The latter is much larger than in *Pontoporia* and is similar in size to that of *Pliopontos*. Because of these unique features for a pontoporiid, *Brachydelphis* has been placed in its own subfamily, the Brachydelphinae. It is from the middle Miocene of Peru and lived in a marine environment.

III. Conclusions

There is now a consensus that odontocete taxa which were traditionally placed in the "river dolphins" (the "Platanistoidea" of Simpson 1945) belong to two different groups of dolphins: Platanistoidea, which are an early divergent superfamily of odontocetes, and Inioidea and Lipotoidea, which are included in Delphinida (Lipotoidea + Inioidea + Delphinoidea). Platanistoidea represent the sister group of a clade which includes Delphinida and the fossil superfamily Eurhinodelphinoidea (Fig. 1). Therefore, the "river dolphins" represent a polyphyletic group. They are paraphyletic if only Recent taxa are taken into account. Even the nonplatanistoid "river dolphins" do not represent a monophyletic grouping. Fossil platanistoids are diverse and distributed into several families. Fossil lipotids and inioids are still relatively scarce but can be easily related to one of the three non-platanistoid families of "river dolphins."

As stated earlier, most fossil "river dolphins" are from a marine environment and adaptation to fresh water is a convergence in at least in three groups: Platanistidae, Lipotidae, and Inioidea. Adaptation to this environment also appeared independently in two delphinoids (*Orcaella* and *Sotalia*). It therefore appears necessary to avoid the use of the term "river dolphins," an ecological grouping which is not monophyletic, especially when fossil taxa are considered.

River Dolphins, Relationships

JOHN HEYNING
Natural History Museum of Los Angeles County, California

The term "river dolphin" classically includes among the living species the boto (*Inia geoffrensis*), the franciscana (*Pontoporia blainvillei*), the baiji (*Lipotes vexillifer*), and the Indian river dolphin (*Platanista gangetica*). The boto resides in the freshwater rivers of the Amazon and Orinoco drainage, the Indian river dolphin in the Indian subcontinent rivers of the Ganges and Indus River systems, and the baiji in the Yangtze River. However, the franciscana is a "river dolphin" that lives in the coastal marine environments of eastern South America. To add confusion to this already perplexing terminology, several species of distantly related "oceanic dolphins" (family Delphinidae) such as the Irrawaddy River dolphin (*Orcaella brevirostris*) live in freshwater as well as in the ocean.

In former times, scientists classified these four living genera of "river dolphins" together into the family Platanistidae nestled within the superfamily Platanistoidea based more or less on the following logic: they all have long, narrow jaws with primitive architecture of the skull relating to their jaw closing muscles (Fig. 1) and they all inhabit freshwater (the franciscana was described from a specimen found in the mouth of the La Plata River).

The evolutionary status of the superfamily Platanistoidea is problematic in this classical usage. However, virtually all modern phylogenetic analyses indicate that *Platanista* is not closely related to the other extant river dolphins. The only character that appears to unite the river dolphins is the presence of a long mandibular symphysis, a feature that seems to have evolved in parallel. Consequently, the river dolphins have been split into two clades: the Platanistidae and the Iniidae.

I. Family Platanistidae

The modern members of this taxon include the river dolphins of the Indian subcontinent of the genus *Platanista*. These riverine cetaceans have an extremely long snout with teeth of the greatest length at the end of the snout. In this regard, *Platanista* resembles the crocodilian gavials that inhabit the same waters. *Platanista* is also called the blind river dolphin for it lacks a functional eye lens and therefore cannot discern detailed visual images, only degrees of light and dark. As this dolphin inhabits waters that are consistently turbid, sight has limited value. Two synapomorphies unite this family, including the distinctive maxillary crests (Fig. 1). These impressive crests that dominate the top of the skull can be seen less formed in the Miocene form *Zarhachis*.

In one recent cladistic analysis, the family Platanistidae fell into a clade with the extinct families Waipatiidae, Squalodontidae, and Squalodelphidae. The Squalodontidae, or the shark-toothed dolphins, are typified by relatively larger shark-like, sectorial cheek teeth with stoutly built skulls to accommodate large jaw muscles. Squalodonts were a rather common and widely distributed group that flourished during the late Oligocene through the Miocene.

II. Family Iniidae

The Iniidae, as defined herein, are united by three distinct morphological synapomorphies. In the classification used here, there are three extant species of river dolphins in the family Iniidae: *Inia geoffrensis*, *Pontoporia blainvillei*, and *Lipotes vexillifer*. Some taxonomists have separated each of these genera variously into its own family. Such splitting does not negate the conclusion that all these species form a clade, but merely reflects one's interpretation of "how different" the species are from each other.

The Late Miocene or Pliocene *Ischyrorhynchus* and *Saurodelphis* from fluvial deposits of South America are considered related to *Inia*. The only fossil taxon related to *Lipotes* is *Prolipotes* based on a fragment of mandible recovered from freshwater Neogene deposits of China. The extinct long-snouted genus *Parapontoporia* is considered to be intermediate between *Pontoporia* and *Lipotes* by some workers and similar to *Lipotes* by others. *Parapontoporia* is found in Late

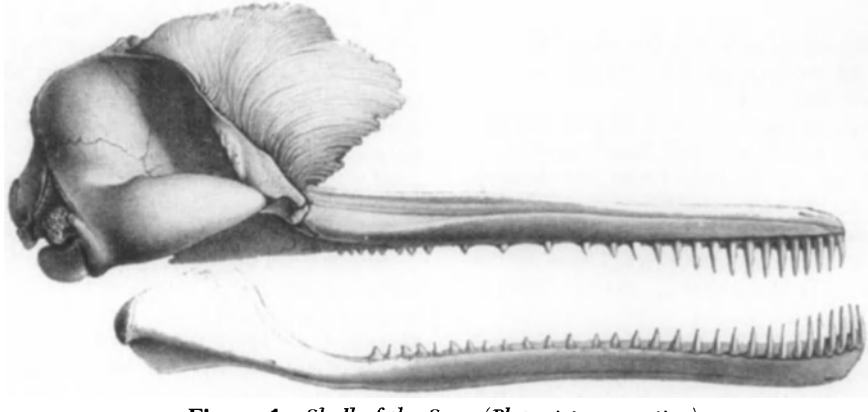

Figure 1 *Skull of the Susu (Platanista gangetica).*

Miocene to Pliocene marine deposits along the eastern North Pacific where it apparently was quite common.

The family Iniidae is currently considered most closely related to the Delphinoidea (the modern dolphins, porpoises, and their relatives) by two synapomorphies: the presence of a vestibular sac along the nasal passages and the reduction of the attachment of the ear bones to the skull. These characters provide evidence that the two groups share a common ancestry. In fact, some of the most primitive delphinoids have been classified as iniids in the past.

Rookeries

GEORGE ANTHONY ANTONELIS
National Marine Fisheries Service, Honolulu, Hawaii

Pinnipeds reproduce in a wide range of marine habitats, including various forms of ice, tidal flats, rock outcroppings, and coastal beaches (Scheffer, 1958). Some species form annual breeding aggregations at traditional locations known as rookeries. These reproductive sites are an integral component of the animals' life history patterns, resulting from a complex suite of adaptive factors involving physiology, morphology, ECOLOGY, and DISTRIBUTION. Rookery-breeding pinnipeds exhibit varying forms of polygyny (Boness, 1991); this mode of social organization is believed to have evolved as a consequence of two key traits: parturition on solid substrate and offshore marine foraging (Bartholomew, 1970). The influence of these traits in conjunction with phylogenetic and ecological constraints has likely influenced the development of the polygynous mating systems observed on rookeries today (Emlin and Oring, 1977; Stirling, 1983; Boness, 1991; Boyd, 1991).

Rookery-breeding pinnipeds are subdivided into two families: Otariidae and Phocidae. Rookeries are formed by all otariids (15 species) and three phocids [2 species of elephant seal, *Mirounga angustirostris* and *M. leonina*, and gray seals, *Halichoerus grypus* (Reeves *et al.*, 1992; Rice, 1998)]. This article describes the salient social–biological, physical–geographical, and environmental characteristics of pinniped rookeries and provides information on the ecological context in which they occur.

I. Social–Biological Characteristics

Rookeries are formed at specific times and locations, which optimize the reproductive success and survival of offspring (Bartholomew, 1970; Stirling, 1983; Boyd, 1991). After foraging at sea during the nonbreeding season, adult males return to rookeries and begin establishing territories shortly before or about the same time as the arrival of parturient females. Overt aggression, frequent threat vocalizations, and ritualized boundary displays are common among males when establishing and defending territories (Fig. 1). Males also attempt to herd females in an effort to keep them within their areas of influence (Fig. 2). Adult females come ashore to find suitable parturition sites and tend to be highly gregarious. Parturient females frequently threaten one another either vocally or visually and are often aggressive toward offspring of other females. Otariid females suckle their pups for about 4–12 months, although longer periods have been documented for some species (Oftedal *et al.*, 1987; Bowen, 1991). Lactation of rookery-breeding phocid females lasts about 0.5 (gray seals) to 1.0 (elephant seals) month. Estrus occurs early in lactation for otariids and late in lactation for phocids (Oftedal *et al.*, 1987). Most copulations occur on land at or near the parturition site, but a few species commonly breed

Figure 1 *Adult male California sea lions* (Zalophus californianus) *compete for territories at San Miguel Island, California (NMFS, George Antonelis).*

Figure 2 *A much larger and darker adult male California sea lion attempts to block an adult female from leaving his territory at San Miguel Island, California (NMFS, George Antonelis).*

Figure 3 *California sea lions are highly polygynous and form dense aggregations on rookeries commonly found along the shoreline at breeding sites on the California Channel Islands (NMFS, George Antonelis).*

aquatically in the intertidal zone where males maintain aquatic territories. Otariid females intermittently leave the rookery to forage between suckling periods, and phocid females fast on land during the entire lactation period. Thus, some pinnipeds rookeries may be occupied continuously, but most breeding is completed within a relatively short time period of about 2 months.

SEXUAL DIMORPHISM is apparent on pinniped rookeries, as adult males usually have distinctly different characteristics and are larger than females. Each sex and species emits stereotypic vocalizations for long- and short-distance communication (Stirling and Warneke, 1971; Miller, 1991). Males emit loud long-distance threat calls toward other males. Lactating otariid females also emit loud pup attraction calls on rookeries to locate their offspring among hundreds of pups. Short-distance threat vocalizations are common on all pinniped rookeries and have less amplitude than long-distance calls. Noise from rookeries initially may be perceived as a cacophony of sounds, but what seems to be chaos is really a well-organized social structure that has evolved over millions of years.

II. Physical–Geographical Characteristics

Pinniped rookeries are typically found on remote offshore islands, although some occur on mainland beaches. Rookeries are formed near shoreline just above the tidal zone in a variety of substraits, including sand, cobble or boulder beaches, rock shelves, and caves. Breeding aggregations usually occur within several hundred meters of the shoreline and also may occur on hillsides or cliffs overlooking the ocean (Fig. 3). Low-growing vegetation such as low grasses or shrubs is common on some rookeries.

The formation of rookeries on substrate near but above the tidal zone provides several functions that reinforce continued use of each site. To ensure survival to weaning, neonates are usually born in locations where high tides do not wash them away from their mothers or compromise their ability to thermoregulate (Fig. 4). The gregariousness of females at these nearshore locations facilitates the ability of territorial males to monopolize estrous females, a key component of their complex polygynous mating system (Emlin and Oring, 1977). During anomalous conditions, however, storm surf associated with El Niño events has flooded pinniped rookeries, resulting in significant neonatal mortality and disruption of their polygynous social structure (Trillmich and Ono, 1991). Such events demonstrate the need for rookeries to occur above normal fluctuations in tide height.

Although pinniped rookeries must be located above the tidal zone, they must also be close enough to the water to facilitate access for THERMOREGULATION, foraging trips by lactating females, or escape from terrestrial predators. During high air temperatures in tropical and temperate environments, many rookery-breeding otariids are known to move regularly to the intertidal zone for cooling.

Figure 4 *A female California sea lion suckles her pup in a location protected from the surf on San Miguel Island, California (NMFS, George Antonelis).*

III. Environmental Characteristics

Environmental characteristics related to the formation, timing, and use of pinniped rookeries vary among species and are likely stimulated by proximate factors such as photoperiod, nutrition, and climate, which ultimately relate to survival and reproductive success (Boyd, 1991). The relative importance of these factors is believed to differ according to species on spatial and temporal scales. Pinniped rookeries occur most commonly during the spring and summer months when climatic conditions are relatively warm and the frequency of inclement weather diminishes. Such conditions increase the probability of offspring survival, especially in subpolar climates. Rookery-breeding phocids are the exceptions and form aggregations on rookeries in the fall and winter.

Most rookeries occur in locations where oceanographic conditions result in high productivity. High productivity increases the availability of potential prey resources vital for the foraging success of otariid females, which must feed intermittently during lactation. Rookery-breeding phocid females do not forage during lactation and rely completely on the energy stores obtained before parturition. The availability of prey near rookeries is therefore much more important to otariids than to phocids. However, the availability of prey for pups either before or after weaning may be an essential component for successful transition to foraging self-sufficiency for the young of most pinnipeds born on rookeries.

Ross Seal

Ommatophoca rossii

JEANETTE A. THOMAS
Western Illinois University, Moline

Less is known about the Ross seal (*Ommatophoca rossii*) than any other pinniped. This solitary seal has a circumpolar distribution around Antarctica, occurs in tight pack ice, and does not use traditional hauling out sites. No breeding concentrations of Ross seals have been observed. A variety of Antarctic investigators from Britain, France, America, Soviet Union, Australia, and New Zealand reported sightings of Ross seals from ships. However, there have been no ice-camp or land-based studies of this species. There has been no systematic, continent-wide census of Ross seals, so population estimates are variable.

I. Characters and Taxonomic Relationships

The Ross seal belongs to the family Phocidae and subfamily Monacinae. There is a single species in the genus *Ommatophoca.* Common names include the big-eyed seal and the singing seal. The closest relatives are the other Antarctic seals (crabeater, *Lobodon carcinophaga;* leopard, *Hydrurga leptonyx;* and Weddell, *Leptonychotes weddellii,* seals) and the monk seals (Caribbean, *Monachus tropicalis;* Mediterranean, *M. monachus;* and Hawaiian, *M. schauinslandi).*

As with other phocids, Ross seals crawl on their belly and are not capable of an upright stance or moving the hindlimbs forward. The head is proportionally smaller compared to the body than in other Monacinae and the snout is exceptionally short. The neck is thick and short. The Ross seal often assumes a posture with the head raised and mouth open, pointing upward. Because of this posture they have been called the "singing seal" (Fig. 1). However, this is a misnomer, as the seal rarely emits sound in this posture. More likely the open mouth displays teeth, and thrusting out of the striped chest serves as an aggressive posture (Fig. 2).

The skull has an exceptionally large orbit (hence the Greek name *omma* or eye). The zygomatic arch extends well below the palate, supporting part of the skull weight when placed on

Figure 1 *Microphone positioned to record airborne vocalizations of the "singing" Ross seal.*

a table. As with other Antarctic pinnipeds, it is assumed they have a tapetum, which assists in seeing in low-light levels during the austral winter and during deep dives, and a nictitating membrane that protects their eyes from blowing snow and allows opening their eyes in salt water. Condylobasal length has been measured at 244 mm in males and 242 mm in females. The mastoid width of the skull is at 172 and 170 mm in males and females, respectively. The soft palate is very long, extending posterior to the level of the occipital condyles. The trachea is expanded, and powerful muscles of the tongue and pharynx assist in swallowing large prey. The external ear is absent. The nostrils are normally closed and opened under voluntary control when seals need to respire. They have 15–17 short mystacial whiskers on each lip, only 10–42 mm in length, and superciliary vibrissae. All vibrissae are unbeaded.

Figure 2 *Typical head-up, mouth-open display given by a Ross seal to an intruder. Display emphasizes the distinct striped throat of this species.*

The mouth is small. The incisors and canines are small and recurved, an adaptation for holding slippery cephalopods. The front teeth are not procumbent and the seals do not maintain breathing holes by "ice sawing," as the Antarctic Weddell seal does. The cheek teeth are reduced, often barely breaking the gum line.

Black claws are reduced and probably useful for gripping the ice or scratching. The phalanges are greatly elongated. The fore and hind flippers are proportionally longer than in other phocids, the latter being 22% as long as the body.

The seals stay warm through a thick fur coat and a layer of subcutaneous fat. Ross seals have short, black fur on their back, with grayish silver streaks along their sides that transition into a solid silvery white belly. They have a unique color pattern of vivid strips running from the lower jaw to the chest and alongside the neck. A lanugo is present in the newborn, which is long, thick, and soft black on the back, fading into a bright yellow underbelly. This yellow color may change into silver as the pup grows.

There is no marked sexual dimorphism in body size, but females tend to be slightly larger. Adult males reach 1.68–2.08 m and adult females are 1.96–2.5 m in length. Weight ranges from 129 to 216 kg in adult males and 159 to 201 kg in adult females, with pregnant females obtaining the greatest weights. The exact age of sexual maturity is uncertain, but based on analysis of reproductive tracts is estimated at 3–4 years of age in females and 2–7 years in males. At birth, pups are 105–120 cm in length and weigh 17–27 kg.

II. Distribution and Ecology

Ross seals (estimated at 1–2% of Antarctic pinnipeds) are the least abundant of all the Antarctic pinniped species. This species is uncommon, numbering an estimated 20,000–50,000 according to Scheffer (1958), but as high as 220,000 according to Erickson *et al.* (1971). Nowak (1991) reported Ross seal populations between 100,000 and 650,000, but considers these estimates unreliable. Ross seals are restricted to the heavy, consolidated pack ice of the Southern Ocean, with the farthest northern sighting at Heard Island. Before 1945, there were fewer than 45 sightings of the species. Only with the use of icebreakers into the dense pack ice were more recent sightings obtained, but most often sightings are opportunistic. Sightings usually are of single animals, but sometimes a pocket of small numbers occurs in a local area. The highest recorded density is 2.9/km^2. Some investigators believe the nonuniform DISTRIBUTION is due to the distribution of their prey, ice type, or both. Occasionally, single seals are seen in southern Australia and some subantarctic islands, such as the South Sandwich, Falkland, Scott, and South Orkney Islands.

III. Behavior and Life History

Mother Ross seals haul out in dense pack ice to give birth during the austral spring (November and December), with peak pupping between 3 and 18 November. The species is solitary and seals do no congregate in large breeding colonies. Although mating has not been observed, it is assumed to be the same as in other Antarctic seals, i.e., takes place in water.

Typically, a single pup is born. When disturbed, mothers vocalize to pups and pups respond with a bawl sound. An obser-

vation of a newborn pup reported it swimming in icy water from one floe to another. Pups wean after about 1 month of nursing.

One adult call is an explosive noise emitted with the mouth open, and two adult calls are made with the mouth closed: a pulsed chug and tonal siren call. Calls of adults are used both on the ice surface and under water. Mating occurs after the pup weans in December and molt soon follows. Because of the need to synchronize the time of pupping to annual ice conditions Ross seals exhibit a delayed implantation of 2 months. This delay in pregnancy allows the mother to molt, feed, and recover from the dramatic weight loss associated with lactation before another fetus develops.

Ross seals exhibit a distinct diel pattern of haulout, with most seals hauled out during the midday. This difference in sightability due to time of day makes accurate population estimates difficult. Stewart (cited in Reeves *et al.*, 1992) documented the diving behavior of one Ross seal with a microprocessor-based dive recorder glued to its back. Most dives were deeper than 100 m and lasted around 6 min. The deepest dive was 212 m and for 10 min.

Subadult seals are rarely seen. This seal has small scars around the neck and shoulders that are attributed to intraspecific interactions. The dense pack ice habitat must provide some protection from predators. The Ross seal does not exhibit the large, distinct scars from leopard seal predation seen on crabeater seals. However, in a few areas, Ross seals are sympatric with leopard seals, so the lack of scarring could indicate total hunting success by leopard seals on this smaller seal. Killer whales (*Orcinus orca*) are known to take other Antarctic seals, so likely would feed on Ross seals if not for habitat segregation from this predatory, ice-edge whale. Longevity is unknown, but is at least 21 years.

The DIET of a Ross seal is primarily cephalopods, even larger species than other Antarctic seals eat. Midwater fish and krill are also eaten. Based on stomach contents analysis, the diet of the Ross seal is 47% squid, 34% fish, and 19% invertebrates. Their specialized diet reduces competition with other Antarctic seals or whales.

IV. Interactions with Humans

Ross seals have little fear of humans because there are no natural land predators (such as polar bears) in the Antarctic. James Clark Ross, commander of the *HMS Erebus and Terror*, secured two specimens of this species during his British Antarctic expedition from 1839 to 1843. Gray of the British Museum described and named the species after the explorer. Barrett-Hamilton published one of the first accounts on the Ross seal in 1901, resulting from the voyage of the *S. Y. Belgica* conducted from 1897 to 1899. There is no record of extensive harvest of this species, except for scientific collection. The Ross seal is totally protected under the Antarctic Treaty and the Convention for the Conservation of Antarctic Seals.

Rough-Toothed Dolphin

Steno bredanensis

THOMAS A. JEFFERSON
Southwest Fisheries Science Center, La Jolla, California

Although widely distributed in all three major oceans, the rough-toothed dolphin has not been well studied. It is a tropical to warm-temperate species and is generally found in deep, offshore waters. In most areas where it is known, it does not appear to be among the most abundant of the small cetaceans. This means that it is not commonly encountered.

I. Characteristics and Taxonomic Relationships

The rough-toothed dolphin is very distinctive, when seen at close quarters. It is the only long-beaked dolphin with a

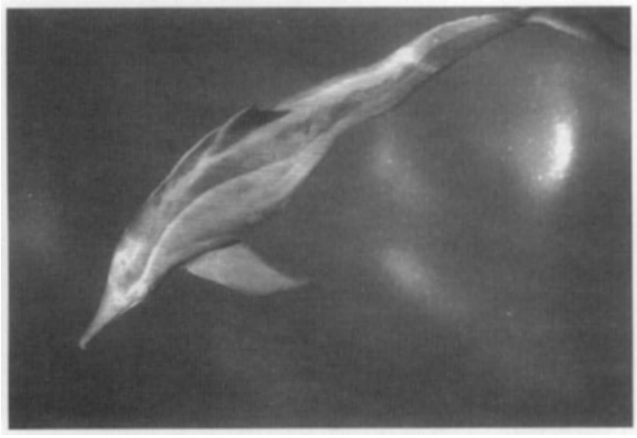

Figure 1 *A rough-toothed dolphin swimming just below the surface in clear waters off Hawaii showing the species' distinctive characteristics. Photo by B. Würsig.*

smoothly sloping melon that does not contain any hint of a crease as it blends into the upper beak (Fig. 1). These dolphins are not particularly slender, and the anterior part of the body may be stocky. The large flippers are set farther back on the body than in most other small cetaceans. They are equal to about 17–19% of the body length. The dorsal fin is tall and generally only slightly recurved. Some large males have a hump of connective tissue posterior to the anus, which gives the appearance of a pronounced keel. These are medium-sized dolphins that can weight up to 155 kg. Males grow to larger sizes than females (known maximums of 265 and 255 cm, respectively), and females may have proportionately longer beaks (Miyazaki and Perrin, 1994).

The color pattern is moderately complex, but consists generally of shades of black, white, and gray (Fig. 2). Rough-toothed dolphins are countershaded, with white bellies and black to dark gray backs. The sides are a medium shade of gray and are separated from the darker back by a dorsal cape that is narrow between the blowhole and the dorsal fin and wider behind the fin. The lower sides and mouth area are often dotted with white patches, splotches, and spots. Many of the white spots are thought to be scars from bites inflicted by cookie-cutter sharks. Young animals have a muted color pattern and generally lack the white spots (Miyazaki and Perrin, 1994).

Figure 2 *Two rough-toothed dolphins socializing at the bow of a research vessel in the Gulf of Mexico. Photo by D. Weller.*

The skulls of rough-toothed dolphins (adult CBL = 472–555 mm) can be distinguished from those of all other dolphins (except humpback dolphins, *Sousa* spp.) by their combination of long beak, concave rostral and maxillary margins, long mandibular symphysis, and large temporal fossae (Fig. 3). Tooth counts can be used to distinguish them from humpback dolphins: rough-toothed dolphins have 19–28 teeth in each row and humpback dolphins usually have >30. The teeth of *Steno* often have longitudinal ridges, which is the reason for the species' common name (Neuville, 1928). Other differences from the skulls of humpback dolphins are the relatively large orbits and the prominent and long cylindrical ridge on the ventral part of the frontal bones in rough-toothed dolphins (Van Waerebeek *et al.*, 1999).

Traditionally, morphological characters have been used to infer a close relationship between the rough-toothed dolphin and two other genera of dolphins (*Sotalia fluriatilis*, the tucuxi, and *Sousa* spp., the humpback dolphins). Recent genetic analyses (LeDuc *et al.*, 1999) have supported the relationship with *Sotalia* (in the subfamily Stenoninae), but not with *Sousa*, which groups phylogenetically with the Delphininae. In captivity, hybrids between *Steno* and *Tursiops truncatus* (bottlenose dolphin) have occurred (Dohl *et al.*, 1974).

II. Distribution and Ecology

The rough-toothed dolphin is a tropical to warm temperate species and is usually found in oceanic waters (Fig. 4). Records from the Atlantic Ocean are mostly between the southeastern United States and southern Brazil across to the Iberian Peninsula and tropical West Africa, with some (probably extralimital) records from the English Channel and North Sea. The normal range includes the Gulf of Mexico, Caribbean Sea, and Mediterranean Sea.

In the Pacific, they occur from central Japan and northern Australia across to southern Baja California, Mexico, and southern Peru. In the eastern tropical Pacific, they are generally associated with warm, tropical waters lacking major upwellings. The range includes the southern Gulf of California and South China Sea. Records from the west coast of the United States and New Zealand are probably extralimital. In the poorly studied Indian Ocean, there are only a few scattered records, but the species probably has an extensive distribution there north of about 20°S.

Essentially nothing is known about population or stock structure in this species. In fact, the ecology and biology of the species are very poorly studied. There have been only a few reports of feeding habits for this species. In the wild, they feed on a variety of fish and cephalopod species, some coastal and some oceanic. Some large fish may be taken, as suggested by the robust dentition of the species. Algae has been found in the stomachs of stranded specimens, but this may have been ingested incidentally.

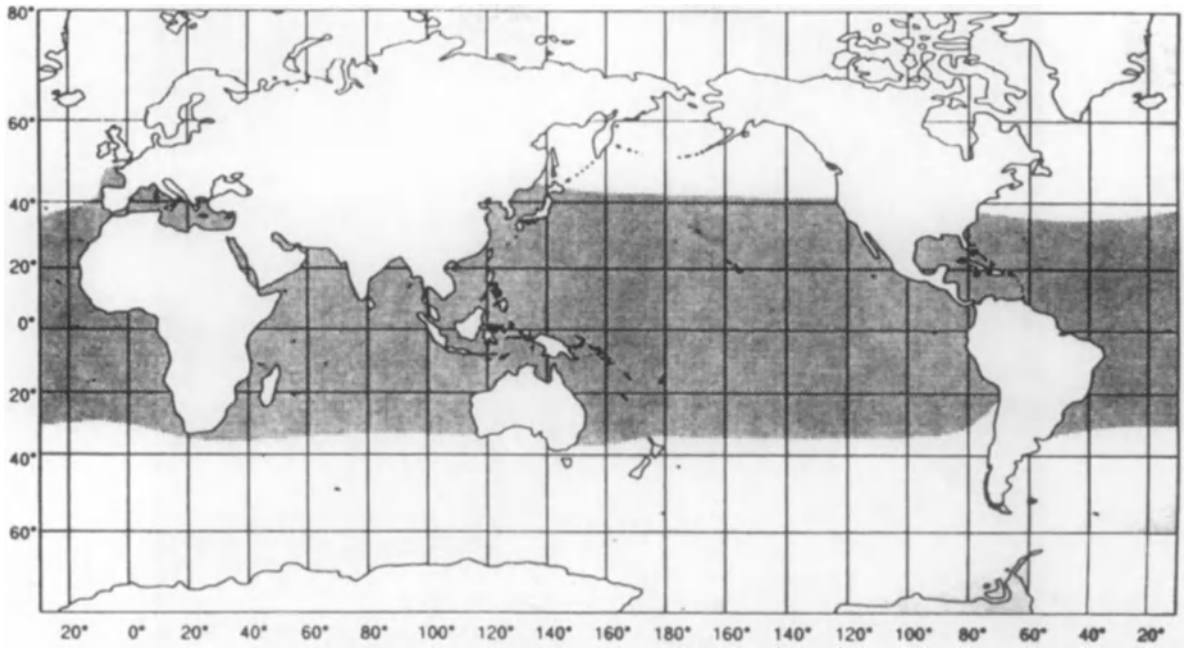

Figure 4 *The approximate distribution of the rough-toothed dolphin. It should be noted that few surveys for marine mammals have been conducted in offshore areas or in the Indian Ocean, so distribution in these regions is especially poorly known.*

III. Behavior and Life History

Rough-toothed dolphins are found in moderate-sized groups, most commonly of 10–20 dolphins, although larger groups have been seen in some areas—over 50 in the eastern tropical Pacific, 300 in Hawaii, and 160 in the Mediterranean (Miyazaki and Perrin, 1994). Mass STRANDINGS have been recorded in several areas of the species' range. They frequently associate with other species of cetaceans, especially other delphinids in the eastern tropical Pacific, where they also often associate with flotsam. Lone animals have been seen with short-finned pilot whales (*Globicephala macrorhynchus*) and Fraser's dolphins (*Lagenodelphis hosei*) in the Sulu Sea.

These animals are not generally fast swimmers and they often appear rather sluggish in the wild. They do ride bow waves and are known for their habit of skimming along the surface at moderate speed with a distinctive splash. Although not highly acrobatic, various leaps and other aerial behaviors have been seen. Rough-toothed dolphins can be found in some shallow, coastal waters in Brazil and elsewhere; in such areas, photo-identification of individual dolphins is considered feasible (Flores and Ximinez, 1997).

Although the maximum recorded dive was only to 70 m, rough-toothed dolphins can probably dive much deeper than this. Behavioral and morphological evidence suggests that they are well adapted for long, deep dives. Submergences of up to 15 min have been recorded. A variety of clicks and whistles have been recorded from these dolphins. Highly directional ECHOLOCATION clicks, with some pulses as high as 200 kHz, are known.

Detailed studies of life history have only been conducted in Japanese waters. There, males reach sexual maturity at about 14 years and 225 cm, and females at 10 years and 210–220 cm. The maximum age is 32–36 years, although some animals may live significantly longer (Miyazaki, 1980: Miyazaki and Perrin, 1994).

IV. Interactions with Humans

Although not generally the major target, rough-toothed dolphins have been taken in directed dolphin fisheries in Japan, Sri Lanka, Indonesia, the Solomon Islands, Papua New Guinea, St. Vincent, West Africa, and possibly St. Helena in the South Atlantic (Miyazaki and Perrin, 1994). Probably much more significant is the incidental kill of dolphins in fishing nets. Takes in tuna purse seine nets are known for the eastern tropical Pacific, and gill-net catches have been documented at least in Sri Lanka, Brazil, and the offshore North Pacific. Undocumented catches probably occur in most other areas of the range.

Habitat degradation impacts and effects of pollutants are probably much less severe for this species than for other, more coastal small cetaceans. Organochlorine levels have generally been much lower than for other species. However, conservation-oriented studies are almost nonexistent, and therefore the uncertainty that exists about population status for this species should be acknowledged.

Rough-toothed dolphins have been held captive in a number of oceanaria, and some success has been encountered in keeping them alive in the captive environment, especially in Hawaii. One specimen lived for over 12 years in captivity. They have been found to be bold and inventive, and one "creative porpoise" at Sea Life Park in Hawaii astounded its trainers by grasping the concept of inventing novel behaviors (Pryor *et al.*, 1969).

Scrimshaw

STUART M. FRANK
Kendall Whaling Museum, Sharon, Massachusetts

Scrimshaw is an occupational handicraft of mariners employing by-products of the whale fishery, often in combination with other found materials. Indigenous to the whaling industry, where it was typically a pursuit of leisure time at sea, it was also adopted in other trades and was occasionally practiced ashore. It arose among Pacific Ocean whalers circa 1817–1824, persisted throughout the classic "hand-whaling" era of sailing-ship days into the 20th century, and persisted in degraded form among "modern" whalers on factory ships and shore stations until the industry shut down in the third quarter of the 20th century. Since the early 20th century, similar materials and techniques have simultaneously been employed by nonmariner artisans for both commercial and hobbyist purposes.

There is no consensus regarding etymology. Plausible and eccentric theories alike have been advanced without any creditable evidentiary basis, whereas academic lexicography (notoriously inconclusive respecting nautical terms) fails to present any convincing hypothesis. The term—also rendered *skrimshank*, *skimshander*, *skirmshander*, and *skrimshonting*—first appeared in American shipboard usage circa 1826, when the recreational practice of scrimshaw was less than a decade progressed. It originally referred not to whalers' private diversions, but to the fairly common practice whereby crewmen were required to make articles for ship's work (such as tools, tool handles, thole pins, belaying pins, and tackle falls). Sperm whale BONE is ideally suited to such uses: on any "greasy luck" voyage it was in plentiful supply at no cost, its workability is equivalent to the best cabinetmaking hardwoods, its tensile strength is greater than oak, and for many applications its self-lubricating properties were highly desirable. Such was analogously the case regarding the adaptability of cetacean bone and ivory to whales' recreational handicrafts, to which the term *scrimshaw* (and its many variants) came to refer by the 1830s.

I. Materials and Species

Materials associated most commonly with scrimshaw are the ivory teeth and skeletal bone of the SPERM WHALE, the ivory tusks of the WALRUS, and the BALEEN of various mysticete species (the toothless, baleen-bearing whales). In the 19th century the principal prey species were, roughly in descending order of importance, sperm whale (*Physeter macrocephalus*), right whales (*Eubalaena* spp.), Arctic bowhead (*Balaena mysticetus*), gray whale (*Eschrichtius robustus*), and humpback (*Megaptera novaeangliae*). These and the long-finned pilot whale or so-called "blackfish" (*Globicephala melas*), which was hunted primarily from shore, were taken primarily for oil, the mysticetes secondarily for baleen. [The fast-swimming blue whale (*Balaenoptera musculus*) and finback (*B. physalus*) could not be hunted effectively prior to the introduction of steam propulsion and heavy-caliber harpoon cannons in the late 19th century.] From the late 16th century, by reason of geographical proximity of Arctic habitats and similar uses of their meat and oil, the hunt for walruses (*Odobenus rosmarus*) was intimately conjoined with commercial whaling. Later, even when whalers were no longer taking walruses themselves, they characteristically obtained walrus tusks through barter with indigenous Northern peoples.

Commercial uses of walrus ivory were few; there was no significant commercial application for cetacean skeletal bone until the 20th century (when it was ground and desiccated into industrial-grade meal and fertilizer); the utility and market value of baleen ("whalebone") were subject to mercurial fluctuations of fashion; and sperm whale teeth had little or no commodity value. They thus became available for whalers' recreational use, as did teeth of the Antarctic elephant seal (*Mirounga leonina*), the lower mandibles of various dolphins and porpoises, and tusks of the elusive NARWHAL (*Monodon monoceros*). (Narwhal ivory proved too difficult and brittle for anything much beyond canes and analogous shafts, such as hatracks or bedposts.)

The characteristic pigment for highlighting engraved scrimshaw was *lampblack*, which is essentially a viscous suspension of carbon particles in oil. (The notion that sailors used tobacco juice for this is a colorful fabrication with no basis in fact.) Lampblack, collected easily from lamps, stoves, and *tryworks* (shipboard oil-rendering apparatus), was in abundant supply on a whale ship. Colors were introduced almost at the outset: Ed-

ward Burdett was using sealing wax and other pigments by 1827 (Fig. 1); full polychrome scrimshaw debuted within the next decade. Sealing wax had the advantages of being universally available, relatively inexpensive, brilliantly colored, and colorfast. Applied properly, it has proven resilient and tenacious, the color as vivid today as when the scrimshaw was new. Improper application—if the cuts are too smooth or insufficiently contoured to grab and hold the wax—results in significant losses from handling and natural desiccation. Sealing wax had the disadvantage of offering only a limited spectrum of colors, all strong. Ambient pigments, however, could be mixed and blended, affording greater subtlety. From the characteristic leeching of pigment into the substrata of some polychrome scrimshaw, a phenomenon that occurs with water- and alcohol-soluble colors but not with waxes or heavy oil-based pigments, it is clear that ambient colors were also favored. Store-bought inks, homemade dyes extracted from berries, and greens from common verdigris seem to predominate; however, their composition has not been investigated comprehensively.

Inlay and other secondary materials—rare on engraved scrimshaw but often encountered on "built" or "architectonic" scrimshaw—were typically obtained at little or no cost, such as other marine byproducts (tortoise shell, mother-of-pearl, sea shells), various woods brought from home or obtained in various ports of call (including exotic tropical species from Africa and Polynesia), and miscellaneous bits of metal (fastenings and finials were often crafted from silver- or copper-alloy coins, typically coins minted in Mexico and South America).

II. Scrimshaw Precursors

Medieval European artistic productions in walrus ivory and cetacean bone were many, but the whalers themselves had no part in them beyond gathering the raw materials. Cetacean bone panels and stilettos survive from the Viking era, some incised with rope patterns and animal figures, and cetacean bones served as beams in vernacular buildings in Norway and the Friesian Islands, but even these do not appear to have been made by whalers and are not known to have been part of their occupational culture. Monastic artisans in Denmark and East Anglia carved walrus ivory and cetacean bone into votive art, primarily altar pieces, friezes, and crosses, whereas craftsmen at Cologne and elsewhere produced secular game pieces and chessmen from the same materials. So important was the "Royal Fish" to the Viking economy that a highly sophisticated body of law evolved to regulate whaling itself and the ownership, taxation, distribution, and export of whale products, whether acquired fortuitously (from stranded carcasses) or by hunting. Pliny the Elder (first century C.E.), Olaus Magnus (1555), Conrad von Gessner (1558), and Ambroise Paré (1582) listed the uses of baleen for whips, springs, garment stays, and umbrella ribs; and the emergence of pelagic Arctic whaling in the 17th century encouraged a search for new applications, especially in Holland. The search, however, proved fruitless and was abandoned by circa 1630, occasioning the appearance of sailor-made baleen objects: there was simply no longer any reason to restrain whalers from using baleen for their private diversions (two centuries later the same principle would make sperm whale teeth available for scrimshaw).

Ditty boxes were the first manifestation of whalers' work. Typically, these have polished baleen sides bent to the oval shape of a wooden bottom 30–35 cm long, to which the baleen is fastened with copper nails and fitted with a wooden top. Two made in 1631 by an anonymous Rotterdam whaling commandeur have baleen sides incised with portraits of whaleships, the wooden tops relief carved with the Dutch lion rampant

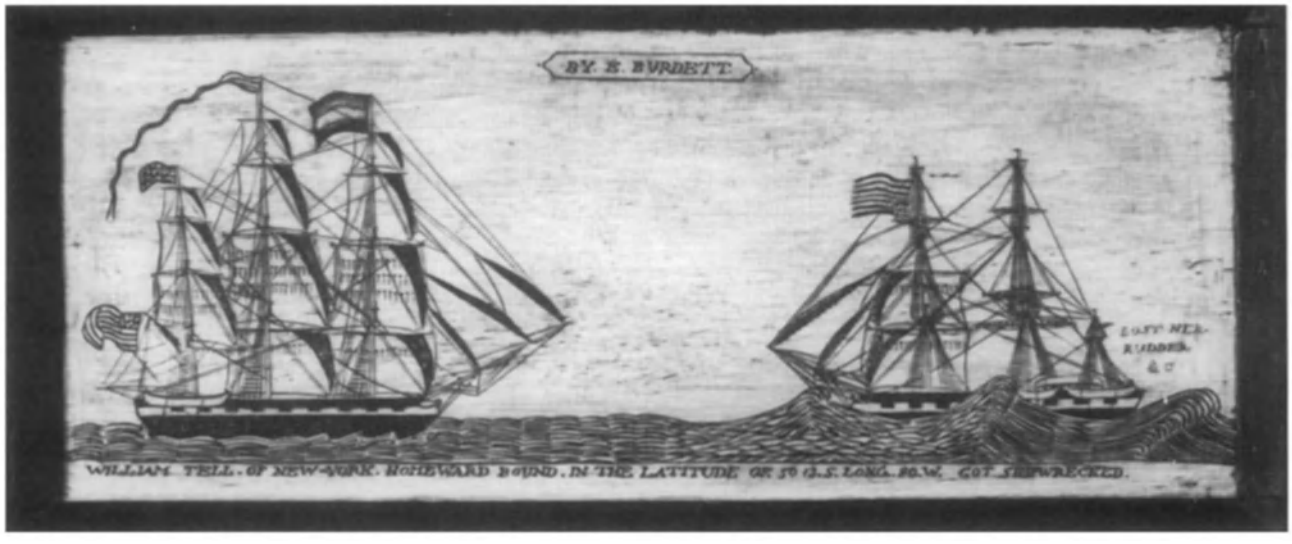

Figure 1 *Panbone plaque by Edward Burdett (1805–1833) of Nantucket, circa 1828. The earliest known scrimshaw artist, Burdett was active from 1824 until he was killed by a whale in 1833. His work is characterized by a bold, confident style, with deep blacks and red sealing-wax highlights. He was serving as a mate in the* William Tell *when he engraved this section of sperm whale bone, inscribed "William Tell. of New York. homeward bound. in the latitude of. 50 13. S. long[itude] 80. W. got shipwrecked"; "lost her rudder & c."; "by. E. Burdett." 15.7 × 31.8 cm. From the Kendall Whaling Museum, Sharon, Massachusetts.*

surrounded by nautical symbols, human figures, and decorative borders. A few North Friesian whaleman–artists of the next generation are known by name. Jacob Floer of Amrum engraved buildings, trees, and geometrical borders on the baleen sides of an oval box, signed and dated 1661. Peter Lorenzen of Sylt signed and dated another in 1687. The form continued for the duration of Arctic whaling and was perpetuated with myriad variations by American and British scrimshaw artists in the 19th century.

Another early form was the *mangle* (paddle for folding cloth). An Amsterdam whaling commandeur decorated one with carved geometric ornaments, signed, dated, and inscribed, "Cornelis Floerensen Bettelem. Niet sonder Godt [Not without God]. Anno 1641." A century later a North Friesian whaling master, Lødde Rachtsen of Hooge, made one for his daughter's dowry: it has a pierced-work handle and carved geometric and floral decorations, the broadside portrait of a spouting bowhead whale, and a carved inscription dated 1745. Respecting technical aspects of execution and the iconography of their decoration, this kind of piece is the direct ancestor of the sperm whalemen's decorated baleen corset-busks of the 19th century.

III. Origins and Practice

Pictorial engraving on sperm whale teeth—the quintessential manifestation of scrimshaw—resulted from changing circumstances in the fishery in the aftermath of the Napoleonic wars (of which the American theater was the so-called War of 1812). It arose collectively among British and American whalers in the 1820s in the Hawaiian Islands, where (beginning in 1819) the fleets customarily laid over for weeks on end between seasonal cruises, providing ample opportunities for fraternization and foment.

In the late 17th century, British colonists on the Atlantic seacoast of New York and Massachusetts hunted right whales along shore—an ancillary day fishery, prosecuted by fishers and farmers in rowboats launched from sandy beaches. In the 18th century, expanding markets occasioned offshore cruises in small sailing vessels. The discovery of sperm whales in proximity to New England is ascribed by tradition to Captain Christopher Hussey of Nantucket when he was blown off course while right whaling in 1712. The colonists tuned their technology to accommodate sperm whaling, pioneered the refining of sperm whale oil and the manufacture of spermaceti candles (America's first industry), and developed thriving export networks. Whaling evolved into a full-time occupation, and a distinctive caste of whaler–mariners emerged with its own occupational culture. Scrimshaw would become an integral component of this culture, but it took a whole century for the right circumstances to gel.

Colonial whaling cruises were seasonal, following the Atlantic trade winds on comparatively short passages to and from the grounds. Only a few whales were required to fill the hold before heading home, usually after only a few weeks. The opening of the Pacific grounds in the 1790s changed shipboard dynamics dramatically. Voyages necessarily became longer, as much as 3 or 4 years by the 1840s. The larger catch required to make long voyages profitable mandated larger vessels with larger crews so that three to five whaleboats could be launched for the hunt. The effective result was overmanning and an unprecedented abundance of shipboard leisure—long outward and homeward passages, and idle weeks, even months between whales, when there was little to do but maintain the ship and wait. Most sailors worked "watch-on-watch" in 4-hr shifts, day and night, whenever the ship was underway, but whaleship crews had most nights off: the hunt could not be prosecuted effectively in darkness, and cutting in (flensing) a carcass with sharp blubber spades was dangerous enough even in daylight. Apart from rendering blubber already on hand, there was little work to do evenings. More than in any other seafaring trade, 19th-century whalers had time to spare. They filled it with reading, journal-keeping, drawing, singing, dancing, gamming (visiting among ships at sea), and a host of other diversions.

At the critical juncture, just when things were ripe for scrimshaw, teeth were in short supply. For in the meanwhile, the China Trade, pioneered in the 1780s, had established a network of Far East destinations and products that involved barter with Pacific islanders to obtain goods for Canton. China traders soon realized that many island cultures placed great value on whale teeth, from which they crafted various totemic and decorative objects. Teeth could be obtained cheaply from whalers (there being no other market), so the China merchants bought them up for barter in the Pacific. Such scrimshaw as there was in the 18th century was therefore limited primarily to implements made of skeletal bone—straightedges, hand tools, a few early swifts (yarn-winders), and corset busks; of these, comparatively few were made prior to the florescence of scrimshaw commencing in the 1820s.

Captain David Porter of the U.S. Naval frigate *Essex* was the inadvertent catalyst for the emergence of scrimshaw. Porter's wartime purpose had been to inflict depredations on British shipping and to disrupt British whaling in the Pacific. His narrative (published in 1815, reissued in an expanded edition in 1821) was valued by mariners for its explicit accounts of conditions in the Marquesas and Galapagos Islands and on the coast of Chile and Peru. It also incidentally revealed the barter value of whales teeth in Polynesia and disclosed particulars of how they could be gathered cheaply—this at just around the time the vanguard of the whaling fleet reached Hawaii (1819). There was soon a surplus of whales teeth on the Pacific market; as the teeth were no longer valuable as a commodity, they could be relegated to sailors for private use.

Accordingly, the earliest authentic date on any pictorial sperm whale scrimshaw is 1817—a tooth commemorating a whale taken by the ship *Adam* of London off the Galapagos Islands (Fig. 2); and the earliest provisionally identifiable whaleman–engraver of sperm whale ivory is J. S. King, whaling master of London and Liverpool, to whom two teeth are attributed, one perhaps as early as 1821. These suggest a possible British genesis of pictorial scrimshaw; however, the earliest definitively attributable work is by an American, Edward Burdett of Nantucket, who first went whaling from his native port in 1821 and was scrimshandering by 1824. Fellow Nantucketer Frederick Myrick was the first to sign and date his scrimshaw—three dozen teeth produced during 1828–1829 as a seaman aboard the Nantucket ship *Susan*. Two teeth by Burdett and two "Su-

Figure 2 *Genesis of scrimshaw, circa 1817. The oversize tooth is inscribed, "This is the tooth of a sperm whale that was caught near the Galapagos Islands by the crew of the ship Adam [of London], and made 100 barrels of oil in the year 1817." Produced in the wake of the Napoleonic Wars, when the British and American whaling fleets were endeavoring to recover their former prowess in the Pacific, it is believed to be the earliest full-scale work of engraved pictorial scrimshaw. Length 23.5 cm. From the Kendall Whaling Museum, Sharon, Massachusetts.*

san's Teeth" by Myrick were accessioned by the East India Marine Society of Salem, Massachusetts, prior to 1831, while both artists were still living—the first scrimshaw to enter a museum collection. That Myrick's work was listed generically as "Tooth of a Sperm Whale, curiously carved" and "Another, carved by the same hand," with no mention of the exquisitely engraved pictures on them, nor of the artist's name (both are signed), nor of the term *scrimshaw*, testifies to the newness of the genre, perhaps also to the low esteem in which sailors' hobby work was held by the great merchants of Salem at the time.

In the 1830s scrimshaw became widely generalized. On some whaling vessels virtually the entire ship's company participated. In his journal of the New Bedford bark *Abigail* during 1836–1838, Captain William Hathaway Reynard remarked, "The cooper is going ahead making tools for scrimsham. We had a fracas betwixt the cook and the stewart [sic] . . . All hands employed in scrimsa." In other ships the best ivory and bone may have been relinquished to some particularly talented member of the crew, such as Joseph Bogart Hersey of Cape Cod on the Provincetown schooner *Esquimaux* in 1843: "This afternoon we commenced sawing up the large whale's jaws . . . the bone proved to be pretty good and yielded several canes, fids, and busks. I employed a part of my time in engrav[ing] or flowering two busks. Being slightly skilled in the art of flowering; that is drawing and painting upon bone; steam boats, flower pots, monuments, balloons, landscapes &c &c &c; I have many demands made upon my generosity, and I do not wish to slight any; I of course work for all."

The whaleship labor force was very young on average, with green hands often in their early teens; common seamen and even seasoned harpooners were rarely over thirty. Among the greatest scrimshaw artists, Frederick Myrick retired from whaling and from scrimshaw at age 21, Edward Burdett was barely 28 when he was killed by a whale, and Welsh ship's surgeon W. L. Roderick left the fishery at 29. Nevertheless, although in the minority, older hands contributed mightily. Seaman Silas Davenport may have been in his forties when he constructed a fine swift of bone and ebony. Former whaleman N. S. Finney was still engraving walrus ivory on commission in San Francisco in his sixties. Ship's carpenters and coopers—trained craftsmen with skills well adapted to scrimshaw, especially architectural pieces—were normally older than the average crewman. So, too, whaling captains, many of whom were devoted scrimshaw artists: Manuel Enos cut brilliant polychrome portraits into whale ivory right up to the time he was lost at sea at age 55; Frederick Howland Smith was scrimshandering from age 14 until he retired at 61; and the grand old man, Captain Ben Cleveland, was still making napkin rings, mantle ornaments, and scrimshaw gadgets in the 1920s, at age eighty.

Scrimshaw was quintessentially a diversion of the whalemen's ample leisure hours, to fill time, and produce mementos as gifts for loved ones at home. It was occupationally rooted in and wholly indigenous to the deepwater whaling trade, but was eventually also adopted by merchant sailors, navy tars, and occasionally the seafaring wives and children of whaling masters.

Unfortunately, practitioners in whatever trade rarely signed or dated their work, and family provenance has seldom preserved details of the origins of legacy pieces. Thus, scrimshaw has hitherto been mostly anonymous, the names of only a handful of practitioners known. However, systematic forensic studies commencing in the 1980s have made stylistic and iconographical attributions increasingly possible, and the names and works of a few hundred individual artists are now documented with varying degrees of specificity.

IV. Taxonomy

Scrimshaw took many forms. Henry Cheever mentions whalers "working up sperm whales' jaws and teeth and right whale [baleen] into boxes, swifts, reels, canes, whips, folders, stamps, and all sorts of things, according to their ingenuity" (*The Whale and His Captors*, 1850); and Herman Melville alludes to "lively sketches of whales and whaling-scenes, graven by the fishermen themselves on Sperm Whale-teeth, or ladies' busks wrought out of the Right Whale-bone, and other like skrimshander articles, as the whalemen call the numerous little ingenious contrivances they elaborately carve out of the rough material in the hours of ocean leisure" (*Moby-Dick*, 1851). Various tools were used for cutting and polishing, but forensic scrutiny corroborates Melville's observation that the ordinary knife predominated: "Some of them [the whaleman-artisans] have little boxes of dentistical-looking implements, specially intended for the skrimshandering business. But in general, they toil with their jack-knives alone; and, with that almost omnipotent tool of the sailor, they will turn you out anything you please, in the way of a mariner's fancy."

Scrimshaw objects intended for practical use included hand tools, kitchen gadgets, sewing implements, toys, and even full-sized furniture. Some, such as fids, straightedges, tool handles, seam-rubbers, napkin rings, and even some canes, could be

carved or turned from a single piece of ivory or bone. Although they had a specific function, corset busks (made of bone, walrus ivory, or baleen) were often elaborately engraved; even apart from being products of painstaking labor, as intimate undergarments they were not bestowed casually. Other implements were constructed from two or more pieces joined or hinged together—pie crimpers with rotating jagging wheels and fold-out forks (Fig. 3); canes with shafts of one material, pummels of another, and inlay of a third. The most elaborate forms were truly "built" and may properly be called *architectural* or *architectonic.* Swifts (yarn winders) have numerous moving parts, with metal pinions and ribbon fastenings (Fig. 4). Bird cages, a labor-intensive technical challenge, could run the gamut of Victorian complexity. Sewing boxes, ditty boxes, chests of drawers, lap secretaries, pocketwatch stands, mantle ornaments, and other composite constructions typically employed combinations of wood, ivory, and bone and may have hinged lids, internal compartments, legs, finials, handles, drawers, drawer pulls, inlay, and all manner of ornamentation.

The quintessential form of purely decorative scrimshaw is engraved ivory and bone, usually rendered in a single medium—a tooth or pair of teeth; a tusk or pair; or a plaque, strip, or section of sperm whale panbone (jawbone). Finished teeth were sometimes set into wooden, silver, or coin-silver mounts; plaques might be framed by the artist; engraved strips of baleen could become oval boxes. Alternately, teeth and tusks could be carved into stand-alone sculptural forms, such as human or animal figures, or could become the components of complex ship models.

Figure 3 *Pie crimper in the form of a mermaid, New Bedford, circa 1875. Practical in origin, these classic kitchen implements inspired some of the scrimshaw's most creative forms and elaborate ornamentation. The jagging wheel was used for crimping pie crusts; they often also had ivory forks to puncture the top of the crust. This one was made aboard the New Bedford ship* Europa, *Captain James H. McKenzie, during 1871–1876. Length 18 cm. From the Kendall Whaling Museum, Sharon, Massachusetts.*

Figure 4 *Swift of sperm whale ivory and skeletal bone by Captain James M. Clark, circa 1835–1850. Made by a Yankee whaling captain, this exquisite piece typifies the best of the scrimshaw genre. It is inlaid with abalone shell and baleen, fastened with copper, tied with silk ribbons, fitted with two turnscrews in the form of clenched fists, and has a silver presentation plaque inscribed "R W Vose from Ja Clark." Height 40.7 cm. Swifts were a distinctly American form, used for winding the yarn employed in knitting and occasionally other domestic handicrafts and cottage industries. From the Kendall Whaling Museum, Sharon, Massachusetts.*

There were no rules and few precedents governing the choice of subject matter for pictures on scrimshaw. The earliest work—by the anonymous *Adam* engraver, J. S. King, Edward Burdett, and Frederick Myrick—was almost exclusively devoted to ship portraiture and whaling scenes. Figures of Columbia, Liberty, and Britannia appeared by around 1830. The ensuing generation enlarged the vocabulary to include patriotic portraiture (notably of Washington and Lafayette), inanimate patriotic devices, female portraiture, landscape, naval engagements, sentimental family scenes, and mortuary motifs (Fig. 5). Gradually, these were canonized as standard genre conventions. Some individual artists developed distinctive styles and themes. George Hilliott's polychrome teeth dialectically juxtapose a Polynesian *wahinee* in a grass skirt on one side and a New England lady in

Figure 5 *Family album wall hanging, New England, circa 1850. This unusual, elaborate construction features 12 tintype photographic portraits mounted in a triangular framework of walrus ivory and bone. The polychrome engraving on the walrus tusks is particularly interesting, as the woman-and-child portrait pair on the right is no doubt copied from a magazine fashion plate (in typical whalers' fashion), whereas the woman-with-telescope on the left appears to be an original image. Height 50 cm. From the Kendall Whaling Museum, Sharon, Massachusetts.*

a fashionable gown on the other. The anonymous "Banknote engraver" did meticulous portraits with banknote-like borders (hence the pseudonym). The "Eagle Artisan" engraved red-and-black American eagles and bold portraits. The "Lambeth Busk Engraver" made busks with London vignettes: a prime example features Lambeth Palace. Much naval scrimshaw is adorned with patriotic devices and naval engagements. Like whalemen's scrimshaw, some examples refer to specific vessels and events. A notable British example is credited to HMS *Beagle* on the same voyage on which Darwin evolved his theory of natural selection. Edward Yorke McCauley—later an admiral and noted Egyptologist—when he was a young midshipman aboard the U.S. Frigate *Powhattan* on Perry's historic Japan expedition in the 1850s, engraved two walrus tusks with portraits of the *Powhattan* and *Susquehanna*, exotic Oriental watercraft, and glimpses of Japan, Hong Kong, and Brunei. Even a Confederate infantryman tried his hand: Hampton Wilson, Irish immigrant, North Carolina sharecropper, Confederate draftee, and Union prisoner of war, while recuperating in a military hospital in Kentucky successfully "flowered" a pair of walrus tusks with military and naval vignettes, using materials and methods presumably supplied by a Yankee whaling veteran among his fellow patients.

Most scrimshaw pictures were inspired by or adapted from illustrations in contemporaneous books and periodicals; copying and even direct tracing were standard scrimshaw conventions. Because of their specific functional objectives, scrimshaw implements and architectonic forms were also mostly derivative. However, some of the best pieces—and many of the worst—were truly original creations, drawn from the maker's experience or imagination. A few have authentic stature as significant art, whereas others are little more than mere valentines. In the aggregate, anonymity and quality aside, as an indigenous occupational genre scrimshaw comprises some of the most characteristic and revealing documents of any occupational group, capable of providing profound insights into the life, work, and intentionality of the mariners who made them.

V. Museum Collections

Hull Maritime Museum, Kingston on Hull, England. Municipal museum in England's most historic Arctic whaling port; the most significant scrimshaw collection outside the United States.

Kendall Whaling Museum, Sharon, Massachusetts. World's largest and most comprehensive scrimshaw collection; world's only Scrimshaw Forensics Laboratory; annual Scrimshaw Collectors' Weekend; many scrimshaw publications.

Mystic Seaport Museum, Mystic, Connecticut. Comprehensive collection includes important loan deposits from other private and institutional collections; notable for substantive exhibition and informative catalogue.

Nantucket Whaling Museum (Nantucket Historical Association), Nantucket, Massachusetts. Eminent collection in the birthplace of sperm whaling and hometown of scrimshaw pioneers Edward Burdett and Frederick Myrick.

New Bedford Whaling Museum (Old Dartmouth Historical Society), New Bedford, Massachusetts. Large museum; extensive scrimshaw collection in the world's greatest whaling port.

Peabody Essex Museum of Salem, Massachusetts. Outstanding collection, brilliantly exhibited; museum founded 1799 as East India Marine Society; world's oldest collection of scrimshaw (1831).

In addition, there are modest but worthwhile collections at the Christensen Whaling Museum (Sandefjord, Norway), the Providence (Rhode Island) Public Library, the Scott Polar Research Insitute (University of Cambridge, England), South Street Seaport Museum (New York City), Whaler's Village (Lahaina, Maui, Hawaii), the Whaling Museum at Cold Spring Harbor (New York), and several state and municipal museums and libraries in Australia (Sydney; Melbourne; Hobart; and Launceston, Tasmania).

Sea Lions, Overview

DARYL J. BONESS
National Zoological Park, Smithsonian Institution, Washington, DC

Sea lions, like the fur seals, are members of the family Otariidae. There are presently seven sea lion species in five genera, with one genus exclusive to the Northern Hemisphere (Steller sea lion, *Eumetopias jubatus*), one that occurs in both hemispheres [in the north, the California (*Zalophus californianus*) and Japanese (*Z. japonicus*) sea lions, and in the south, the Galapagos sea lion, (*Z. wollebaeki*)], and three that are solely in the Southern Hemisphere (southern sea lion, *Otaria flavescens;* Australian sea lion, *Neophoca cinerea;* New Zealand sea lion, *Phocartos hookeri*).

I. Origins, Classification, and Size

Sea lions originated in the North Pacific region, sharing a common ancestor with fur seals. Although the fossil record for sea lions is poor, it appears they crossed into the Southern Hemisphere about three million years ago. Generally the sea lions have been thought of as a separate subfamily (Otariinae) within the family Otariidae. However, as more genetic analyses are done, this view is being questioned. For example, in one analysis the northern fur seal appears to be more closely related to the sea lions than to the other fur seals, which are all in the genus *Arctocephalus*. In another analysis, two sea lion species clustered with three *Arctocephalus* species to the exclusion of the northern fur seal. The only substantial diagnostic morphological distinction between sea lions and fur seals is the presence of an underhair in fur seals but not in sea lions. Sea lions do tend to be larger than fur seals, with both groups exhibiting substantial differences in body mass, and smaller differences in body length, between males and females, a phenomenon known as sexual dimorphism (Fig. 1). Male sea lions are between two and four times heavier than females and up to one and a half times the length. The body mass of males in the different sea lion species ranges from about 250 to 1000 kg and in females from about 75 to 325 kg. In contrast, the heaviest fur seal male is about 300 kg and the heaviest female is about 75 kg. Lengths of male and female sea lions range from 205 to 330 and 180 to 270 cm, respectively.

II. Morphology and Physiology

Sea lions, like fur seals and walruses, differ anatomically from the true seals (phocids) in several ways. Probably most notably is their ability to walk or run rather than crawl on land. Underlying this capability is the ability to rotate the pelvis to a position that allows bringing the hind flippers under the body. As a result, sea lions have more efficient terrestrial locomotion than phocids. Another obvious anatomical feature of sea lions is the extended and flattened fore flippers. Again, this is a feature they have in common with their otariid fur seal cousins, although the walrus and phocids have relatively short fore flippers. These differences reflect the different swimming modes of these two groups of seals. The sea lions and fur seals use fore flippers to provide thrusting power and the walrus and phocids use their rear flippers.

Consistent with being shallow divers, sea lions have a relatively small lung capacity compared to many other marine mammals. They also have lower oxygen stores (40 ml O_2/kg) than true seals (60 ml O_2/kg), which are generally deep divers, but still much higher stores than humans (20 ml O_2/kg), for example. Additionally, the relative distribution of oxygen stores is different for sea lions. Sea lions have about 47% of their oxygen in blood, 35% in muscle, and 19% in their lungs. Phocids, however, have 64% of their oxygen in blood, 31% in muscle, and only 5% in their lungs. This larger percentage of oxygen in the lungs of sea lions correlates with the smaller degree to which the lungs collapse from water pressure. In humans, 51% of the oxygen is stored in the lungs.

III. Life History and Reproduction

Sea lions follow a life style typical of that of all the otariids, with some characteristics common to all seals. They are long-lived (probably 15–20 years), have delayed sexual maturation, and have physical and social sexual bimaturation with males maturing more slowly than females. For the three sea lion species adequately studied, females normally give birth for the first time at 4–5 years of age. For six of the seven sea lion species there is an annual breeding cycle, but one species, the Australian sea lion, has a unique cycle of just under 18 months. The net result of this cycle is that there is a gradual shift in the time of year and season when the breeding period occurs. For

Figure 1 *A male and several female California sea lions illustrating the size differences between males and females (sexual dimorphism). The male is the largest individual. Note the female on the right that is carrying a newborn pup using her teeth.*

example, over a 19-year period, between 1973 and 1991, the median date of pupping occurred in every month of the year. No other species of seal exhibits such a pattern. Why this pattern exists is unclear, but it does link to a lactation length of about 17 months in this species.

The reproductive behavior of female sea lions follows the typical maternal foraging cycle seen in all other otariids. Females give birth at traditional sites, usually on sandy beaches. Almost without exception a single pup is born to each female. During what has been termed a perinatal period, the female remains with her pup continuously, nursing it frequently. This period ranges from about 7 to 10 days. At the end of the perinatal period, females will have depleted stores of body fat because they have been fasting and begin to make foraging trips to sea, leaving their pups behind on the beach. In some species, most females will come into ESTRUS before they begin foraging trips, whereas in others, estrus will occur after foraging trips have begun. The duration of foraging trips is variable both within and between species (ranging from about 0.5 to 3 days), although they tend to be shorter among the sea lions than among the fur seals (1–12 days). Between foraging trips, females return to their pups on land, nursing them over a period of 0.5 to 1.5 days. This cycle is continued throughout lactation, which lasts about a year for all sea lions, except the Australian sea lion mentioned earlier, which has a 17-month lactation.

A physiological component of this maternal strategy of sea lions is relatively high-fat milk, which provides the energy needed by the pups as they try to grow during the "feast and famine" situation produced by maternal foraging. We do not have measures of milk fat for all sea lion species, but for those that have been studied the fat content of maternal milk ranges from about 15 to 45%, and most likely the level of fat in a milk relates to the typical length of foraging trips. The best example of this is seen in *Zalophus* spp. The California species, which has maternal foraging trips of about 2.5 days, produces milk with 43% fat, whereas the Galapagos species, which forages for about a half day before returning to pups, has milk containing only 21% fat. Interestingly, the daily growth rates of sea lion pups, after taking the body size of adults into account, are very similar, suggesting that the maternal strategies are finely tuned to ecological conditions.

The reproductive behavior of male sea lions has been investigated unevenly among the various species. We know almost nothing about the New Zealand and Japanese sea lions but a considerable amount about the California, Galapagos, Steller and southern sea lions. Because females gather on land to give birth and care for their young and estrus is temporally linked to parturition, the conditions are ideal for strong sexual selection through male–male competition. In brief, the tendency for female sea lions to be highly clustered, indeed lying in contact with one another, provides the potential for males to compete for and maintain control over multiple females. The ability to control and mate with multiple females in a given reproductive period is known as polygyny.

As is typical of virtually all otariids, male sea lions return to traditional breeding grounds and vie for positions in areas where females have previously given birth or spent time cooling off during the hottest part of the day. In some species or populations, males may actually defend sites or territories, whereas in others they may be more flexible, defending females directly. Factors that are most important in determining which behavior is typical at a colony are the extent to which females move before they become receptive and the level of competition that exists among males. Female movement is most often associated with the need to cool off because of high ambient temperature. One species for which all studies have shown males only to defend territories is the Steller sea lion. This is likely a result of

the high latitude at which this species breeds and the fact that females exhibit little, if any, thermoregulatory movement.

In contrast, the southern sea lion has been shown to behave variably depending on the breeding habitat. At sites where there tend to be large numbers of tidal pools, around which females cluster, males defend territories. However, where there are long narrow sand or pebble beaches, females shift up and down the beach with changes in the state of the tide and air temperatures. Under these conditions, males do not defend territories but shift as females do and defend the females directly.

The level of reproductive success, or number of females mated by the most successful males, may be similar regardless of which pattern of behavior is typical. What seems to constrain the maximum success is the degree to which females are clustered in space and time. If receptive females are too dispersed in time, an individual male may not have enough energy stores to remain competitive throughout the entire season. As food sources are usually not close to the breeding grounds, males must fast during the breeding season; rarely are individual males seen leaving their positions on land. This is true even during the hot part of the day. Minimum estimates of the maximum mating success for the most successful male among the sea lion species are highly variable. The estimate for the most successful Australian sea lion male, a species in which females tend to be quite dispersed, is 7 females mated compared to between 30 and 50 females for California and New Zealand sea lions, species in which females are much more clustered.

This intense competition among males is what produces the extreme sexual dimorphism we see in sea lions and many other seals. At this point it is unclear as to whether the large size of male sea lions is most important in direct competition, i.e., fights and threats with one another, or in the ability to remain ashore for longer periods of time because larger males can store more body fat. In some energetic studies of phocid seals, evidence suggests that it is the amount of energy stores that is more important.

IV. Feeding Habits

Our understanding of sea lion foraging ecology is much poorer than that of fur seals. Diet studies based mainly on analysis of food remains in scats (i.e., feces) do provide a picture of the feeding habits of sea lions, although this is with some bias. In all seven species, evidence suggests that they are primarily fish eaters and secondarily eat cephalopods (e.g., squid and octopus). The southern sea lion and the Australian sea lion, which live in proximity to penguin populations, have been found to prey on penguins occasionally. Penguin predation has not been reported in Galapagos sea lions, however, despite being sympatric with the Galapagos penguin. The two larger sea lions, Steller and southern, also prey periodically on northern and South American fur seal pups, respectively.

V. Population Status

The status of sea lion populations is variable. Two species, the California sea lion and the southern sea lion, are not currently listed as being in trouble. The Japanese sea lion has not been sighted since the 1970s and is now considered extinct. The World Conservation Union (IUCN) considers the Galapagos sea lion vulnerable because there has been no reliable population estimate since the 1970s, at which time the Galapagos sea lion was thought to number about 30,000. California sea lions are probably in excess of 300,000, and southern sea lion populations probably exceed 200,000. What is not clear is how many southern sea lions in Peru died during the severe El Niño of 1997/1998. The sea lion species for which there is greatest concern at present is the Steller sea lion. Although it is not the smallest population by far (estimated at about 96,000), it has declined by about 80% since the 1970s. It is currently considered endangered by the IUCN and as endangered in the western and threatened in the eastern U.S. stock under the U.S. Endangered Species Act. While the precise cause of the decline is unclear, there is some evidence to implicate a decline in food supply, perhaps resulting from a mixture of commercial fishing and environmental changes known as climatic regime shifts. The Australian and New Zealand sea lions are known for their small populations historically and are at less than 15,000 animals each. The Australian species, which has been classed as rare, has been removed from the IUCN list because the population has been increasing and now appears to have leveled off. The New Zealand species remains listed as threatened, having undergone a major die-off in 1998, with 53% of the pups and perhaps as many as 20% of the adults perishing.

Sea Otter

SEE *Otters*

Sei Whale

Balaenoptera borealis

JOSEPH HORWOOD
Centre for Environment, Fisheries and Aquaculture Science, Lowestoft, United Kingdom

I. Identification and Nomenclature

The diversity of thought about our great whales is characterized by quotes from the biologist R. C. Haldane on the sei whale. He described the species as the "most graceful of all the whales, as its proportions are so perfect, and wanting the clumsy strength of the two larger *Balaenoptera*, sperms and *Megaptera*." He added, "it is also far the best to eat, the flesh tasting of something between pork and veal and quite tender."

The sei whale (*Balaenoptera borealis*, Lesson, 1828) is a typical, sleek rorqual, illustrated in Fig. 1. It is the third largest whale, reaching a maximum length of almost 20 m. More typically it is 15 m, weighing 20 metric tons.

Identification of the sei whale at sea can be difficult. By size alone, adult blue and fin whales are obviously larger and minke whales smaller. The dorsal fin is a useful cue, being relatively taller than that of blue and fin whales. It is also strongly concave on its dorsal edge, similar to a minke whale. For a long time it was not distinguished from its close relative, the warm-water Bryde's whale (*B. edeni*). The Bryde's whale has three distinct ridges, running the length of the head, whereas the sei whale has only one (Fig. 1).

The color helps in identification. It is dark gray dorsally and on the ventral surfaces of the flukes and flippers, and there is no whitening of the lower lip as found in fin whales. However, in a few individuals some white baleen plates occur. Often the body can be heavily scarred with healed lamprey bites. Sei whales dive more by sinking than an arched dive, but the other rorquals can also dive in this quiet manner.

A more detailed external inspection allows a more definite identification. In sei and minke whales the ventral grooves end well before the umbilicus. In other *Balaenoptera* spp., including Bryde's whale, they end at, or posterior to, the umbilicus. The number of ventral grooves varies considerably from whale to whale. In sei whales they vary between 40 and 65 with a mean number of about 50. This is less than in blue (*B. musculus*), fin (*B. physalus*), and minke whales (*B. acutorostrata* and *B. bonaerensis*) but about the same as in Bryde's whales.

The baleen of sei whales is a dark gray, but often with a yellowing-brown hue, and often with some anterior white plates. The plates number about 350 on each side of the jaw, and the largest is less than 80 cm long. The width of the plate is relatively narrow compared to blue, fin, and Bryde's whales. In the sei whale the length-to-breadth ratio is typically over 2.2, whereas in the Bryde's whale it is always less than 2.2. The bristles of the sei whales' baleen are particularly fine. At their base they are about 0.1 mm in diameter compared with 0.3 mm for the other rorquals.

The sei whale is closely related to the Bryde's whale. Wada and Numachi (1991) showed that genetic differentiation of the rorquals took place over 4 million years ago, but the sei and Bryde's whales separated less than 300,000 years ago.

The sei whale is derived from the Norwegian "sejhval," as it would arrive off Norway at the same time as the "seje" or saithe (*Pollachius virens*). There are a variety of other common names, but English forms have disappeared from usage in favor of the sei whale.

II. Distribution

The sei whale can be found in all ocean basins. It undertakes extensive, seasonal, latitudinal MIGRATIONS, spending the summer months feeding in the subpolar higher latitudes and returning to the lower latitudes to calve in winter. Figure 2

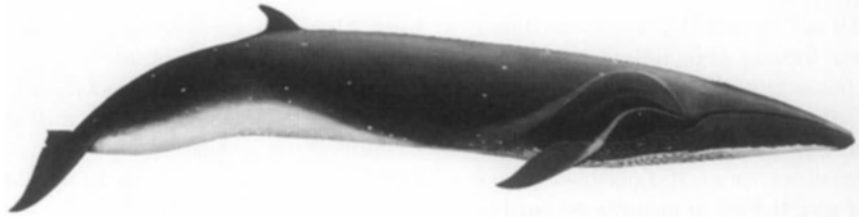

Figure 1 *Smaller than blue or fin whales and larger than minke whales, sei whales* (Balaenoptera borealis) *can be distinguished by a relatively larger dorsal fin and by only one distinct ridge extending the length of the head. Sei whales occur in all oceans. Pieter A. Folkens/Higher Porpoise DG.*

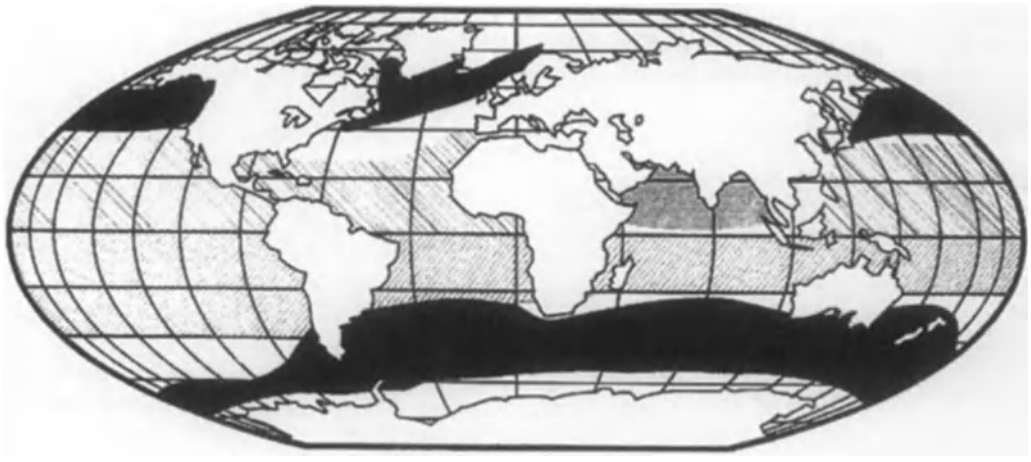

Figure 2 *Global distribution of sei whales. Filled areas are the summer feeding distributions, and hatched areas represent breeding areas.*

shows the global distribution of sei whales in summer and winter. In the Southern Hemisphere, they rarely penetrate as far south as blue, fin, and minke whales, with summer concentrations mainly between the sub-Tropical and Antarctic convergences. Sei whales are seen, and have stranded, in the northern Indian Ocean, but their distribution and migrations are undetermined.

III. Populations and Biology

Genetic studies show the existence of different populations in the Northern and Southern Hemispheres but have failed to identify separate populations within ocean basins. However, biologists have separated populations, for MANAGEMENT purposes, on the basis of different migrations and biological characteristics.

In the Southern Hemisphere, six populations are assumed, as for the other rorquals. In the North Pacific, two or three populations have been proposed. In the North Atlantic, as many as eight populations have been suggested, but only three are considered for management purposes.

The migratory behavior, spatial distribution, and fine baleen structure of the sei whales are associated with the nature of their preferred copepod prey. They feed on patches of copepods, near the surface, usually by skimming, and predominantly at dawn. The other rorquals would probably find such food too scarce, and the sei whale's feeding habits are nearer to those of the right whales than the other rorquals. Sei whales also feed on shoals of fish and squid if they are encountered. Sei whales have a specific feeding niche different from, but sometimes overlapping, that of the other baleen whales.

Maturity is at about 10 years for males and females. Females are larger than males. Sei whales are bigger in the Southern Hemisphere, and here males mature at about 13–14 m and females at 14 m. In most seas, the age of maturity declined by 2 to 3 years, after the populations were depleted by whaling. In the Southern Hemisphere, young are conceived in June and births are in December in northern waters. The young are carried for almost a year and are born at a size of 4.5 m. Most calves are weaned in 7 months, after they have migrated to colder waters with their mothers.

As for most mammals, sei whales can be expected to have increased rates of mortality when very young or old, but actual rates are poorly known. From observations of age compositions, the rate of natural mortality is typically about 5–10% per year. They die naturally from predators, such as killer whales, and weakening from disease and parasites.

IV. Status of Populations

A fast rorqual, the sei whale was not exploited until the era of modern whaling at the end of the 1800s. Off north Norway, 4000 sei whales were killed between 1885 and 1900. Since then, sei whales were caught in the North Atlantic from land stations in Canada, Faeroes, Iceland, Ireland, Iberia, Norway, and Scotland. In the North Pacific, they were caught from California, Canada, Japan, Kamchatka, and Kuril and by pelagic fleets. In the Southern Hemisphere, they were caught from Brazil, Chile, Peru, South Africa, and South Georgia. The largest catches were made by the Antarctic pelagic fleets, after the numbers of blue and fin whales had been reduced, and between 1960 and 1970 over 110,000 sei whales were killed. Whaling is regulated by the IWC, and whaling for sei whales ceased in the Southern Hemisphere in 1979 and in the North Pacific in 1975. In the North Atlantic, whaling was prohibited from 1986, but limited catches continued for a few years, at Iceland, under a scientific special permit and through subsistence whaling from Greenland.

The size of populations is poorly determined, but whaling significantly depleted populations in all areas. In the Southern Hemisphere the original population was about 100,000, and in 1980 was thought to be 24,000. In the North Pacific, a population of over 60,000 was reduced to about 15,000. By now there may be 70,000 in both areas. The status of the North Atlantic sei whale is more uncertain, but recent sightings surveys indicate about 10,000 sei whales in the central and northeastern North Atlantic.

Sexual Dimorphism

KATHERINE RALLS
National Zoological Park, Smithsonian Institution, Washington, DC

SARAH L. MESNICK
Southwest Fisheries Science Center, La Jolla, California

Dimorphism means two forms. "Sexual dimorphism" means that the two sexes of a species differ in external appearance or other features. Males and females may differ in size, color, shape, the development of appendages (such as horns, teeth, feathers, or fins), and also in scent or sound production. Species in which males and females are identical in appearance or other features are said to be "monomorphic." This article describes the types of dimorphic traits found in marine mammals and explains some of the reasons why these traits might have evolved and what can be inferred about the lives of males and females in a particular species from the pattern of sexual dimorphism. The quality of the information available on sexual dimorphism varies widely across marine mammal species. We know quite a lot about a few species, which are used repeatedly as examples, and virtually nothing about others. Despite the technical difficulties of studying marine mammals, our understanding of the evolution of sexual dimorphism is increasing steadily as observations of rarely encountered species accumulate and new techniques are developed.

I. Evolution of Sexual Dimorphism

Sexual dimorphism has fascinated biologists since before the time of Darwin. Darwin considered that most sexual dimorphism was due to sexual selection, in which evolutionary forces acted separately on the sexes (Darwin, 1871). For example, females might choose to mate with highly ornamented males (e.g., the peacock's tail) or males might develop characters useful for fighting with other males to win in contests for access to females (e.g., large body size and antlers in deer). Today, these two processes are often referred to as female choice and contest competition, respectively. More recently, scientists have learned that males compete not only by physical fighting and display but also, in species where females mate with more than one male, by sperm competition within the female reproductive tract.

Although Darwin's ideas about sexual selection have stood the test of time, some cases of sexual dimorphism seem to be best explained by natural selection. For example, males and females in some species of birds [e.g., Galapagos finches (genus *Geospiza*) and the extinct New Zealand huia (*Neomorpha acutirostris*)] have radically different bill morphologies that are best explained by sex differences in foraging habits (Anderson, 1994). In some species, females appear to be larger than males primarily because big mothers are better mothers (more eggs, better at defending their brood; Ralls, 1976). The emerging view is that the degree of sexual dimorphism in a species is the result of the difference between the sum of all the selective pressures (natural selection and sexual selection) affecting the male and the sum of those affecting the female.

II. Types of Sexual Dimorphism

The adult males and females of a species may differ in size, color, shape, the development of appendages (such as horns, teeth, feathers, or fins), scent, or vocalizations (Fig. 1). In marine mammals, one of the most striking sexually dimorphic characters is size. In some species, males are dramatically larger than females. For example, in southern elephant seals (*Mirounga leonina*), adult males (maximally at 3700 kg) weigh 4–10 times as much as the adult females (which weigh 350–800 kg). Males in some species also possess greatly enlarged TEETH that are lacking in females and are used in fights between males. The best known example is the unicorn-like tusk of the NARWHAL (*Monodon monoceros*). The tusk, which is actually a greatly enlarged left upper tooth, usually erupts only in males and can grow to an extraordinary size, exceeding 3 m in length and 10 kg in weight. In some odontocete species (e.g., bottlenose whales, genus *Hyperoodon*), males have greatly enlarged and densely ossified heads, which they use to ram other males during fights. In otariids, males have thick necks and massive chests that tend to be covered by a dense mane of hair. The noses of males are sometimes bizarrely modified. For example, the most distinctive feature of the male hooded seal (*Cystophora cristata*) is an inflatable hood and bright red nasal sac that may function in agonistic and courtship displays. The appendages of males (flippers, flukes, caudal peduncles, and dorsal fins) are sometimes greatly enlarged. The best known example of dorsal fin enlargement is seen in male killer whales (*Orcinus orca;* Fig. 1b).

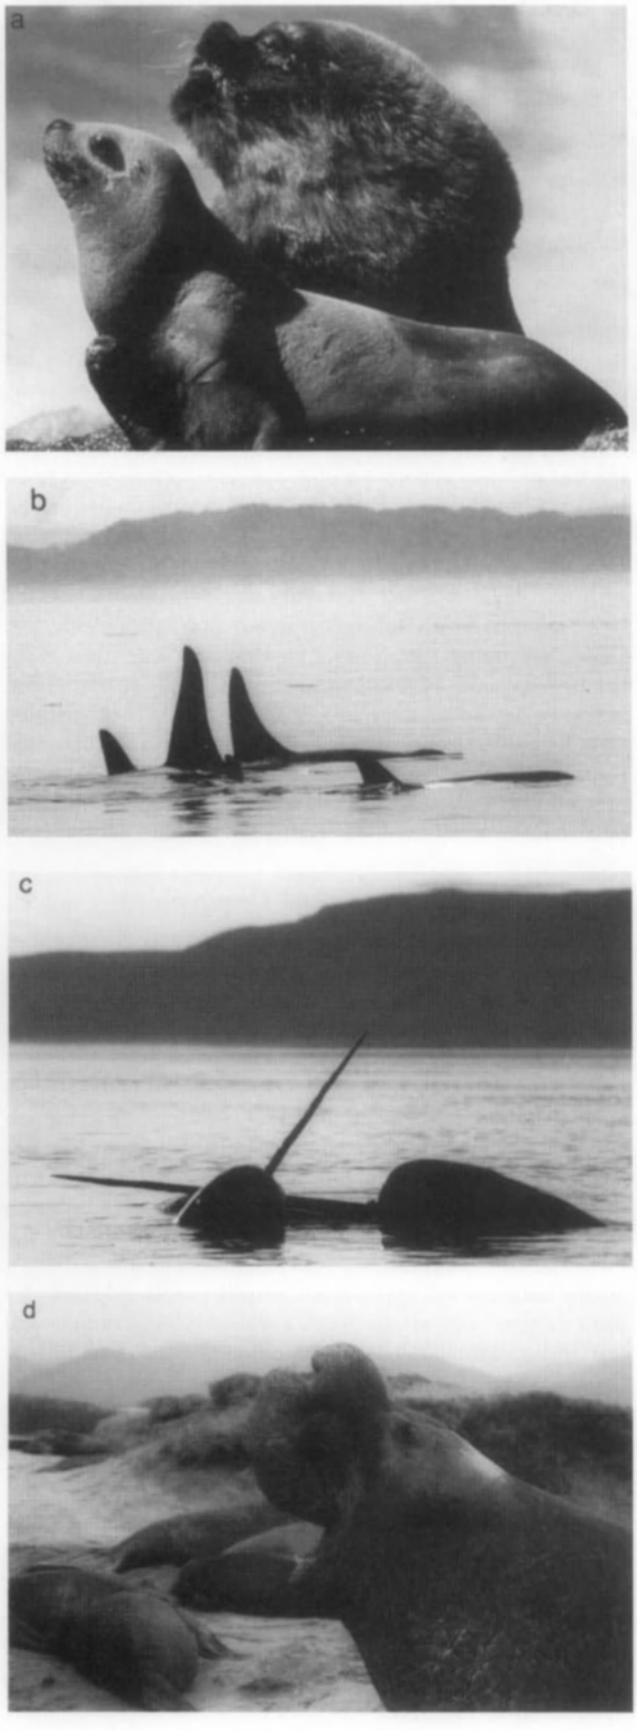

Figure 1 *Types of sexual dimorphism in marine mammals. (a) Size. Adult male South American sea lions* (O. flavescens) *are two to three times heavier than females; males grow to 2.8 m and weights of 340 kg; females to 2.2 m and 144 kg. There is extreme sexual dimorphism in body shape and pelage as well as size; males have massive necks, a broad head with a characteristically upturned muzzle, and a thick mane of long guard hairs. Photo by William Conway. (b) Dorsal fins. A pod of killer whales* (O. orca), *Alaska. In adult males, the dorsal fin is erect and may grow to 1.8 m in height whereas the dorsal fins of females are less than 0.7 m and distinctly falcate. Sexual dimorphism also occurs in body size, flipper size, and genital pigmentation pattern. Photo by Flip Nicklin (Minden Pictures). (c) Teeth and tusks. Dueling male narwhals* (M. monoceros), *Canada. The unicorn-like tusk of the narwhal is actually a greatly enlarged left upper tooth. The tusk generally erupts only in males and may exceed 3 m in length and 10 kg in weight. Sexual dimorphism also occurs in body size, pigmentation pattern, and the shape of the flukes and pectoral fins. Photo by Flip Nicklin (Minden Pictures). (d) Noses. Threat vocalizations resonate in the greatly enlarged proboscis of adult male northern elephant seals* (M. anguistirostris), *Año Nuevo, California. There is extreme dimorphism in body size and shape; males grow maximally to 4 m and 2300 kg and females to 3 m and 360–710 kg. The skin on the neck of the adult males is thick, rugose, and scarred by fights, and canine teeth are sexually dimorphic in size and shape. Males are darker brown than females. Photo by Sarah L. Mesnick. (e) Postanal hump. The postanal hump of adult male eastern spinner dolphins* (S. longirostris orientalis) *is exaggerated tremendously. The dorsal fin of adult males is also forward canted and the tips of the flukes curl up. Photo by Robert L. Pitman.*

Although sexual dimorphism traditionally referred to differences in morphological traits, the sexes can also produce different vocalizations or odors or be differently colored or patterned. Among marine mammals, differences in color are usually limited to fairly minor differences in pattern or density of pigmentation. For example, in ribbon seals (*Histriophoca fasciata*), the banding pattern is similar in both sexes but paler and less distinct in females. There are numerous examples of sexually dimorphic vocalizations in marine mammals, such as

the roars and bellows of male sea lions and fur seals (Otariidae), the songs of male humpback whales (*Megaptera novaeangliae*), and the loud clicks of male sperm whales (*Physeter macrocephalus*). In terrestrial mammals, males and females often produce different scents via urine, feces, or specialized scent glands. This has not been observed much in marine mammals but may well occur. It is known, for example, that male ringed seals (*Pusa hispida*) produce a strong odor in the breeding season. Male sea otters (*Enhydra lutris*) frequently investigate the anogenital areas of other otters, and male common bottlenose dolphins (*Tursiops truncatus*) investigate the urogenital region of possibly estrous females with their rostrums.

III. Taxonomic Distribution

A. Baleen Whales

Sexual size dimorphism is "reversed" among the 13 species of baleen whales with females attaining asymptotic lengths that are generally 5% longer than males. Baleen whales typically undertake long-distance migrations between their northern or southern feeding areas and their tropical breeding areas and may not feed while migrating or on the breeding grounds. Females have the added stress of pregnancy and lactation during the nonfeeding periods; a larger size may enable them to store more energy resources in the form of BLUBBER to meet their greater reproductive demands.

Sexually dimorphic vocalizations are well known in humpback whales. Male humpbacks sing lengthy, elaborate songs, the function of which has been the subject of much speculation. Songs might function to attract females, signal status to other males, space males on the breeding grounds, synchronize estrus in females, or some combination of these. The humpback song is particularly intriguing because songs change over time, yet all members of a population sing similar songs at any one time. Male fin whales (*Balaeoptera physalus*) have a patterned call, which has been termed a breeding display, but observations of COURTSHIP or competitive interactions are sparse. Sexually dimorphic vocalizations may also exist in blue whales (*Balaenoptera musculus*). There is dimorphism in the shape of the upper jaw of fin whales and, to a lesser extent, Bryde's whales (*Balaenoptera edeni*), but the function of this dimorphism is unknown.

Observations of clear AGGRESSION between males are known only in humpback and southern right whales (*Eubalaena australis*). Thus, it is not surprising that there are few accounts of sexually dimorphic structures that might be used in contest competition. Male right whales, however, have larger and more numerous callosities (the raised thickened patches of skin on the head) than females, which may function as weapons in contests between males. Male right whales are also scarred more heavily than females.

B. Toothed Whales

The relative size of the sexes varies widely among the 70^{+} species of toothed whales. Males are larger than females in many species, with the most pronounced dimorphism in sperm whales, killer whales, bottlenose whales, narwhals, belugas (*Delphinapterus leucas*), and pilot whales (genus *Globicephala*). In sperm whales, for example, females reach about 11 m in length and 15 tons, whereas physically mature males are approximately 16 m long and weigh 45 tons. Females are slightly larger than males in Baird's beaked whales (*Berardius bairdii*), the franciscana (*Pontoporia blainvillei*), the Indian river dolphin (*Platanista gangetica*), harbor porpoise (*Phocoena phocoena*), and dolphins in the genus *Cephalorhynchus*. Some species are monomorphic in size, including the Clymene dolphin (*Stenella clymene*), Atlantic spotted dolphins (*Stenella frontalis*), dwarf and pygmy sperm whales (genus *Kogia*), tucuxi (*Sotalia fluviatilus*), and some dolphins in the genus *Lagenorhynchus*.

Differences between the sexes may occur in the size and shape of the head, teeth, thoracic girth, flukes, flippers, dorsal fin, caudal peduncle, postanal hump, and length of the beak. In general, males tend to have larger appendages than females, the exception being the few species in which females have longer rostra than males [both species of south Asian river dolphin, the franciscana, and the rough-toothed dolphin (*Steno bredanensis*)]. Dimorphism in the size and shape of the head may be a result of enlargement of the nose (in sperm whales) or the forehead [in bottlenose whales (genus *Hyperoodon*), pilot whales, and to a lesser extent in bottlenose dolphins] of adult males. The massive nasal complex of adult male sperm whales may be one-quarter to one-third the length of the animal and is probably used in the generation of sound. In bottlenose whales, the forehead is extremely steep and the surface becomes flattened in mature males. Dimorphism in the density of ossification of the bones in the head occurs in bottlenose whales (the cranium) and beaked whales of the genus *Mesoplodon* (the rostrum, which has one of the highest reported densities of any mammalian tissue). Differences between the sexes in the ossification of the head in these species are not surprising given observations of head butting between adult male bottlenose whales and heavy scarring on adult males of several beaked whale species of the genus *Mesoplodon*. The sexually dimorphic pattern of scarring in *Mesoplodon* species is consistent with the idea that adult males use their rostrum, and the exposed teeth on the lower jaw, in fights with other males.

Dimorphism in the size, shape, and/or number of teeth is known in the narwhal, sperm whale, Cuvier's beaked whale (*Ziphius cavirostris*), bottlenose whale, and in beaked whales of the genus *Mesoplodon*. In most of these species (exceptions being sperm whales and narwhals) the teeth erupt only in males and only at sexual maturity.

Differences between the sexes are known in flipper length (killer whales and melonheaded whales, *Peponocephala electra*), serration (Heaviside's dolphins, *Cephalorhynchus heavisidii*), and shape of the trailing edge (belugas). In some species, including sperm whales and Dall's porpoises (*Phocoenoides dalli*), males have deeper caudal peduncles than females, which may function to give more power to the flukes. Postanal humps (thought to be composed of muscle and connective tissue) are exhibited in mature males of several species, although they have been properly described and correlated with age and sex in only a few. The postanal hump of the male eastern spinner dolphin (*Stenella longirostris orientalis*) is exaggerated tremendously (Fig. 1e). While the function of the postanal hump remains unknown, it has been suggested to be an anchor for

external genitalia and may serve to enhance sexual performance. It may also serve as a visual signal that makes adult males easily recognizable. Dorsal fins may be larger and more erect in males than females, more hooked, or more forward-canted (Figs. 1b and 1e). The most exaggerated examples of dorsal fin enlargement are seen in male killer whales and pilot whales. The significance of these differences in dorsal fin size and shape is unknown but they may serve a thermoregulatory function and/or as a visual signal. Differences between the sexes also occur in the flukes, which may be longer and broader in males, or differently shaped. In Dall's porpoises and sperm whales, for example, the trailing edge of the flukes of males are convex, and in male eastern spinner dolphins, the tips of the flukes curl up. As is true for mammals in general, the distance between anal and genital openings of odontocetes tends to be greater in males than in females.

Sexual differences in pigmentation patterns are most common in the genital area but are also known to occur on the face, head, and body. Sexual dimorphism in genital pigment patterns is known in several species [killer whales, dolphins in the genus *Cephalorhynchus* and *Lissodelphis*, shortbeaked common dolphins (*Delphinus delphis*), Burmeister's porpoises (*Phocoena spinipinnis*), and Dall's porpoises]. Pigmentation differences may be related to sexual recognition, advertisement (for either males or females), or may help suckling young locate the teats. In most species of beaked whales, the body gets lighter in color with age. The lightening is especially noticeable in adult males and is primarily due to an accumulation of body scars, but may also be due to changes in pigmentation and, in several species, both. In Risso's dolphins (*Grampus griseus*), ontogenetic lightening and an accumulation of body scars make older animals of both sexes appear almost pure white, and the pattern may be more prevalent in males. Adult male spotted dolphins (*Stenella attenuata*) bear conspicuous white rostrum tips, visible at a great distance. In Fraser's dolphins (*Lagenodelphia hosei*), the intensity and thickness of the eye-to-anus stripe becomes more exaggerated (darker and thicker) in adult males. Another type of pigment dimorphism is the occurrence of visible (white or nonpigmented) linear scarring, suggested to result from a lack of repigmentation of damaged tissue from the tooth rake wounds of conspecifics. In some odontocete species, both sexes exhibit heavy scarring [e.g., Baird's beaked whale (genus *Berardius*) and Risso's dolphins]. However, in others (*Mesoplodon* spp., the narwhal, and the sperm whale), males are scarred more heavily than females. In these species, scarring is likely the result of wounds inflicted during male fights.

At present, acoustically dimorphic calls are known only in sperm whales. However, because odontocetes produce a wide range of sounds, dimorphic acoustic signals are likely to occur in several other species as well. Because larger animals make larger sounds, it is also reasonable to expect that other sexually dimorphic species, such as pilot whales, will produce acoustically dimorphic calls.

C. Pinnipeds

The 36 species of pinnipeds show the greatest range in sexual size dimorphism of any higher vertebrate group (Fig. 2). Adult males are up to 10 times as heavy as adult females in some species, whereas females are slightly larger than males in others. For virtually all pinnipeds studied to date, data support, or are highly suggestive of, a polygynous mating system. However, the potential for polygyny varies greatly among species and there is a strong correlation between the degree of polygyny and the degree of dimorphism. The mating system in turn, depends to a large extent on whether breeding takes place on land or at sea. In terrestrially mating pinnipeds [this includes sea lions and fur seals and three species of phocid, the northern and southern elephant seal (genus *Mirounga*) and the gray seal (*Halichoerus grypus*)], extreme polygyny is possible because females gather in dense groups on islands to give birth and mate. Under these conditions, a successful male can defend many females. In these species, males exhibit not only large size but also other characteristics useful in fights over females, such as large canines, massive necks and chests, and dense pelage. Large size may also help males of these species achieve greater reproductive success by enabling them to remain longer on the breeding rookery because larger males have bigger energy reserves in the form of blubber.

In the remaining pinnipeds, the WALRUS (*Odobenus rosmarus*) and nearly all of the phocids, mating takes place in the water. Females of many species give birth on ice (and therefore are not as spatially clumped as terrestrially breeding species in part because they have larger expanses of suitable habitat available) and the mating season is short. Thus, males have less opportunity to defend and mate with multiple females. These characteristics inhibit the development of the extreme polygyny and sexual dimorphism found in terrestrially mating otariids and phocids. In general, males of aquatically mating species are only slightly larger than females or females may be slightly larger than males [bearded (*Erignathus barbatus*), Weddell (*Leptonychotes weddellii*), Ross (*Ommatophoca rossii*), crabeater (*Lobodon carcinophaga*), and leopard (*Hydrurga leptonyx*) seals]. The hooded seal is a notable exception, with males considerably larger than females. In ice-breeding species, large female size may help a mother provide large quantities of fat-rich milk for her pup, and because mating takes place in the water in these species, agility, rather than size or strength, may be important in male contests for females.

In addition to the sexual size dimorphism mentioned earlier, the sexes may also differ in pelage length and color, shape of the head and chest, canine development, and the pattern of scarring on the neck and chest. Adult male otariids tend to be bulkier than females and are distinguished readily by their thicker and more powerful necks and their massive chests. The head, neck, and chest of males tend to be covered by longer, rougher hairs, which gives the impression of a mane [e.g., the South American sea lion (*Otaria flavescens*); Fig. 1a]. In older males, the guard hairs are lighter in color and tinged with white, silver, or tan. Adult male California sea lions (*Zalophus californianus*) also develop a pronounced forehead, or sagittal crest, and adult male southern sea lions have a distinctive upturned muzzle. The skin on the necks of adult male elephant seals and gray seals is thickened and wrinkled and marked by scars from fights. In general, adult male otariids, as well as adult males in some species of phocids, tend to be more darkly pigmented than females.

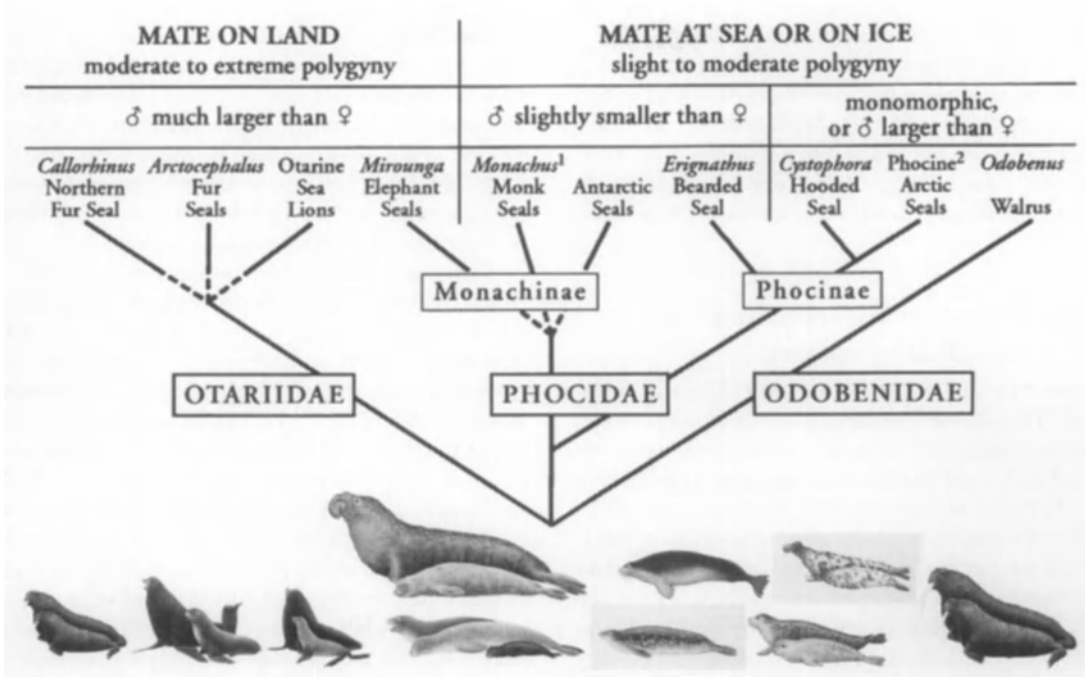

Figure 2 *Sexual size dimorphism in pinnipeds. A composite phylogenetic tree of the Pinnipedia on which sexual dimorphism, mating location, and degree of polygyny have been overlaid. Sexual size dimorphism varies greatly across pinniped species, and there is a strong correlation between the degree of dimorphism and the mating system. In otariids and three species of phocid (both elephant seals and the gray seal), mating takes place on land and extreme polygyny is possible because a successful male can defend many females. Males are much larger than females (2 to 10 times larger) and also exhibit other characteristics useful in fights over females, such as large canines. In the remaining pinnipeds, the walrus and nearly all the phocids, mating takes place in the water or on ice. There is less opportunity for males to mate with multiple females and agility, rather than size or strength, may be important in male contests for females. Males are equal, slightly, or moderately (up to 1.5 times) larger than females or females may be slightly (up to 1.1 times) larger than males in these species. [1]Females are slightly larger than males in the Hawaiian monk seal; males are slightly larger than females in the Mediterranean monk seal. [2]Among phocines, the gray seal represents a notable case because it can exhibit both terrestrial and aquatic mating and males are maximally 3 times larger than females. Pieter A. Folkens/Higher Porpoise DG.*

Many pinnipeds have sexually dimorphic vocalizations that may function to establish and maintain dominance relationships or to attract females. In some species, the sounds are amplified or resonated in the proboscis (as in hooded and elephant seals; Fig. 1d) or an internal air sac (as in ribbon seals, bearded seals, and walruses). Hooded seals produce numerous sounds as they inflate and deflate their hood and bright red nasal sac in response to disturbances and as part of the courtship display. Male elephant seals also have greatly enlarged noses, and snouts of male gray seals are broader and more elongated than those of females. Males of these species establish dominance hierarchies through stereotyped visual and airborne acoustic threats and, less often, physical aggression. Male harbor, bearded, ribbon, Weddell, ringed, and harp (*Pagophilus groenlandicus*) seals are known for their acoustic courtship displays. Male harbor seals engage in complex hierarchical acoustical mating displays in which several subordinate males passively muzzle singing dominant males underwater. Much of the roaring and bellowing of adult male otariids is thought to intimidate rivals but acoustic displays may also be used to advertise to females. The walrus has the most elaborate courtship display of all pinnipeds involving intricate acoustic and visual components. Vocalizing adult male walruses apparently compete for females in lek-like groups in the water near ice floes on which females gather to pup and rest. Their surface vocal repertoire includes barks, whistles, and growls, and underwater vocalizations sound bell like. It is also thought that the massive tusks may play a role as a visual symbol of rank and as a display to females. Male walruses are larger than females in both body and tusk size. In marine mammals, the only well-documented sexually dimorphic scent of which we are aware occurs in the ringed seal. Male ringed seals give off a strong scent during the breeding season.

D. Sirenians, Sea Otters, and Polar Bears

Manatees (genus *Trichechus*) are generally monomorphic in size and appearance. Dugongs (*Dugong dugon*) exhibit no obvious sexual dimorphism apart from the short tusks (upper

incisors), which usually erupt in adult males, although females may grow to a slightly larger size than males. Male dugongs compete for access to females by patrolling exclusive areas and engaging in threats, fights, and song. Adult male sea otters are larger than adult females. Second only to pinnipeds, polar bears (*Ursus maritimus*) exhibit the greatest sexual size dimorphism among mammals. Male polar bears may be over twice as heavy as females.

IV. What Can We Infer from Sexual Dimorphism?

The variation in sexual dimorphism among marine mammal taxa is striking. The sexes are visually indistinguishable in some species, whereas in others the differences between the sexes are so extreme that males and females live essentially separate lives except when they meet to mate. This rich variation in sexual dimorphism has prompted scientists to offer a variety of explanations. The various mechanisms of sexual selection—female choice, contest competition, and sperm competition— probably account for a large proportion of sexual dimorphism in marine mammals. However, some dimorphic traits may reflect ecological differences between the sexes (e.g., differences in beak length between the sexes in south Asian river dolphins). Others may be important for females and their young (e.g., larger females make better mothers or urogenital pigment patterns may highlight the mammary glands and help young to find them).

The functional significance of most sexually dimorphic traits in marine mammals remains untested, which is not surprising given the difficulty of observing, let alone experimenting on, most species. In general, the behavior of pinnipeds (which often breed where they can be observed) is better known than the behavior of cetaceans that breed at sea. However, extended observations of behavior have also been possible in a few cetacean species (e.g., bottlenose dolphins, humpbacks, and right whales) that breed close to shore. Nevertheless, we can often infer the functional significance of sexual dimorphism in species whose behavior is poorly known by analogy to well-studied species. The type and degree of sexual dimorphism and its association with other characteristics such as relative testis size and pattern of bodily scarring provide clues to the intensity of sexual selection (the skew in male mating success) in a species and the probable underlying mechanisms of sexual selection.

Based on studies of terrestrial mammals, a positive correlation is generally assumed between the amount of sexual dimorphism in a species and the deviation of the breeding system from monogamy. Thus, in polygynous species, male competition for access to females is severe and males are expected to exhibit traits, such as large size and big canines, favored in fights with other males over access to females. The correlation between sexual size dimorphism and the degree of polygyny has been shown across pinniped taxa (Alexander *et al.*, 1979). For example, among otariids, the northern fur seal (*Callorhinus ursinus*) and Steller sea lion (*Eumetopias jubatus*) show the greatest relative dimorphism in body weight and defend the greatest number of females in their territories as compared to less dimorphic species. Within a species, a large body size has also been shown to be correlated with greater mating success (via dominance rank, endurance, and tenure on rookeries; e.g., elephant seals, gray seals). It is important to note, however, that species that lack sexual size dimorphism do not necessarily lack male–male competition for mates. In these species, sexual selection may be intense, but due to different forms of competition among males for access to mates, and the consequences may not be reflected in size but in other characters, such as song, visual display, or agility.

Sexual dimorphism in size and weaponry (big teeth, enlarged heads, and strong flukes) suggests that contest competition for access to mates plays an important role in the mating strategies of males in many marine mammal species. Contest competition may take the form of ritualized displays (visual or acoustic), by which potential rivals assess relative size or strength, or physical aggression. Among odontocetes, dimorphism in weaponry is correlated to patterns of body scarring and observations of head butting among males. In certain species, such as sperm whales, beaked whales, and narwhals, teeth erupt or are enlarged only in adult males, a pattern that suggests their function has shifted from feeding to use in social interactions. Adult males of many of these same species are heavily scarred, another trait that suggests males use their teeth in physical battles with other males.

Among terrestrial mammals, the relationship between relative testis size and mating system is so strong that relative testes size can be used as a good indicator of the mating system (Gomendio *et al.*, 1998). In general, where copulatory frequency is high, the testes are large, and where copulation is infrequent, the testes are small. In right whales, observations of multiple males mating with single females, together with huge (1 ton) testes, strongly suggest that sperm competition is a principal mating strategy in this species, and probably also in bowhead (*Balaena mysticetus*) and gray (*Eschrichtius robustus*) whales (Brownell and Ralls, 1986). Odontocete species such as sperm whales and beaked whales that exhibit dimorphic traits associated with intense physical combat (e.g., large size, enlarged teeth) tend to have small testes. The testes of sperm and beaked whales represent less than 0.5% of the body weight, weigh only a few kilograms, and can be held in one hand. At the other extreme, species having the largest testes, suggesting the likelihood of significant sperm competition, do not exhibit the extreme dimorphic traits associated with physical combat. These species tend to be sexually monomorphic or have dimorphic traits that may be associated with agility or visual display. For example, harbor porpoises, finless porpoises (*Neophocaena phocaenoides*), and dusky dolphins (*Lagenorhynchus obscurus*) have testes that represent greater than 5% of their body weight. Humans, for comparison, at about the same body mass as these dephinid species, have testes of only 0.08% of body mass (Kenagy and Trombulak, 1986).

In three-dimensional habitats, agility, rather than size or strength, may sometimes determine the outcome of male contests. Agility may be useful in scramble competition for access to mates and it may function as a visual display for female choice. This may be the case in some species, such as the aquatically mating phocids, in which males compete underwater and are smaller than females. Among odontocetes, larger body size typically means that the male's propulsion structures are also pro-

portionally larger than those of the female. The importance of speed and maneuverability is suggested by sexual dimorphism in the flippers, flukes, caudal peduncle, and dorsal fin. Tolley *et al.* (1995) suggested that the larger body size, caudal peduncle, flukes, and dorsal fin of male bottlenose dolphins, and the pattern of dorsal fin scarring, are consistent with males competing for access to dispersed females. Features such as flukes and dorsal fins are used for propulsion, maneuvering, and thermoregulation and in offensive or defensive encounters with other males. More power to the flukes could increase the strength of blows and greater speed could aid in the herding of females.

Traditionally, behavioral ecologists have tended to emphasize the importance of male–male competition in the evolution of exaggerated male traits. More recently, based primarily on bird data, they have found that female choice often plays a critical role. Recordings of male song and the existence of exaggerated morphological traits that make adult males easily recognizable suggest the importance of female choice in marine mammals. The same features that appear to provide advantages in contests between males, such as large size, big canines, or deep roars, may also be used by females to select mates and/or may function to control or intimidate females (Wells *et al.*, 1999). Whether females actually use these traits to assess males or what these traits might signal (e.g., status, fitness, or readiness) is unknown. The enlarged postanal hump of males in some dolphins and porpoises may serve an important biomechanical function for males by facilitating copulation. It may also be important as a visual signal that makes adult males easily recognizable within schools, by both females and other males. Similarly, enlarged dorsal fins, which may have a thermoregulatory function, may also serve as a visual signal. The calls of male pinnipeds may function as male displays to females, in species recognition, and in contests between males. Evidence supporting the idea of lekking in walrus and dugongs suggests an increasing role for female choice in the evolution of vocal mating displays.

Caution is warranted when making inferences about the evolution of sexually dimorphic traits. First, our knowledge of sexual dimorphism across marine mammal taxa is incomplete. There are rarely encountered species for which we have very little information about sexual dimorphism. While our understanding of morphological differences between the sexes is growing, our knowledge of acoustic and pheromonal differences is in its infancy. As we fill in these gaps in our knowledge, our ability to understand the underlying evolutionary patterns and processes will increase. Second, a sexually dimorphic trait may have evolved for different reasons in different species. For example, among odontocetes, males are much larger than females in sperm whales, "resident" killer whales, and long-finned pilot whales (*Globicephala melas*), but it is unlikely that a single explanation fits all three cases. In sperm whales, adult males are solitary and roam great distances searching for females. Males possess large teeth, have massive heads, are scarred, and have been observed ramming each other head on. It is likely that large size serves male sperm whales well in contest competition over access to females. In contrast, adult male "resident" killer whales and long-finned pilot whales live in stable social groups with their maternal relatives, are not scarred, and we know of no accounts of aggressive interactions between males. In contrast to sperm whales, "resident" male killer whales and long-finned pilot whales may increase their reproductive success, not only by mating with females in other pods, but by assisting kin in their natal pods. At this point, we can only speculate about the advantages that large size confers on males of these species, but assistance in a communal foraging strategy ("resident" killer whales) and protection of the pod (long-finned pilot whales) are possibilities. Females may prefer large males as mates in all these species, but large size may confer different advantages to individuals in each of the three cases.

Despite the technical difficulties of studying marine mammals, our understanding of the evolution of sexual dimorphism is increasing steadily. New techniques, such as scoring molecular genetic markers from tissue samples, are providing insight into social structure and variance in male reproductive success. Video, acoustic recordings, and "critter cams" (small television cameras that can be mounted on individual animals) are providing exciting new data on the behavior and interactions of animals underwater. Clearly, research opportunities abound, and the prospects for increased future understanding of the abundant sexually dimorphic traits in marine mammals are bright.

Shepherd's Beaked Whale

Tasmacetus shepherdi

JAMES G. MEAD
National Museum of Natural History, Smithsonian Institution, Washington, DC

Shepherd's beaked whale is a rare animal, being known only from 21 strandings in the Southern Hemisphere. It is unusual in that it is the only beaked whale with a full set of functional teeth in both jaws.

I. Diagnostic Characters

Shepherd's beaked whale (*Tasmacetus shepherdi*, Oliver, 1937) is the only beaked whale to have a full set of functional teeth (Fig. 1). It has between 17 and 21 upper teeth on each side and between 18 and 28 lower teeth. The first tooth in the mandible is enlarged, and it is thought that size difference makes it homologous to the single teeth of other beaked whales. It was initially thought to be a primitive member of the beaked whale family (Ziphiidae) on the basis of retention of teeth. There has not been a good study of the evolutionary relationships of the beaked whales, but *Tasmacetus* seems in ways other than the teeth to be just as specialized as the remainder of the family. Adults are between 6 and 7 m in length. The only known calf was 340 cm long. This calf had plastic debris in its stomach, but it is not known whether it had begun to take normal solid food. The pigmentation pattern (Fig. 2) is dark gray dorsally, with a white field ventrally extending dorsally on both the anterior and posterior sides of the flipper. The dark dorsal field extends onto the flipper. Another extension of the white ventral field lies dorsal to the anus.

II. Distribution

The geographic records of *Tasmacetus* are illustrated in Fig. 3. It is known from strandings in New Zealand (12), Australia (1), Argentina (3), Juan Fernandez Islands (2), and the south Sandwich Islands. There are two published sightings attributed to this species: one from New Zealand and one from the Seychelles Islands. It is limited to temperate waters and may not ordinarily come as far north as the tip of Africa.

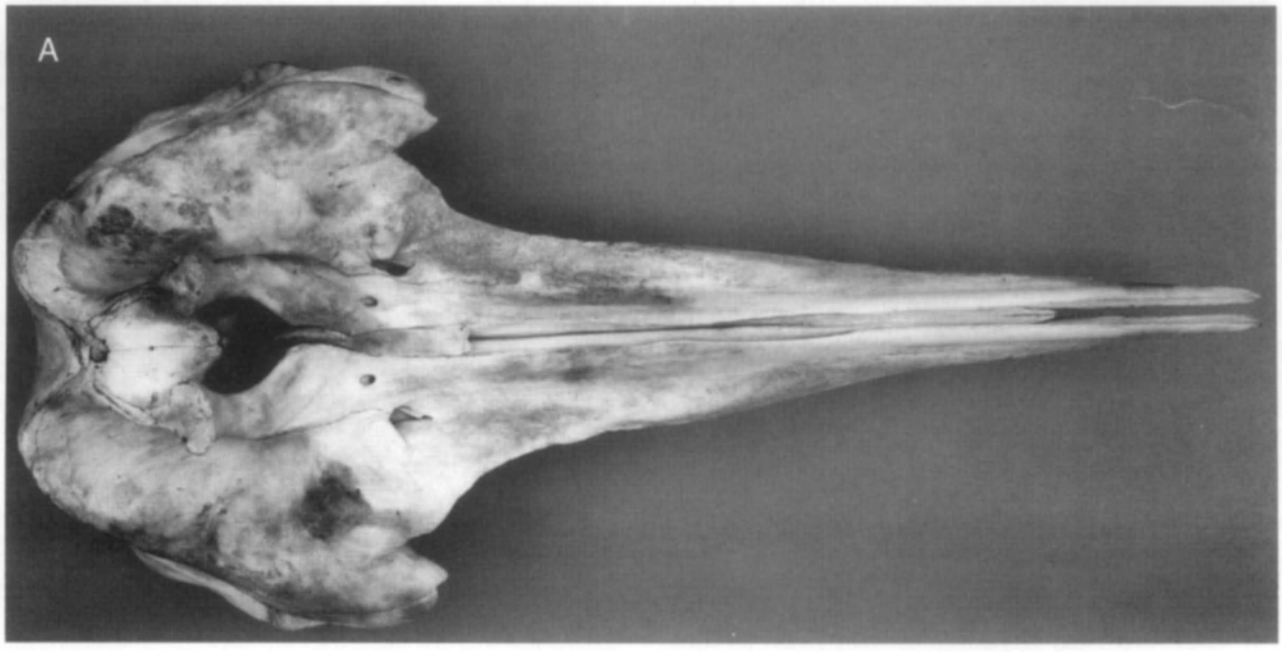

Figure 1 *(A) Dorsal view of skull, (B) ventral view of skull, (C) right lateral view of skull, and (D) right lateral view of mandible of a* Tasmacetus shepherdi *660-cm female. All figures are shot at the same scale; 10-cm scale bar is in D.*

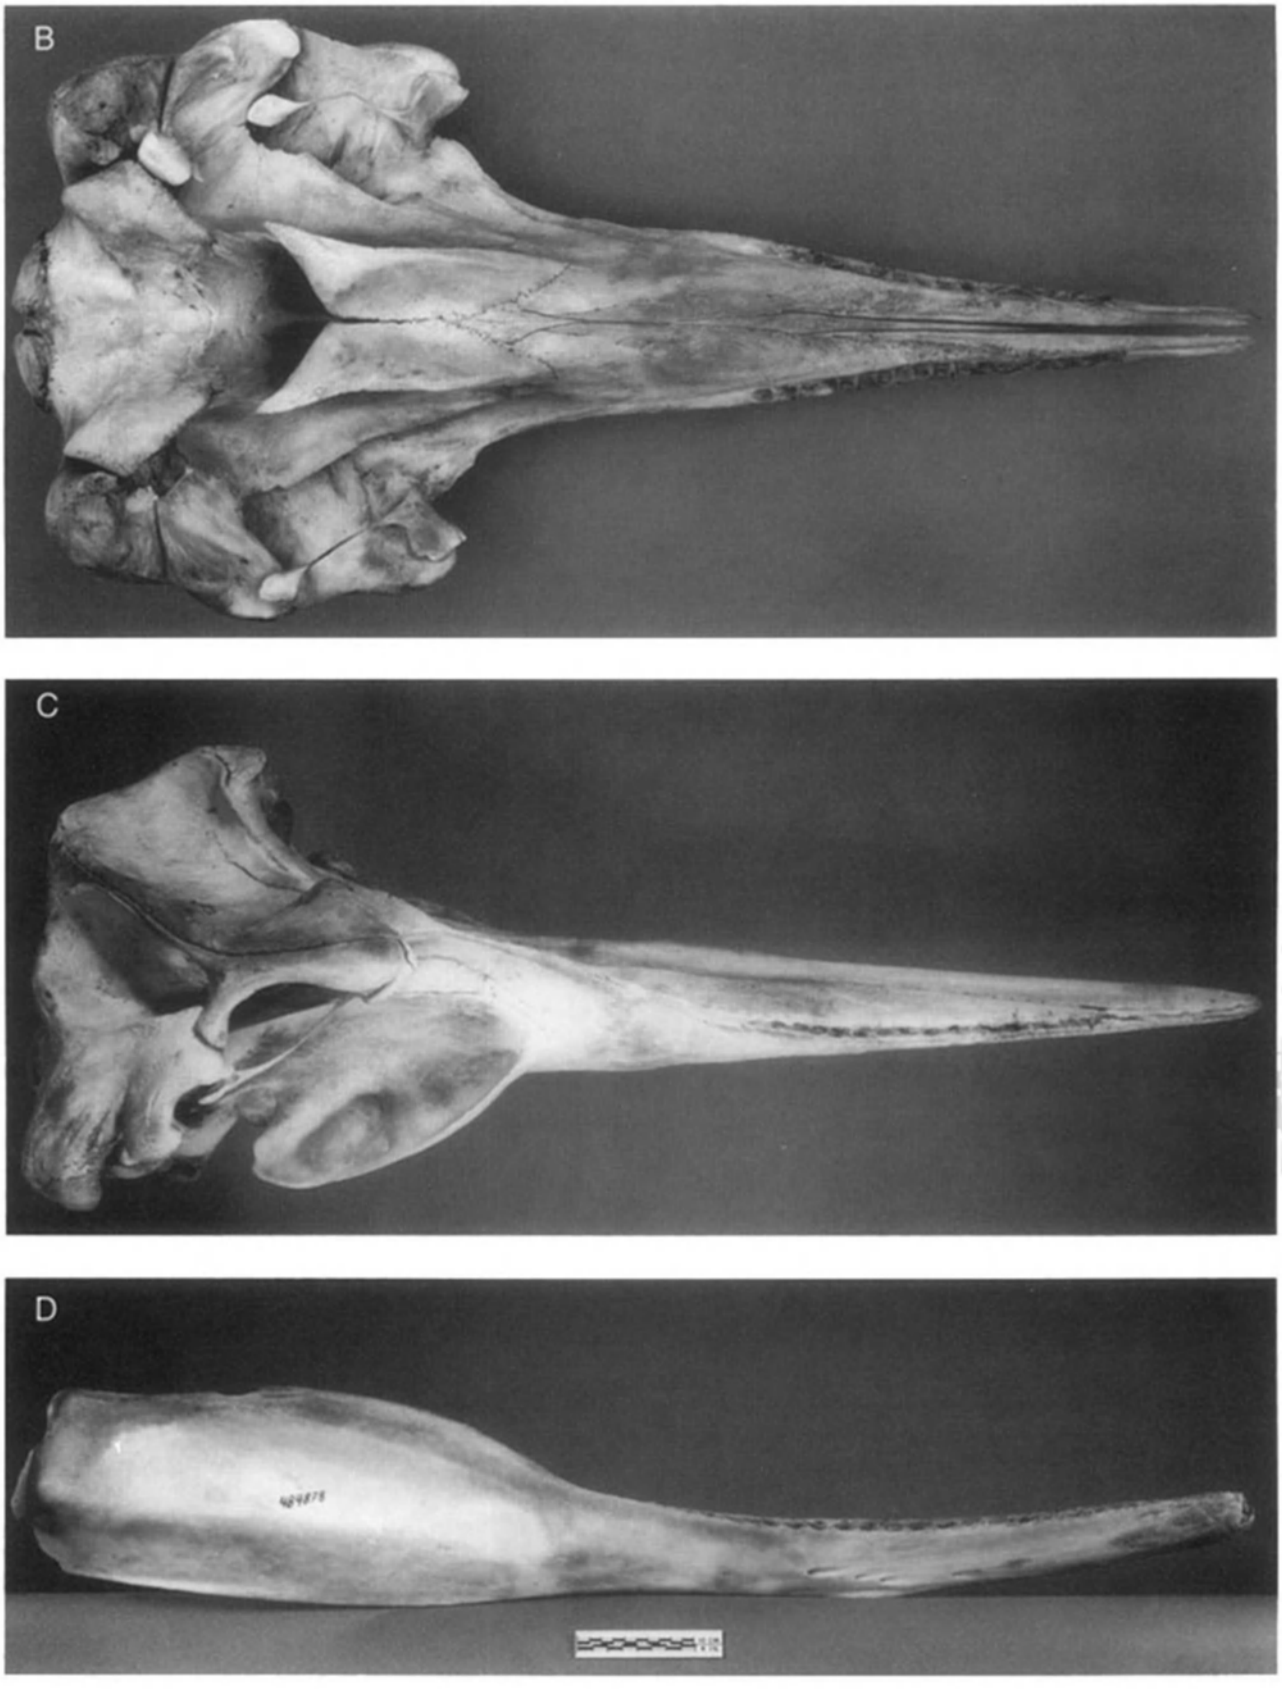

Figure 1 *(Continued)*

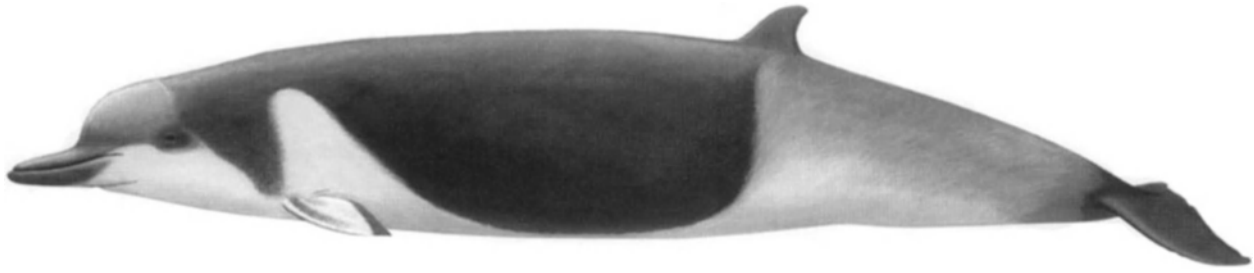

Figure 2 *External view of an adult female* T. shepherdi *(reconstruction by Pieter Folkens).*

III. Ecology (Habitat, Prey, and Predators)

This species presumably feeds primarily on squid and fish. One stranded adult female had traces of bottom fish, squid, and one small crab. All of the beaked whales that are moderately well known feed offshore in deep water.

IV. Interactions with Humans

Shepherd's beaked whale has not been known to be involved in any fisheries and certainly has not been kept in captivity. It was first known to science by a publication on a stranded adult female, which Shepherd found and collected in 1933.

Signature Whistles

LAELA S. SAYIGH
University of North Carolina, Wilmington

Signature whistles were first described for several species of captive delphinids by David and Melba Caldwell in the 1960s. They found that individual dolphins, while isolated for medical attention, produced primarily one stereotyped individually distinctive whistle contour (Fig. 1). Other researchers had speculated that dolphin whistles might be context specific, i.e., with certain contours being produced in times of distress or to indicate the presence of food. However, it was difficult to support or refute these claims as dolphins do not make any visible movement associated with vocalization; thus it is not possible to identify who is vocalizing within a group. By recording individual dolphins in captivity, the Caldwells were able to get around this problem. Signature whistles have now been documented in more than 300 individual dolphins in a variety of locations, both captive and wild.

Since the Caldwells' pioneering work, most work on signature whistles has focused on the bottlenose dolphin, *Tursiops truncatus*, and it has focused on four major questions. First, do sounds produced during isolation occur in the typical vocal repertoire of dolphins? Second, how do signature whistles function in the natural communication system of dolphins? Third, what is the role of whistle copying in the natural communication system of dolphins? Fourth, how do signature whistles develop in young animals?

The first two of these questions were raised in a study of 10 captive dolphins by McCowan and Reiss (1995), in which no evidence was found for stereotyped signature whistles. However, Janik and Slater (1998) found that captive dolphins tended to produce signature whistles primarily when one group member was voluntarily isolated from the rest of the group. Their study provided strong support for the use of signature whistles as cohesion calls, a finding that was also supported by a study of wild dolphins by Smolker and colleagues (1993). Thus, dolphins that are in close proximity and in visual contact, such as in the McCowan and Reiss study, may not need to produce signature whistles. Playback experiments with temporarily captured dolphins in Sarasota, Florida, also showed that dolphins can discriminate among different signature whistles and that they are thus likely to function in individual recognition (Sayigh *et al.*, 1999). Again, for captive dolphins that are housed in close proximity to one another, there may be little need for such a function.

Additional evidence in support of the idea that whistles produced during isolation also occur in the typical vocal repertoire of dolphins came from a study of vocal production in free-ranging dolphins in Sarasota, Florida (Hill and Sayigh, 1999). Approximately 50% of whistles produced during normal activities matched signature whistles that had been produced by the same individuals during temporary capture. The other 50% of whistles were comprised by various contours, many of which took on the general form of an upsweep. The functions of these whistles are unknown.

The first study to address copying, or imitation, of signature whistles was conducted by Peter Tyack (1986). He used a telemetry device called a "vocalight," which dolphins wore on their heads and which lit up when a sound was produced, and found that socially interactive dolphins not only produce signature whistles, but that they also produce imitations of each other's signature whistles. Such copying of signature whistles has now been documented in several other studies. Two of these studies (Smolker and Pepper, 1999; Watwood *et al.*, 1999) have found that close male associates tend to converge on a similar whistle type. New technologies that enable localization of vocalizing animals are necessary to study how both signature and nonsignature whistles (including whistle copies) are used in the natural communication system of dolphins.

In addition to discovering signature whistles, David and Melba Caldwell were the first researchers to investigate vocal development in bottlenose dolphins. They found that young dolphins produce tremulous, quavery whistles and then gradually converge on a stereotyped whistle contour during their first year of life. This contour then usually remains stable throughout the life of the animal. In a study of signature whistles produced by dolphins in Sarasota, Florida, Sayigh *et al.* (1990, 1995) found that female calves tended to produce whistles that were highly distinct from those of their mothers. Males were more likely than females to produce whistles similar to those of their mothers. These findings raised the possibility that dolphins may be learning their signature whistles from conspecifics.

Much evidence now supports the idea that dolphins learn their signature whistles, which sets them apart from many other nonhuman mammals, in which vocal production is largely innate. However, little is known about what factors govern the "choice" of whistle contours by calves. Again, studies that utilize acoustic localization with concurrent behavioral observations promise to shed light on this interesting question.

Signature whistles are an important class of vocalizations produced by bottlenose dolphins. They function both in individual recognition and in maintaining group cohesion, and they appear to be learned. Much work remains to be done in order to learn how these whistles develop and how they are used in the natural COMMUNICATION system of dolphins.

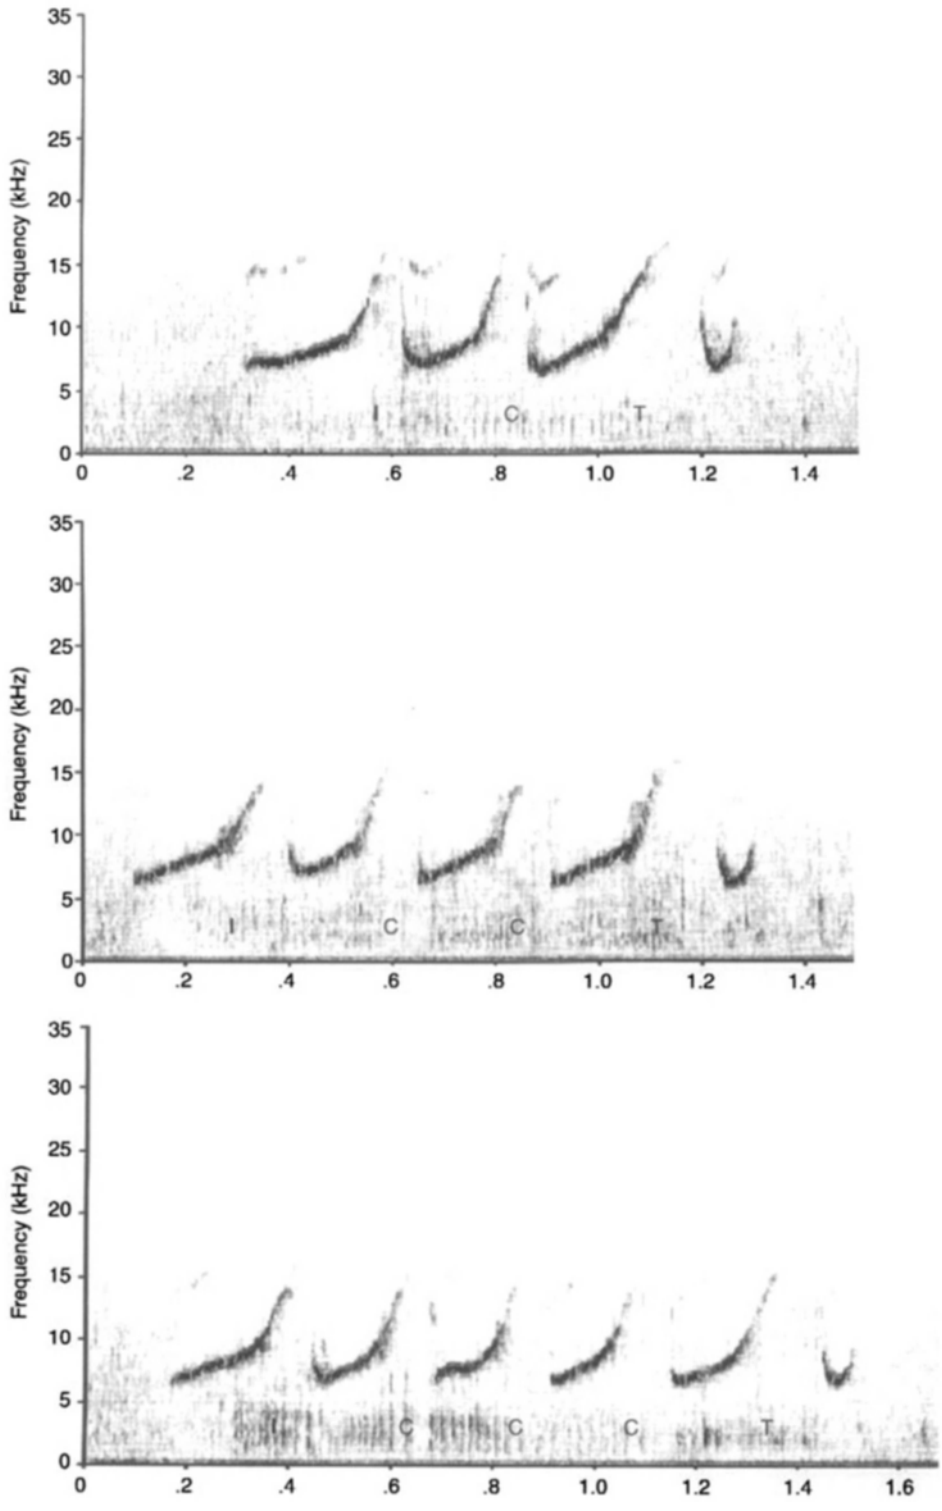

Figure 1 *Examples of a "multilooped" signature whistle of an adult female bottlenose dolphin recorded during temporary capture in Sarasota, Florida, in 1984. Her whistle typically consists of an introductory loop (labeled "I"), a terminal loop (labeled "T"), and a varying number of central loops (labeled "C"). Shown are whistles with one, two, and three central loops. Spectrograms were made with SIGNAL (Engineering Design, Belmont, MA) at a sample rate of 80,000 Hz and a 512 point FFT.*

Sirenian Evolution

DARYL P. DOMNING
Howard University, Washington, DC

Sirenia are the order of placental mammals comprising modern sea cows (manatees and dugongs) and their extinct relatives. They are the only herbivorous marine mammals now living, and the only herbivorous mammals ever to have become totally aquatic. Sirenians have a known fossil record extending over some 50 million years (early Eocene–Recent). They attained a modest diversity in the Oligocene and Miocene, but since then have declined as a result of climatic cooling, other oceanographic changes, and human depredations. Only two genera and four species survive today: the three species of manatees (*Trichechus*) live along the Atlantic coasts and rivers of the Americas and West Africa; one, the Amazonian manatee, is found only in fresh water. The dugong (*Dugong*) lives in the Indian and southwest Pacific oceans. [For comprehensive references to technical as well as popular publications on fossil and living sirenians, see Domning (1996).]

I. Sirenian Origins

The closest living relatives of sirenians are Proboscidea (elephants). The Sirenia, the Proboscidea, the extinct Desmostylia, and probably the extinct Embrithopoda together make up a larger group called Tethytheria, whose members (as the name indicates) appear to have evolved from primitive hoofed mammals (condylarths) in the Old World along the shores of the ancient Tethys Sea. Together with Hyracoidea (hyraces), tethytheres seem to form a more inclusive group long referred to as Paenungulata. The Paenungulata and (especially) Tethytheria are among the least controversial groupings of mammalian orders and are strongly supported by most morphological and molecular studies. Their ancestry is remote from that of cetaceans or pinnipeds; sirenians reevolved an aquatic lifestyle independently of (though simultaneously with) cetaceans, ultimately displaying strong convergence with them in body form.

II. Early History, Anatomy, and Mode of Life

Sirenians first appear in the fossil record in the early Eocene, and the order was already diverse by the middle Eocene (Fig. 1). As inhabitants of rivers, estuaries, and nearshore marine waters, they were able to spread quickly along the coasts of the world's shallow tropical seas; in fact, the most primitive sirenian known to date (*Prorastomus*) was found not in the Old World but in Jamaica.

The earliest sea cows (families Prorastomidae and Protosirenidae, both confined to the Eocene) were pig-sized, four-legged amphibious creatures. By the end of the Eocene, with the appearance of the Dugongidae, sirenians had taken on their modern, completely aquatic, streamlined body form, featuring flipper-like front legs, no hind legs, and a powerful tail with a horizontal caudal fin, whose up-and-down movements propel them through the water, as in whales and dolphins (Fig. 2). The last-appearing of the four sirenian families (Trichechidae) apparently arose from early dugongids in the late Eocene or early Oligocene. The sirenian fossil record now documents all the major stages of hindlimb and pelvic reduction from completely "terrestrial" morphology to the extremely reduced condition of the pelvis seen in modern manatees, thereby providing one of the most dramatic examples of evolutionary change to be seen among fossil vertebrates.

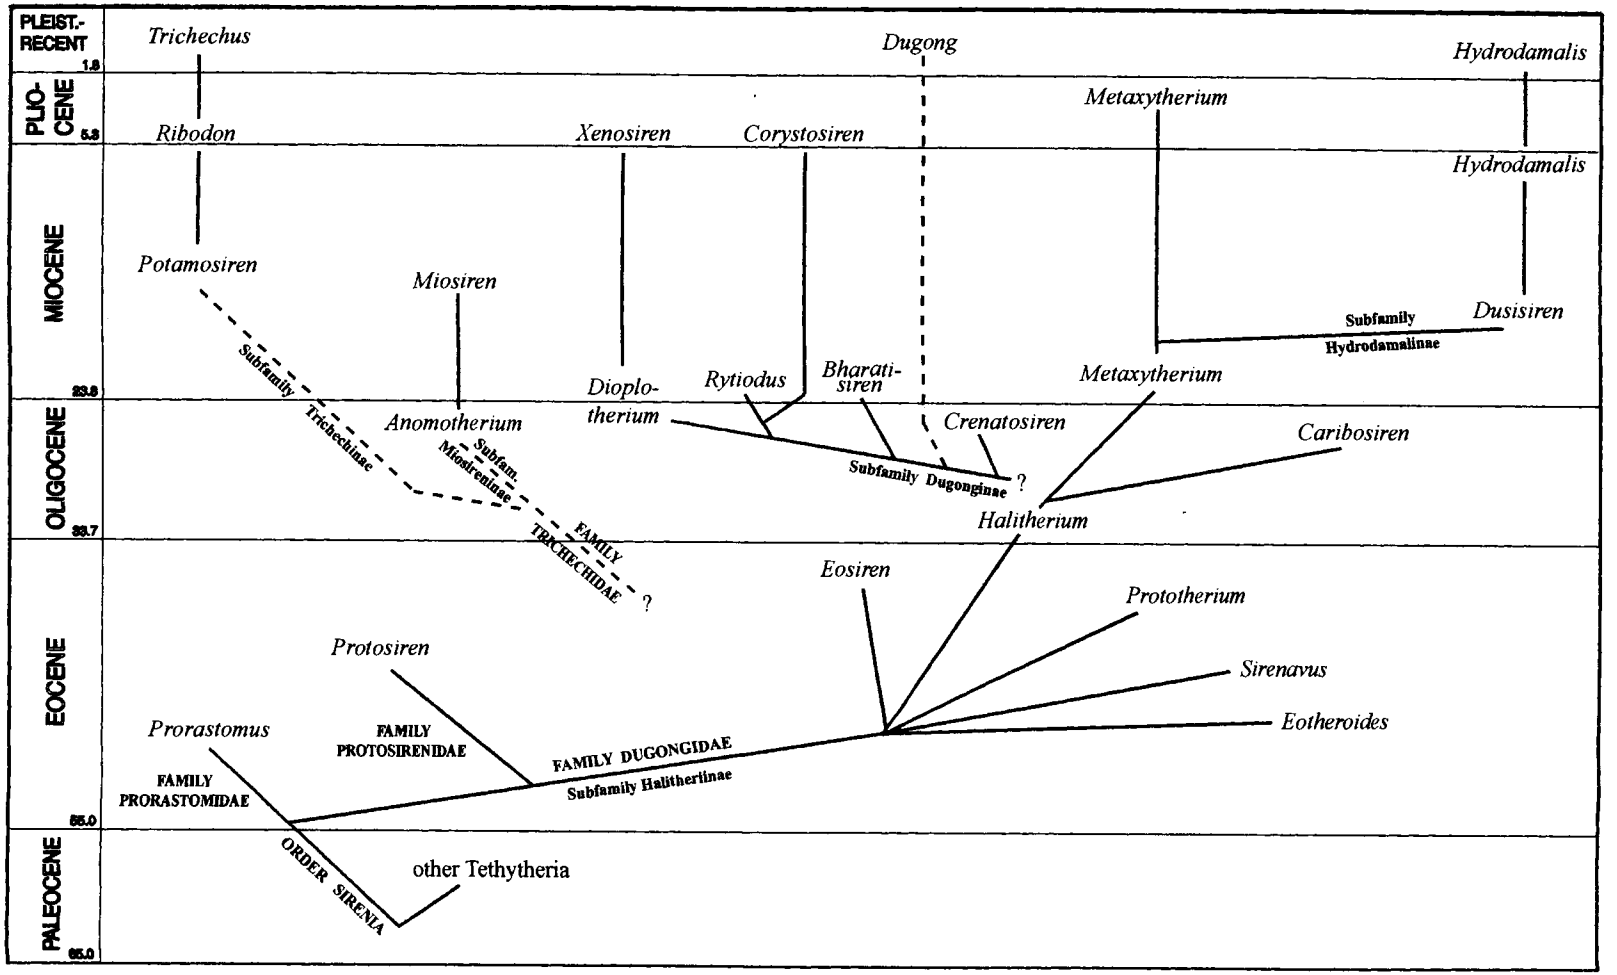

Figure 1 *Simplified phylogeny of Sirenia, including only better-known genera. The time scale (at left) is in millions of years. "Ghost lineages" (ancestral groups undocumented by fossils) that span multiple epochal boundaries are shown as dashed lines.*

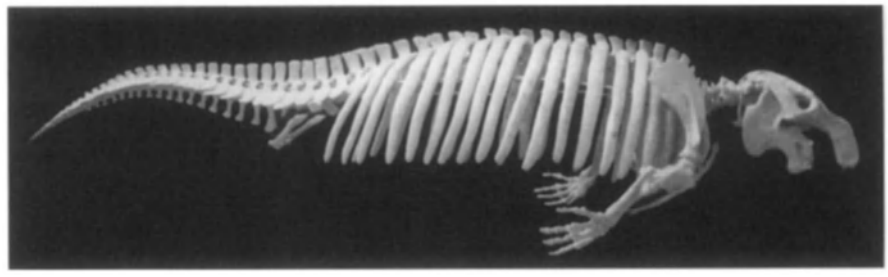

Figure 2 *Skeleton of* Metaxytherium floridanum, *a Miocene halitheriine dugongid. Total length about 3.2 m. After Domning (1988); reproduced with the permission of the* Journal of Vertebrate Paleontology.

From the outset, sirenians were herbivores and probably depended on seagrasses and other aquatic angiosperms (flowering plants) for food. To this day, almost all members of the order have remained tropical, marine, and eaters of angiosperms. No longer capable of LOCOMOTION on land, sirenians are born in the water and spend their entire lives there. Because they are shallow divers with large lungs, they have heavy skeletons, like a diver's weight belt, to help them stay submerged: their bones are both swollen (pachyostotic) and dense (osteosclerotic), especially the ribs, which are often found as fossils.

The sirenian SKULL is characterized by an enlarged and more or less downturned premaxillary rostrum, retracted nasal opening, absence of paranasal air sinuses, laterally salient zygomatic arches, and thick, dense parietals fused into a unit with the supraoccipital. Nasals and lacrimals tend to become reduced or lost, and in most forms the pterygoid processes are large and stout. The periotic is snugly enclosed by a socket in the squamosal and is fused with a ring-shaped tympanic. The mandibular symphysis is long, deep, laterally compressed, and typically fused and downturned; in all but prorastomids the mandibular foramen is enlarged to expose the dental capsule. Incisors, where present, are arranged in parallel, longitudinally aligned rows. In all but the most primitive taxa, the infraorbital and mental foramina are enlarged to accommodate the nerve and blood supply to the large, prehensile, vibrissae-studded lips, which are moved by muscular hydrostats (cf. Marshall *et al.*, 1998).

Eocene sirenians, like Mesozoic mammals but in contrast to other Cenozoic ones, have five instead of four premolars, giving them a 3.1.5.3 dental formula. Whether this condition is truly a primitive retention in the Sirenia is still being debated. The fourth lower deciduous premolar (dp4) is trilobed, like that of many other ungulates; this raises the further unresolved question of whether the three following teeth (dp5, m1, and m2) are actually the homologues of the so-called m1–3 in other mammals.

Although the cheek teeth are relied on for identifying species in many other mammalian groups, they do not vary much in morphology among Sirenia but are almost always low-crowned (brachyodont) with two rows of large, rounded cusps (bunobilophodont). (The most taxonomically informative parts of the sirenian skeleton are the skull and mandible, especially the frontal and other bones of the skull roof; Fig. 3.) Except for a pair of tusk-like first upper incisors seen in most species, front teeth (incisors and canines) are lacking in all but the earliest fossil sirenians, and cheek teeth in adults are commonly reduced in number to four or five on each side of each jaw: one or two deciduous premolars, which are never replaced, plus three molars. As described later, however, all three of the Recent genera have departed in different ways from this "typical" pattern.

After Domning (1997); reproduced with the permission of the* Journal of Vertebrate Paleontology.

III. Dugongidae

Dugongids comprise the vast majority of the species and specimens that make up the known fossil record of sirenians. The basal members of this very successful family are placed in the long-lived (Eocene–Pliocene) and cosmopolitan subfamily Halitheriinae (Fig. 1). This paraphyletic group included the well-known fossil genera *Halitherium* and *Metaxytherium*, which were relatively unspecialized seagrass eaters.

Metaxytherium (Fig. 2) gave rise in the Miocene to the Hydrodamalinae, an endemic North Pacific lineage that ended with Steller's sea cow (*Hydrodamalis*)—the largest sirenian that ever lived (up to 9 m or more in length) and the only one to adapt successfully to temperate and cold waters and a diet of marine algae. It was completely toothless, and its truncated, claw-like flippers, used for gathering plants and fending off from rocks, contained no finger bones (phalanges). It was hunted to extinction for its meat, fat, and hide circa A.D. 1768.

Another offshoot of the Halitheriinae, the subfamily Dugonginae, appeared in the Oligocene (Fig. 3). Most dugongines were apparently specialists at digging out and eating the tough, buried rhizomes of seagrasses; for this purpose many of them had large, self-sharpening blade-like tusks (Domning, 2001). The modern *Dugong* is the sole survivor of this group, but it has reduced its dentition (the cheek teeth have only thin enamel crowns, which quickly wear off, leaving simple pegs of dentine) and has (perhaps for that reason) shifted its diet to more delicate seagrasses and ceased to use its tusks for digging.

IV. Trichechidae

Trichechidae have a much less complete FOSSIL RECORD than dugongids. Their definition has been broadened by Domning (1994) to include Miosireninae, a peculiar and little-known pair of genera that inhabited northwestern Europe in the late Oligocene and Miocene (Fig. 1). Miosirenines had massively reinforced palates and dentitions that may have been used to crush shellfish. Such a diet in sirenians living around the North Sea seems less surprising when we consider that modern dugongs and manatees near the climatic extremes of their ranges are known to consume invertebrates in addition to plants.

Manatees in the strict, traditional sense are now placed in the subfamily Trichechinae. They first appeared in the Miocene, represented by *Potamosiren* from freshwater deposits in Colombia. Indeed, much of trichechine history was probably spent in South America, whence they spread to North America and Africa only in the Pliocene or Pleistocene.

During the late Miocene, manatees living in the Amazon basin evidently adapted to a diet of abrasive freshwater grasses by means of an innovation still used by their modern descendants: they continue to add on extra teeth to the molar series as long as they live, and as worn teeth fall out at the front, the whole tooth row slowly shifts forward to make room for new ones erupting at the rear. This type of horizontal tooth replacement has often been likened, incorrectly, to that of elephants, but the latter are limited to only three molars. Only one other mammal, an Australian rock wallaby (*Peradorcas concinna*), has truly evolved the kind of tooth replacement seen in manatees.

Sirenian Life History

DANIEL K. ODELL
SeaWorld, Inc., Orlando, Florida

Sirenians are unique among the marine mammals in that they are herbivores. The mammalian order Sirenia has fossil representatives on the order of 50 million years old (Eocene epoch), making them as old as the cetaceans. While there are similarities between the two groups in terms of adaptation to the aquatic environment (e.g., streamlining, loss of hindlimbs, use of the tail for propulsion), the sirenians stayed on the path to herbivory while the cetaceans switched from the herbivorous habits of their terrestrial ancestors to become carnivores. Modern sirenians include three species of MANATEES (family Trichechidae: Amazonian manatee, *Trichechus inunguis;* West African manatee, *T. senegalensis;* West Indian manatee, *T. manatus;* the latter is divided into two subspecies: Antillean manatee, *T. m. manatus*, and Florida manatee, *T. m. latirostris*). The Sirenia also includes the family Dugongidae

(dugong, *Dugong dugon*), and STELLER'S SEA COW (family Dugongidae: Steller's sea cow, *Hydrodamalis gigas*). The manatees, as their common names suggest, are distributed in the coastal tropical and subtropical regions of the Atlantic Ocean. The dugong is found in the South Pacific and Indian Ocean regions. The manatees and the dugong are considered ENDANGERED or threatened under various national laws and international conservation schemes. The Steller's sea cow is the exception, not only is it extinct (eliminated by overhunting about 25 years after its discovery in 1765) but it inhabited the islands in the western reaches of the Aleutian archipelago in the North Pacific Ocean. Definitely not a tropical clime!

I. Methodology

Robert Ricklefs (1973) stated that "The life history of an organism can be described in terms of fecundity, growth and development, age at [sexual] maturity, parental care, and longevity." These parameters are closely linked and are acted on by natural selection. While these parameters are easy to state, they are not always easy to measure. It is easy to study a colony of mice in the laboratory but not so with an animal like the Florida manatee that may reach a length of over 4 m and a weight in excess of 1500 kg. How, then, does one get this information for sirenians? Approaches to this question involve both field and "laboratory" (i.e., animals in captivity in marine zoological parks and zoos) studies. In the field, one can learn to identify individual animals using shape, size, and various markings and color patterns or one can mark (using various methods) individual animals. For large, long-lived, aquatic mammals like the sirenians, this becomes an extremely expensive and time-consuming operation. However, in many cases, it is the only way to obtain the desired information. Alternatively, one can collect data from animals that die from both natural and unnatural (i.e., human-related) causes. Animals killed for human consumption or those killed as a result of other human activities provide a sample, albeit potentially biased (nonrandom), of males and females of all age classes. Marine mammal stranding networks collect life history data on animals found dead (i.e., stranded, beach cast, beached). In Florida, the Florida Fish and Wildlife Conservation Commission operates a network dedicated to the collection and examination of all manatees found dead in the state. From these carcasses one can gather information on, among others, reproductive status (immature, mature, pregnant, number of pregnancies) and age. Estimating the age of an animal is critically important in the estimation of life history parameters. Toothed cetaceans and pinnipeds, for example, have permanent teeth with roots that grow continually (but slowly) from birth to death. One can section these teeth and, under the microscope, count growth layer groups (GLGs). If one then knows the frequency with which these GLGs are deposited (e.g., one per year, 2 per year), GLG counts can be directly converted to and estimated age in years. The frequency of GLG deposition can be estimated using known age animals and using chemical markers deposited in the teeth of live animals. There is variability in the reliability of this process from species to species and the only way to know the true age of an animal is to follow it from birth to death. Growth layers are also often deposited in growing bone. The dugong has tusks that erupt through the gums in the male but not in the female. These tusks grow throughout the life of the animal and GLGs accumulate on an annual (assumed) basis. Manatees, however, do not have permanent teeth. While some growth layers are present in the tooth roots in young animals, these are lost through resorption, as manatees have a continual, horizontal (back to front) tooth replacement throughout life. However, because other growing bones accumulate GLGs, scientists discovered that GLGs in manatee ear bones can be used to estimate age. Studies with chemical markers demonstrated that manatee GLGs accumulate on an annual basis.

Studies with dead animals are very useful and relatively inexpensive, but long-term studies on live animals are necessary to fill in the life history blanks. For example, by following a female from year to year, it is possible to document when she has a calf and how much time elapses between successive calves. While radio and satellite tracking allows scientists to follow individual manatees over long periods of time, it is virtually impossible to watch them from minute to minute. However, studies on manatees in captivity (aka "the laboratory") can fill some of these life history gaps, particularly in the areas of reproductive biology and growth and development. In captivity manatees *can* be observed continually if necessary. Blood and urine samples can be collected to document estrous cycling and gestation in females and testicular activity cycling in males. Parental care of the offspring can be documented in great detail.

II. Longevity

Detailed age estimation studies have only been done for the Florida manatee and for the dugong. Using tetracycline marking, we know that Florida manatees deposit one GLG per year. Based on growth layer groups in the ear bone complex, some Florida manatees may live to be 60 years of age. However, due to bone resorption, 60 years may be a minimum estimate. A manatee born in the Miami Aquarium in 1948 is alive and well today (August 2000) at an aquarium in Bradenton, Florida. This animal provides a good measure of validation for the 60-year estimate. The average longevity for Florida manatees has not been well estimated but is probably on the order of 30 years less. This estimate may be biased downward by manatee deaths resulting from human activities (e.g., watercraft collisions). Average longevity may vary between sexes and among year classes. Longevity data do not exist for Antillean, Amazonian, or West African manatees.

Based on GLGs in their tusks, the oldest dugong examined to date was a female with 73 GLGs, which translates to 73 years if we assume one GLG per year. Tusks in male dugongs erupt through the gums and are worn down, eliminating the early GLGs in older animals. Minimum maximum longevity estimates for male dugongs are about 35 years.

III. Age at Sexual Maturity

Female Florida manatees reach sexual maturity between 2.5 and 6 years of age. Male Florida manatees reach sexual maturity between 2 and 11 years of age based on the presence of active spermatogenesis in the testes. It is important to note that even if a male manatee is sexually mature at an early age, it may

not be physically large enough to compete for mating rights in an estrous (mating) herd. However, under circumstances wherein there are not other competing males, small manatees may be able to mate successfully and produce offspring. There are no data on age at sexual maturity for Antillean, Amazonian, or West African manatees.

Even though the estimated maximum life expectancy for the dugong is similar to that of the Florida manatee, dugongs appear to mature at greater ages, and the age at sexual maturity may vary among populations. Female dugongs in Australia and Papua New Guinea mature at 9.5 to 17.5 years. Male dugongs in the same areas mature at 9 to 16 years of age. These differences could reflect distinct genetic differences between populations or the effects of density-dependent factors.

IV. Parental Care

In both manatees and dugongs the male plays no apparent role in the care of the young. After mating, males and females go their separate ways. Florida manatee calves will stay with their mothers for 1–2 years on average. Most calves (about 70%) stay with their mothers through one winter season and the remainder through two winter seasons. Nutritional weaning is a gradual process but there are few data on the length of lactation in the Florida manatee or in the dugong. Lactation may last 1.5 years in dugongs and is probably similar in the manatee. Some wild and captive manatees appear to lactate for several years under certain circumstances. Most Florida manatee and dugong calves start feeding on vegetation at a few weeks of age and may be nutritionally independent before they reach the age of 1 year. However, at least in the case of the Florida manatee, calves probably learn the locations of feeding areas and warm water refugia by following their mothers through at least one winter season. The latter is extremely important for weaned juvenile survival during cold winters.

V. Growth and Development

Florida manatee calves average about 120 cm in length at birth, but viable calves may have a birth length ranging from about 80 to 160 cm. This, along with variable individual growth rates, results in a highly variable length at age distribution. For example, 2-year-old manatees at Blue Spring (Florida) may range from 210 to 260 cm total length. From a sample of carcasses of Florida manatees in the age class >1 and <2 years, total lengths ranged from about 120 to over 260 cm. Florida manatees grow rapidly during the first few years, and body length becomes asymptotic at about 300 cm and an age of 8–10 years. The birth weight for Florida manatees ranges from 30 to 50 kg and the average adult body weight is about 500 kg. The Antillean and West African manatees are probably similar to the Florida manatee in these respects. The Amazonian manatee is smaller and has a birth length of 85–100 cm and a birth weight of 10–15 kg. Large adults may reach lengths of 280 cm and weights of 480 kg. The dugong has a birth length of 100–130 cm and a birth weight of 25–35 kg. Adult dugongs average 270 cm in length and 250–300 kg body weight.

VI. Fecundity

As with other aspects of sirenian life history, data on fecundity are limited and based primarily on studies of the Florida manatee and the dugong. A key factor in assessing fecundity is the gestation period, which, despite numerous conceptions and births of Florida manatees, is not known for any sirenian species. However, scientists generally agree that gestation for the Florida manatee and the dugong is in the range of 12–14 months and that the other species of sirenians are probably similar. The known interbirth interval for wild Florida manatees averages 2.5–2.6 years. The estimated interbirth interval for Florida manatees ranges from 2.5 to 3.0 years when gestation period estimates of 12, 13, and 14 months are applied. This suggests that the true gestation period may be close to 12 months. Estimated interbirth intervals for the dugong range from 2.7 to 5.8 years depending on the length of the gestation period assumed (12, 13, or 14 months) and the population of dugongs used. We do know that Florida manatees resume estrous cycling within 1–2 months after the loss of a calf and become pregnant shortly thereafter. Whereas manatees and dugongs (both males and females) display seasonal reproductive activity, there is scant evidence to suggest that they have reproductive senescence as many mammals, including humans, do.

Other factors important in the calculation of fecundity are the number of offspring per birth and the sex ratio of offspring at birth. Wild Florida manatees have been documented producing twin offspring (but no more) in about 1.4 to 1.8% of births. Estimates of twinning based on Florida manatee carcass studies are as high as 4%. Limited and/or anecdotal data suggest that twinning occurs in the Antillean manatee and in the dugong. The sex ratio of the offspring at birth appears to be 1:1 for both the Florida manatee and the dugong. It is probably reasonable to assume that both Amazonian and West African manatees have similar patterns of twinning and offspring sex ratio.

Applying all of our knowledge of and assumptions about Florida manatee life history, the average fecundity (number of female births per female per year) for age classes 4–29 years was estimated at 0.189, 0.238, and 0.127 using different sets of data obtained from the examination of carcasses. Similarly, estimates of annual pregnancy rate (APR) and gross annual recruitment rate (GARR) ranged from 0.190 to 0.394 and 0.044 to 0.90, respectively, depending on the set of carcass data and gestation period used. Similar calculations for the dugong based on a smaller data set yielded apparent (annual) pregnancy rates of 0.093 to 0.353 over a series of years.

VII. Summary

Even though the Florida manatee and the dugong have been studied intensively since the 1980s, detailed data on many aspects of their life history are only beginning to be elucidated and there is considerably less information on the other species of sirenians. Given the threatened or endangered status of this unique group of marine mammals, every effort should be made to learn about their biology so that we may ensure their survival.

Skeletal Anatomy

SENTIEL A. ROMMEL
Florida Marine Research Institute, St. Petersburg

JOHN E. REYNOLDS III
Eckerd College, St. Petersburg, Florida

The postcranial skeleton includes all the bones and cartilages caudal to the head skeleton. With a few exceptions, our description is limited to the bones of this region. The postcranial skeleton is subdivided into axial components (the vertebral column, ribs, and sternebrae, which are "on" the midline) and appendicular components (the forelimbs, hindlimbs, and pelvic girdle, which are "off" the midline). The skeleton supports and protects soft tissues, controls modes of locomotion, and determines overall body size and shape. The marrow of some bones may generate the precursors to certain blood cells. Skeletal elements may store lipids (particularly in the Cetacea) and calcium (particularly in the Sirenia) and thus influence buoyancy. Because bones are remodeled continuously in response to biochemical and biomechanical demands over the life span of the marine mammal, they offer information that can help interpret life history events after death.

Skeletons of seven different species of marine mammals are discussed: the Florida manatee (*Trichechus manatus latirostris*), the harbor seal (*Phoca vitulina*), the California sea lion (*Zalophus californianus*), the North Atlantic right whale (*Eubalaena glacialis*), the common bottlenose dolphin (*Tursiops truncatus*), the polar bear (*Ursus maritimus*), and the sea otter (*Enhydra lutris*). The domestic dog (*Canis familiaris*) skeleton is used to provide a familiar reference for comparison with marine mammal skeletons. These species were chosen, in part, because much is known about them and they provide a wide range of biomechanical morphologies. The manatee, dolphin, and right whale represent the many species that have lost their hindlimbs and are permanently aquatic; the other species may spend at least some of their life cycles on land. Note that the seven species are representative of generalized types—even within species, sexual dimorphism may produce different features.

Visualize the articulated (assembled) skeleton by first considering individuals in an absolute sense (left and lower parts of Fig. 1) and then in a relative sense (upper right of Fig. 1). Consider what decisions morphologists must make when comparing the "size" of any one feature among individuals that differ substantially in size. Compare the two methods of scaling by using the human swimmer as an example. Because human sensory systems are comparative and relational comparisons (such as proportions and percentages) are intuitive, we use the relative scheme scale comparisons among species for most of this article.

We will refer to the manatee when describing individual morphological structures but refer to the seven selected marine mammal species when discussing marine mammals in general [for details on the same structures in the dolphin, see Rommel (1990); for the true seals, see Pierard (1971) and Pierard and Bisaillon (1978); for the dog, see Evans (1993); for mammals in general, see Flower (1885)].

I. Axial Skeleton

A. Vertebral Structures

A few structural terms are necessary to better grasp the functional morphology of the vertebral column. Each vertebra (plural, vertebrae) has several "standard" parts (Fig. 2A). The body or centrum (plural, centra) of each vertebra is a subcylindrical structure that forms the primary mechanical support of the vertebral (spinal) column (Fig. 2B). Several kinds of projecting parts or *processes* may extend from the centrum and provide attachment sites, protection for soft tissues, or both. The largest and most common lateral processes are transverse processes, which tend to be long and robust in the lumbar vertebrae (and in the first few caudal vertebrae of permanently aquatic species). In some regions of the vertebral column (e.g., cervical), there may be two transverse processes extending from each side of a single vertebra.

Dorsal to the centrum is an arch of bone (the neural arch), which forms the sides of a neural canal. The neural arch protects the spinal cord. Interestingly, in some marine mammal species, the neural arch is considerably enlarged to accommodate relatively large masses of vascular tissue and/or fat that may be juxtaposed to the dura mater of the spinal cord. Because of these enlargements, the neural canal may not reflect the dimensions of the spinal cord as it does in most terrestrial species (Giffen, 1992). Additionally, each neural arch may extend dorsally as a neural spine (spinous process). The neural spines function as levers to increase the mechanical advantage of the epaxial (epiaxial) muscles to dorsiflex the tail.

Relative motion between adjacent vertebrae is controlled, in part, by the size and shape of the intervertebral disks (Fig. 2C). Intervertebral disks resist compression when skeletal

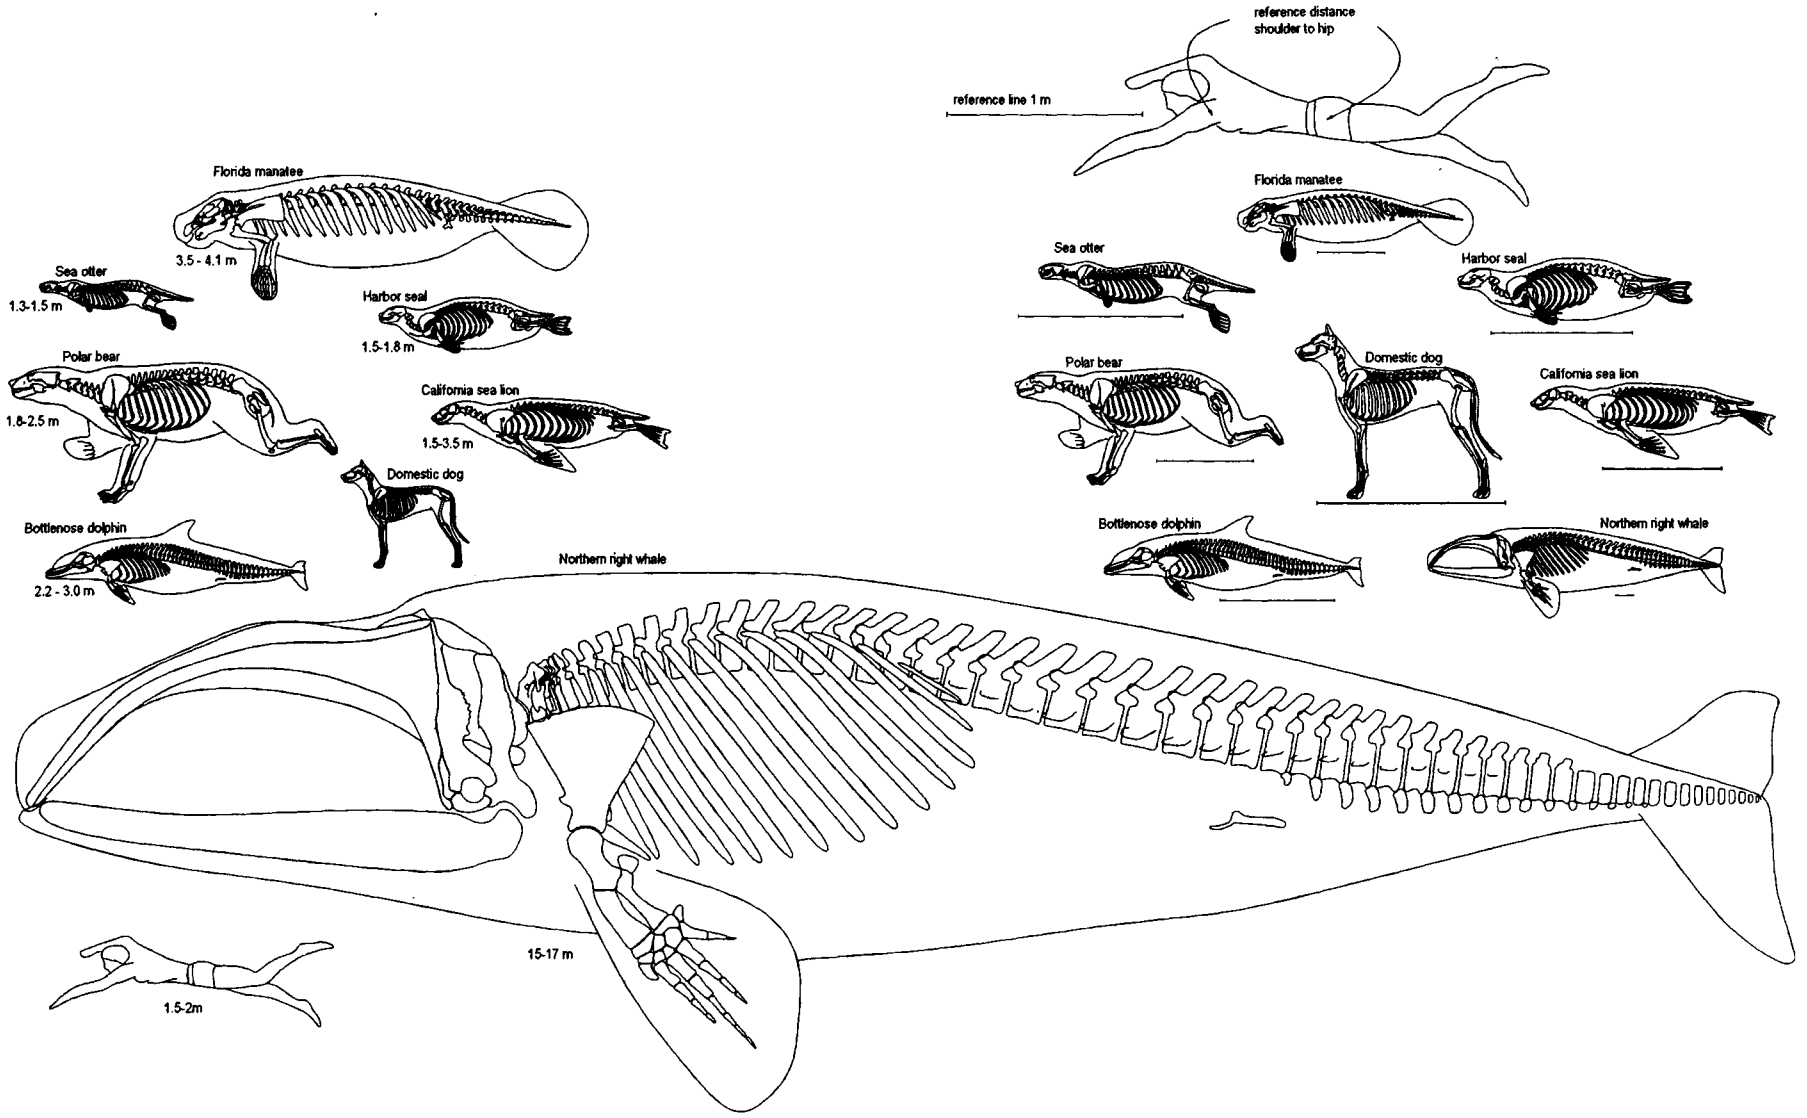

Figure 1 *Selected marine mammal skeletons (the Florida manatee, the harbor seal, the California sea lion, the North Atlantic right whale, the bottlenose dolphin, the polar bear, and the sea otter) compared with the skeleton of the domestic dog. Drawings on the left and bottom are scaled so that 1 m on any one species equals 1 m on all the others in this group. The range of adult total body lengths (snout tip to tail tip; note that human height is measured differently) is given in meters beneath each drawing. This group is sized to fit the right whale onto the page. Skeletons in the group on the upper right are scaled so that the distance between the shoulder and the hip joints is equal in all seven species. Thus, the body cavities of this group are approximately the same length. A reference line representing 1 m is given below each of these drawings; note that it is different for each skeleton in this scaling scheme. Both groups are sized so that the dolphins on the right and left are equal in length. Copyright S. A. Rommel.*

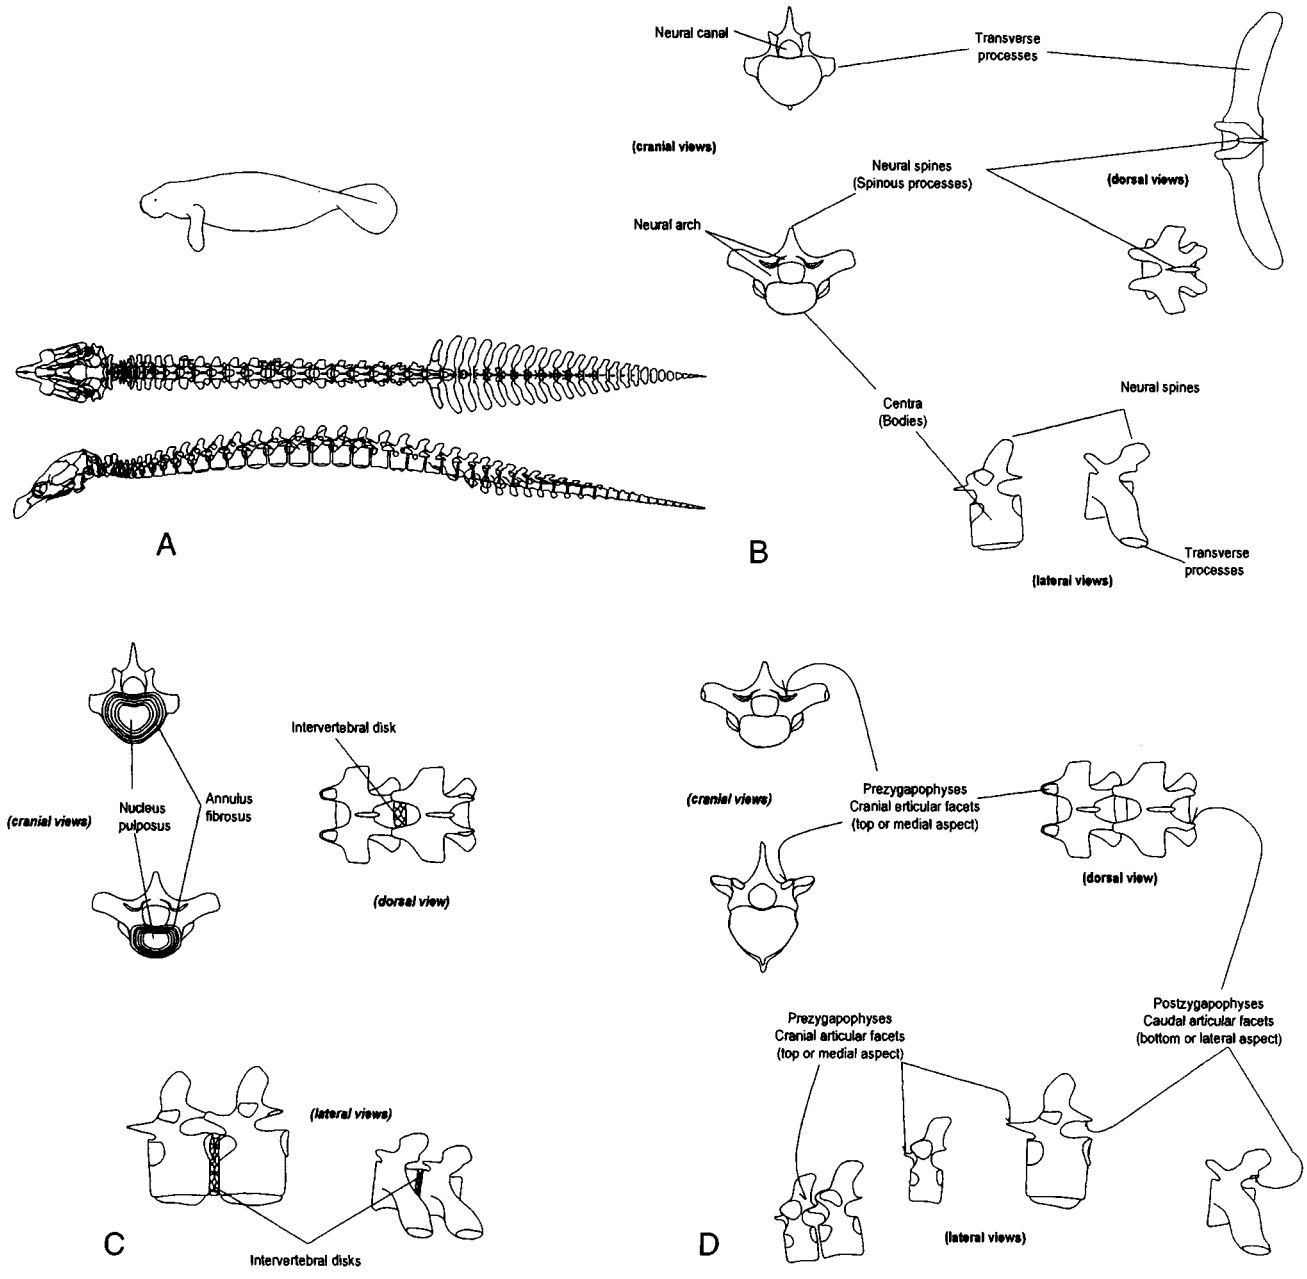

Figure 2 *(A) The manatee and its vertebrae. In this and subsequent illustrations of specific features, we illustrate a particular region of the vertebral column with dorsal and lateral views of that region. (B) Parts of a vertebra. The body, or centrum, of each vertebra is the primary mechanical support of the vertebral column. Vertebral centra help prevent the body of the animal from collapsing when large body muscles contract. Dorsal to the centrum is an arch of bone, the neural arch; within the arch is the neural canal. The neural arch protects the spinal cord and it may extend dorsally as a neural spine or spinous process. (C) The flexible region between adjacent vertebral bodies functions as a tough joint. Intervertebral disks (made of fibrocartilage) have two parts: the inner nucleus pulposus and the outer annulus fibrosus. (D) Zygapophyses are the articular facets that constrain motions between adjacent vertebrae. The cranial pair on each vertebra are prezygapophyses and the caudal pair are postzygapophyses. The region of articulation between prezygapophyses and postzygapophyses of adjacent vertebrae is typically a synovial joint if the facets overlap. In some regions of the vertebral column the facets do not overlap and may be connected by collagen fibers. Copyright S. A. Rommel.*

muscles force vertebrae together. Intervertebral disks are composite structures with a fibrous outer ring, the *annulus fibrosus*, and a semiliquid inner mass, the *nucleus pulposis*. The inner, jelly-like nucleus forms a dynamic joint that can adjust its shape to support complex forces of bending. The outer elastic fibers of the disk are arranged in a resilient ring, or annulus. The same basic design of surrounding a deformable core with elastic fibers is used in baseballs and golf balls.

Flexibility of the vertebral column depends, in part, on the thickness of the disks. Disk thickness varies within and among species, and intervertebral disks represent a substantial proportion (10 to 30%) of the length of the vertebral column. Relaxed (neutral) curvature of the vertebral column is vertebral, *not* intervertebral. That is, the shape of the spinal curve is determined by the shapes of individual vertebrae. Intervertebral disks provide flexibility, whereas curvature is provided by (nonparallel) vertebral body faces (Fig. 3).

In addition to the intervertebral disks, adjacent vertebrae may have other surfaces of articulation (facets). Zygapophyses (singular, zygapophysis) may be located on the neural arch, neural spine, and/or the transverse processes. Zygapophyses are bilaterally paired articular facets, found on the cranial and caudal aspects of each vertebra (Fig. 2D). The cranial pair are termed prezygapophyses, and the caudal pair are postzygapophyses. The region of articulation between prezygapophyses and postzygapophyses is typically a synovial joint if the facets overlap.

Zygapophyses in the neck and cranial thorax tend to be oriented horizontally to allow axial rotation (twisting) and side-to-side motions. Zygapophyses in the caudal thorax and tail tend to be oriented vertically to facilitate up-and-down motions. In some regions of the vertebral column (particularly the tails of most species and under the dorsal fin of dolphins), adjacent vertebrae may have reduced or absent zygapophyses, possibly reflecting the increased flexibility or influence of nonvertebral structures on the mobility of these regions. Test these zygapophyseal constraints on yourself by bending and twisting your body—note how your thorax (rib-bearing region) flexes (most of the axial rotation and some lateral flexion occurs here) when compared with your lumbar (low back) region (where most of the allowable dorsoventral flexion occurs).

B. Vertebral Column

Traditionally, the typical mammalian vertebral column is separated into five regions, each of which is defined by what is or is not attached to the vertebrae. These regions are cervical, thoracic (dorsal in the older literature), lumbar, sacral, and caudal (Fig. 3). The vertebral formula is an alpha-numerical abbreviation for the numbers of vertebrae in each region; note that some regions have similar numbers of vertebrae in most species, whereas other regions have very different numbers of vertebrae in different species. For example, C6:T17:L1:S0:Ca25 describes the 6 cervical, 17 thoracic, 1 lumbar, 0 sacral, and 25 caudal vertebrae in the Florida manatee. Individual vertebrae in each region are also referred to by their position using one or two (regiospecific) letters and a number. For example, the third cervical vertebra is designated as C3, the first thoracic as T1, the first lumbar as L1, the second sacral as S2, and the tenth caudal as Ca10. In some species the morphological distinctions among vertebrae from each region are unambiguous, whereas in others, the distinctions among vertebrae in adjacent regions are less evident (Fig. 3).

The total number of vertebrae, excluding the caudal vertebrae, is surprisingly close to 30 in most mammals (Flower and Lydekker, 1891). With this in mind, examine the manatee vertebral column and contrast the numbers of different vertebrae it has with the number of vertebrae in the other selected species (Fig. 3).

C. Cervical Region

Cervical vertebrae (Fig. 4A) are located cranial to the rib-bearing vertebrae of the thorax. Some cervical vertebrae have movable lateral processes known as cervical ribs, none of which make contact with the sternum. Most mammals have seven cervical vertebrae, but all sirenians and the two-toed sloth (*Choloepus*) have six and the three-toed sloth (*Bradypus*) has nine. Serial fusion (ankylosis) of two or more cervical vertebrae is common in cetaceans, but all cetaceans have seven cervical vertebrae. Contrary to what has been reported in some published works, cervical vertebrae in some cetaceans (e.g., the narwhal *Monodon monoceros*, beluga *Delphinapterus*, and river dolphins) are unfused and provide considerable neck mobility.

The first two cervical vertebrae have unique names: the atlas (C1) and the axis (C2). Unlike all other vertebrae, the atlas and axis are not separated by an intervertebral disk but rather by a synovial joint, similar to the skull–atlas joint, where the occipital condyles of the skull articulate with the atlas (Fig. 4A). The shape of this joint dictates the range of motion between the skull and the first vertebra. Typical head motions on the atlas are up and down and side to side (Fig. 4A). The axis has an elongated centrum, the odontoid process or dens, that extends into and sometimes beyond the foramen of the atlas. The shape of the dens restricts motions between the atlas and the axis to twists or rotations parallel to the long axis of the body. Test these constraints on yourself by twisting your head and neck. Head nodding, as in expressing "yes," is constrained by the atlas; head shaking, as in expressing "no," is constrained by the axis.

Cervical vertebrae provide support for the head and can aid in FEEDING and LOCOMOTION. As a group, they can, in some cases, flex to provide a wide range of postures. Typically, permanently aquatic marine mammals have short necks, even if they have seven cervical vertebrae. In contrast, pinnipeds have relatively long necks, and the external appearance of a short neck in true seals is misleading. Close comparison of the skeletons of the true seal and sea lion reveals that they have quite similar neck lengths, although the distribution of body mass is different. True seals often hold their heads close to the thorax, which causes the neck to form a deep "S" curve in the neck. This provides true seals with a "slingshot potential" for grasping prey (or careless handlers).

Cervical vertebrae may have distinct transverse foramina that perforate the bases of the transverse processes and run parallel to the long axis of the body. Transverse foramina protect the arteries that supply the head and neck from kinking

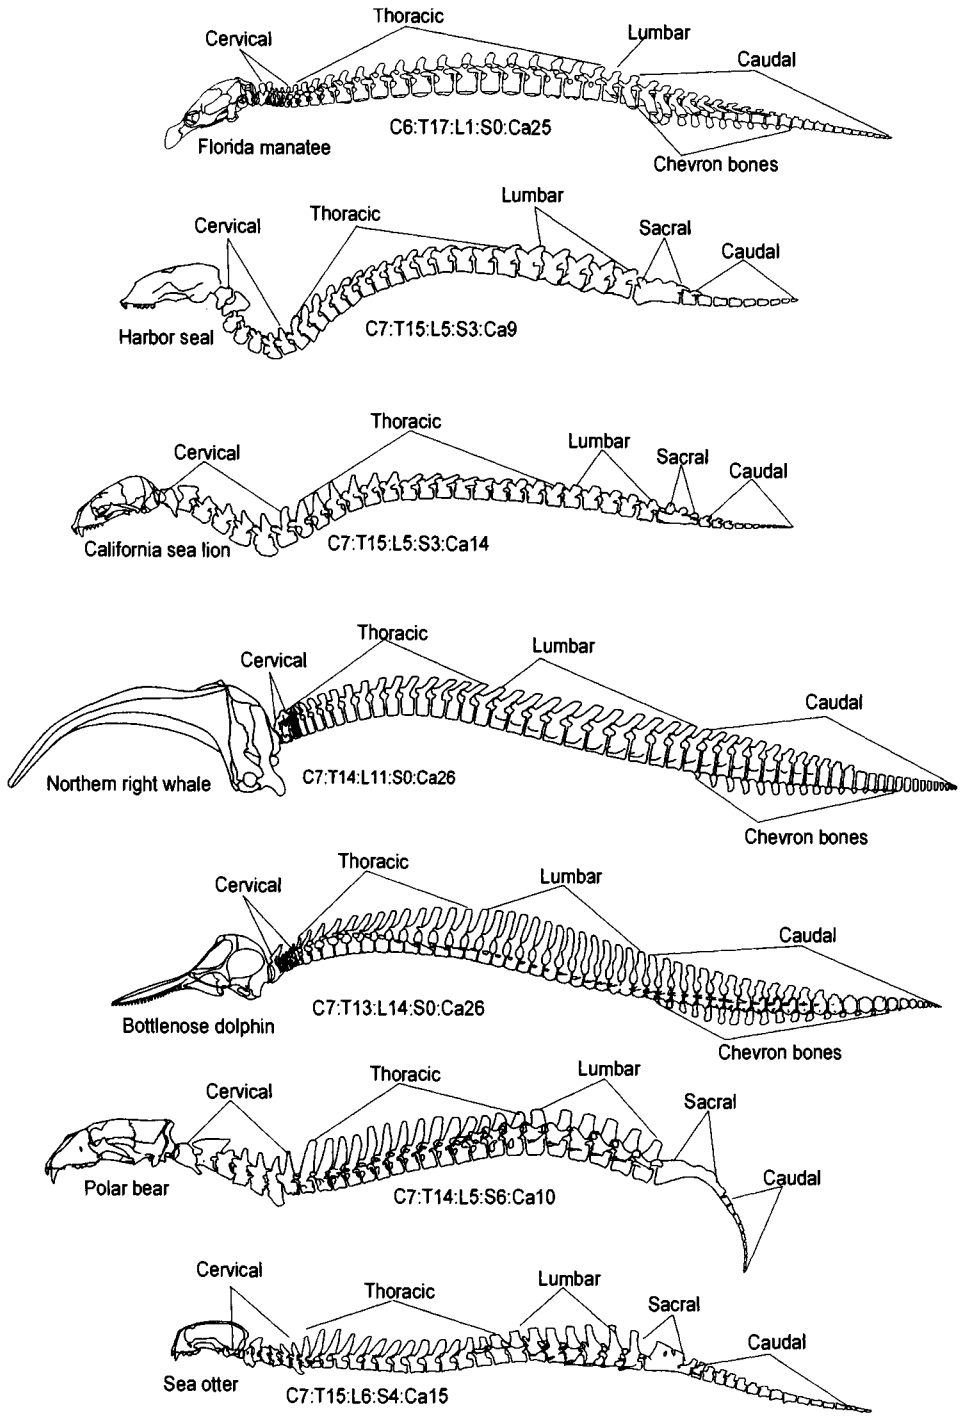

Figure 3 *Vertebral columns of the seven selected marine mammal species; the vertebral column of the dog is similar enough to the vertebral columns of the bear and other carnivorous species to exclude it from this illustration. There are typically five separate regions: cervical, thoracic, lumbar, sacral, and caudal. In this illustration, the first thoracic vertebrae for all the species illustrated are aligned. Each skull and vertebral column is scaled to similar shoulder–"hip" distances. Sacral vertebrae are, by definition, associated with an attached pelvis; therefore, permanently aquatic species with (unattached) pelvic vestiges have no sacral vertebrae. The vertebral formula, an alpha-numerical abbreviation for the numbers of vertebrae in each region, is provided below each vertebral column. The numbers given are for the specimens illustrated; some of these numbers vary between individuals of each species. Copyright S. A. Rommel.*

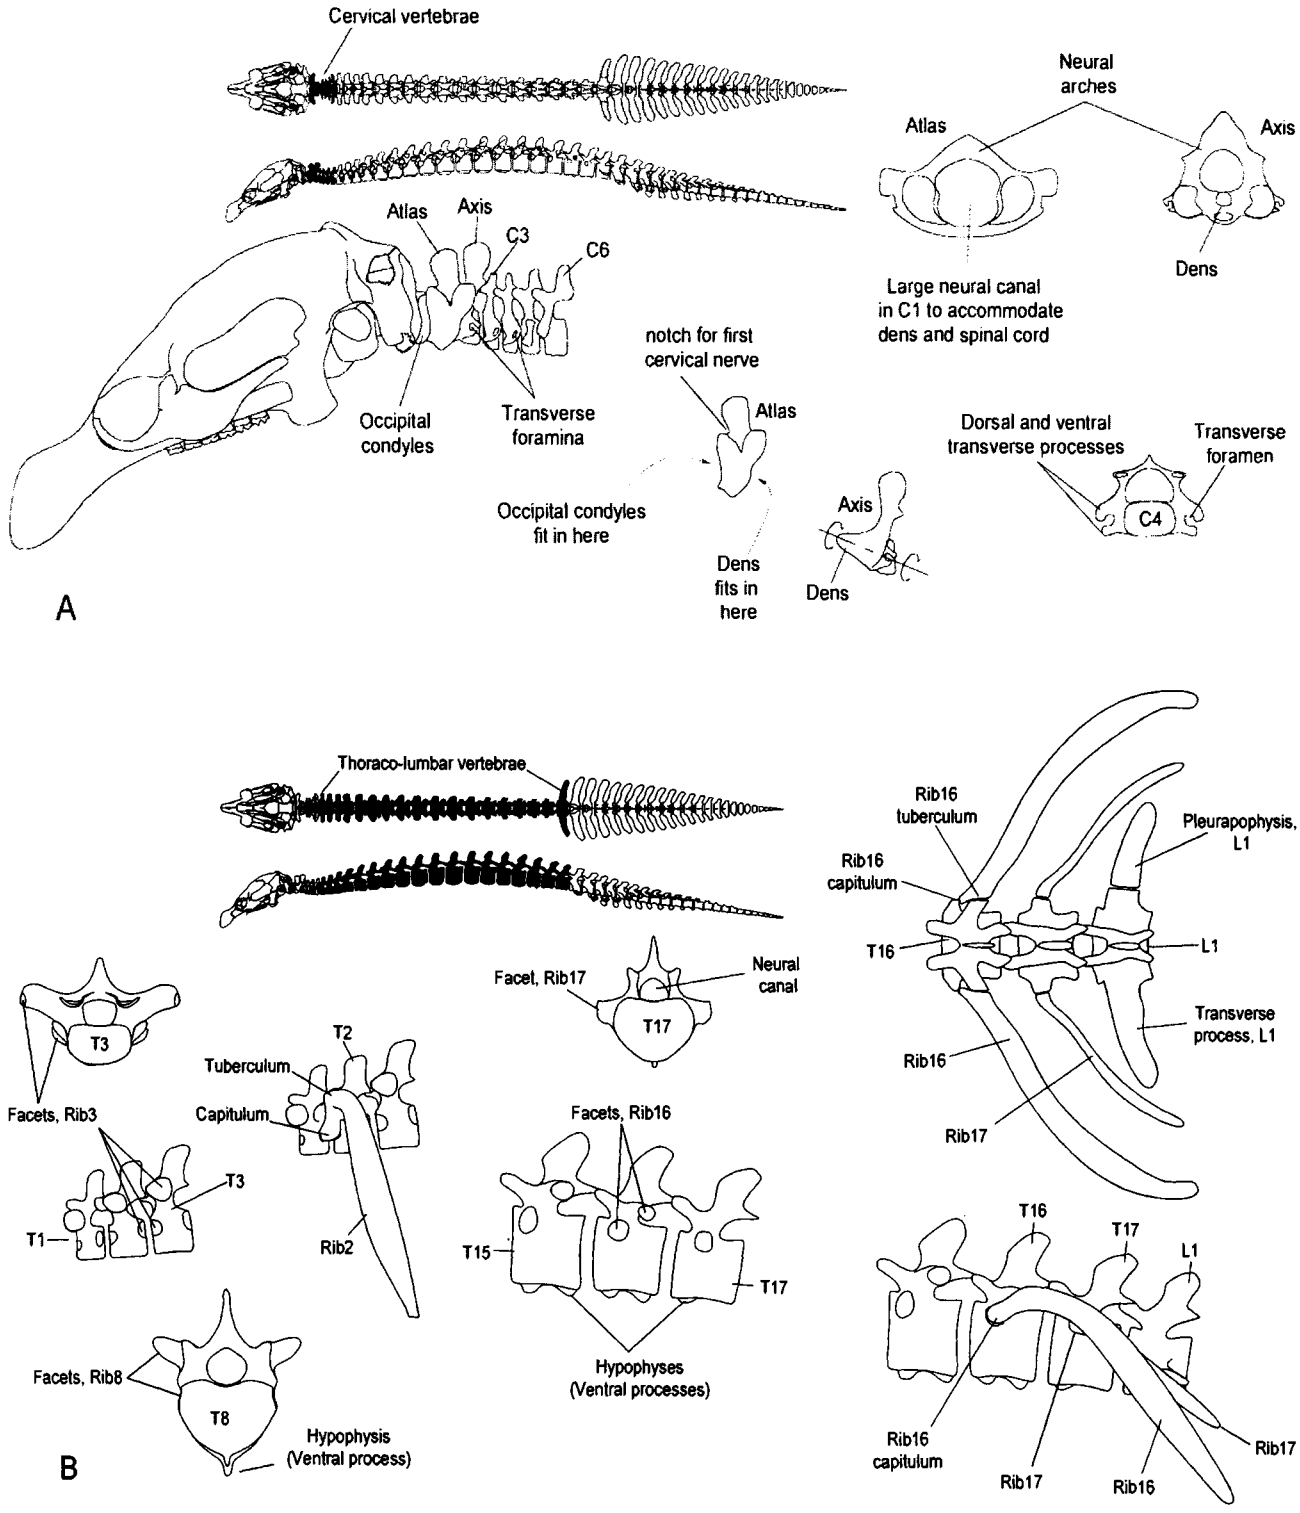

Figure 4 *(A) Cervical vertebrae. At the top of this illustration, these vertebrae are filled in on the dorsal and lateral views of the manatee skeleton. The first and second cervical vertebrae are uniquely named the atlas and the axis, respectively. Cervical vertebrae may have transverse foramina, which perforate the bases of the transverse processes. Typical skull motions on the atlas are up and down and side to side. The axis has an elongated centrum, the dens, that extends into the large neural canal of the atlas. The shape of the dens restricts motions between the first two vertebrae to "twists" or rotations parallel to the long axis of the body. (B) Thoraco-lumbar vertebrae. Thoracic vertebrae support the ribs, which anchor the diaphragm muscles. Some ribs are double headed and articulate with their respective vertebrae via capitula and tubercula. (continues)*

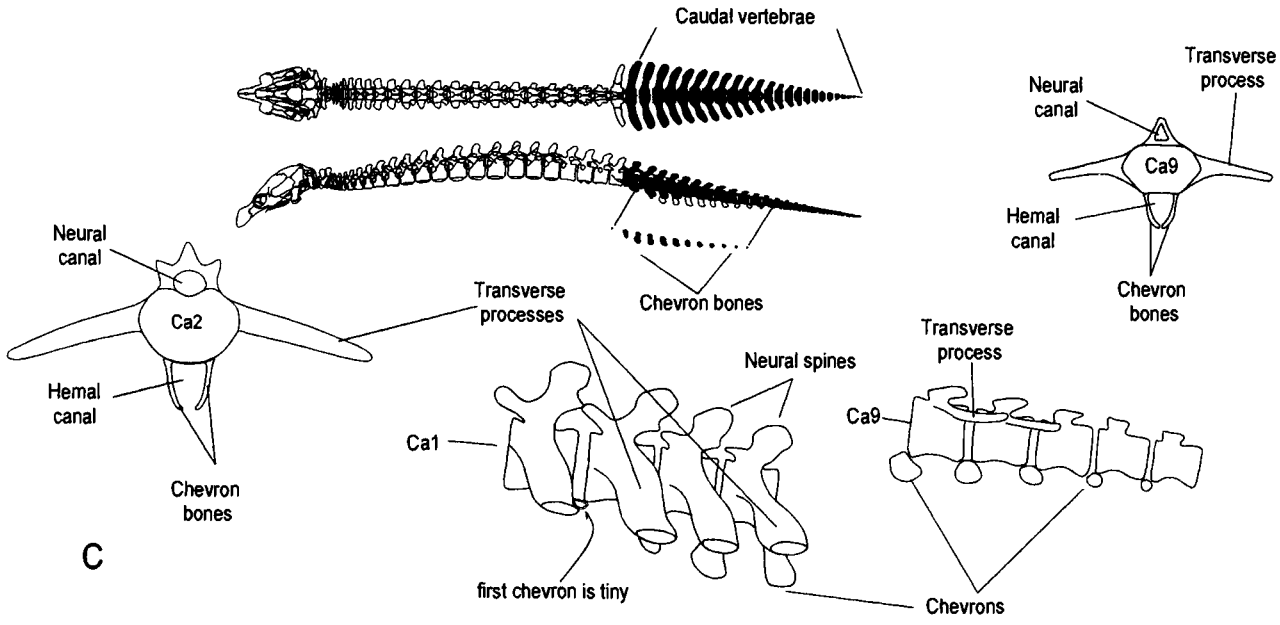

Figure 4 *(Continued) Each capitulum articulates with one or more costal facets on the vertebral centrum at or near the intervertebral disk. Each tuberculum articulates with a facet on the transverse process of its respective vertebra. Lumbar vertebrae are trunk vertebrae without ribs: they have pronounced transverse processes called pleurapophyses. In manatees, there may be a rib on one side and a transverse process on the other side of the same lumbar vertebra. (C) Caudal vertebrae are found in the tail. At the top of this illustration, these vertebrae are filled in on the dorsal and lateral views of the manatee skeleton. In permanently aquatic marine mammals that have no direct attachment between the pelvic vestiges and the vertebral column, the transition between lumbar and caudal vertebrae is defined by the presence of chevron bones. Chevron bones are ventral intervertebral ossifications. By definition each is associated with the vertebra cranial to it. Copyright S. A. Rommel.*

when the neck is flexed. Transverse foramina are particularly distinct in cervical vertebrae of carnivorous marine mammals (and, of course, the dog). A pair of notches (or foramina) in the neural arch of the atlas may be present (Fig. 4A); this opening is for the first spinal nerve that exits the neural canal between the back of the skull and the bulk of the neural arch of C1. Rarely, one finds cervical ribs, which are movable extensions of the ventral transverse processes. Cervical ribs do not extend to the sternum.

D. Thoracic Region

The thoracic region (commonly referred to as the thorax) is defined by the presence of more or less movable (i.e., not fused to the respective vertebrae) ribs (Figs. 3, 4B, and 5). Thoracic and lumbar vertebrae support the trunk—the region occupied by the thorax (with the lungs and heart) and the abdomen (with the remaining viscera). By definition, the first thoracic vertebra has a pair of ribs that, unlike cervical ribs, extend to the sternum. Most thoracic vertebrae have ribs that possess two segments. The proximal, dorsal segment is attached to the vertebral column and is termed a vertebral rib (Fig. 5). A distal, ventral segment is attached to the sternum and is termed a sternal rib (Romer and Parsons, 1986). A joint between the vertebral rib and the sternal rib allows flexibility of the thorax. The distinction between vertebral and sternal ribs is more common in birds and some reptiles, but it is less common in mammals because most mammals have cartilaginous sternal ribs termed costal cartilages. This distinction is made because, unlike most other mammals, odontocete cetaceans have bony rather than cartilaginous sternal ribs (bony sternal ribs are also found in the armadillo, *Priodontes*).

Thoracic vertebrae are constrained by their rib attachments and, thus, tend to be much less flexible than lumbar and caudal vertebrae. Typically, the thorax is relatively more flexible axially and laterally than it is dorsoventrally because zygapophyses tend to be oriented horizontally.

As suggested earlier, the mechanics of motion of the thoracic vertebrae are different from those of either cervical vertebrae or postthoracic vertebrae. Thoracic vertebrae have dual functions of longitudinal support and support of the diaphragm muscles. This dual function is reflected in the arrangement, size, and shape of the zygapophyses. The last thoracic vertebrae (here, we use first and last to designate cranialmost and caudalmost ribs to avoid complicated sentences confusing caudal as a direction and caudal as a region of the vertebral column) have ribs associated with them, but these last ribs may not be attached to their respective vertebrae (floating ribs), and there is little or no indication on their respective vertebrae to indicate their presence. The last ribs of the cetaceans are closely associated with the superficial aspects of the robust hypaxial muscles and may have little to do with support of the diaphragm, whereas those of manatees are

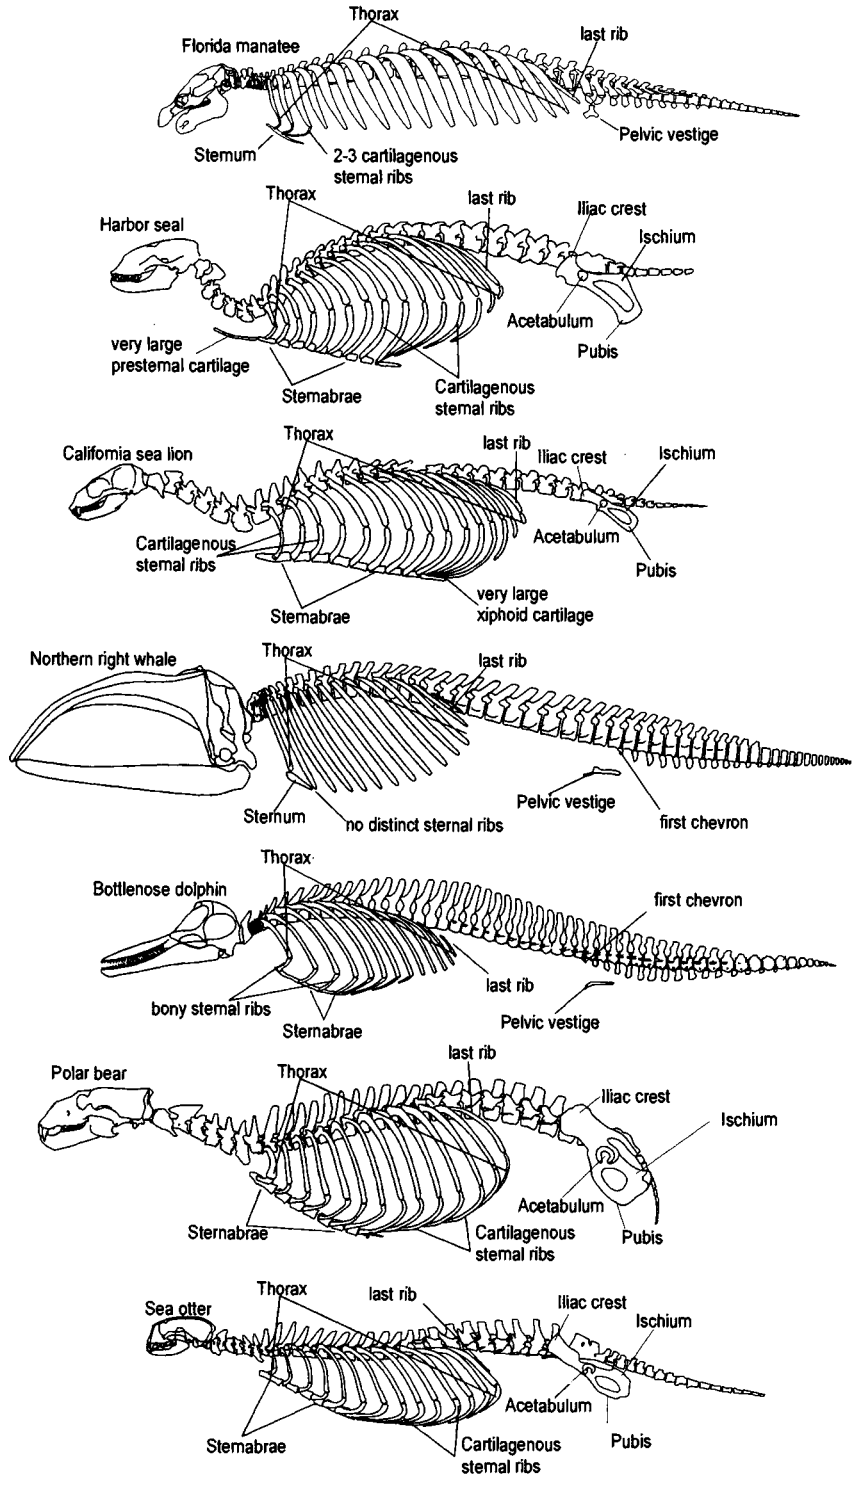

Figure 5 *Axial skeletons plus pelvises of the seven selected marine mammal species; because the axial skeleton and pelvis of the dog are similar to those of the bear and of other carnivorous species, the dog's skeleton was excluded. In this illustration, the first thoracic vertebrae for all the species illustrated are aligned. Vertebral ribs extend from the vertebral column to join the sternal ribs, which extend from the sternum. The sternum develops from a series of sternebrae. In some species (i.e., humans, right whales, manatees), the sternebrae fuse into a single bony unit. Each skull and vertebral column is scaled to similar shoulder–hip distances. Permanently aquatic species (manatee, dolphin, and right whale) have pelvic vestiges. Because the pelvic bones of these three species are not in the same location in relation to the first chevron bones, the first caudal vertebrae (defined by the first chevrons) of these three skeletons are not aligned. Distinct sexual dimorphism has been described for the pelvic vestiges of manatees and dugongs. Copyright S. A. Rommel.*

imbedded in the hypaxial muscles and may provide support for the diaphragm.

The attachment sites of ribs on the vertebrae are called rib facets or costal facets (ribs = costae) if the region of attachment has a distinct articulation (Fig. 4B); rib facets are located on the vertebral centrum, on the transverse processes, or on both. Some rib attachments are made via long connective tissue fibers; the ribs do not actually touch the respective vertebra, and there is no obvious structure on the (cleaned) vertebrae to suggest rib attachment. For this reason, dogmatic adherence to narrow definitions of numbers of thoracic or lumbar vertebrae or both should be avoided. Cetaceans and pinnipeds have very mobile rib cages. Surprisingly, diving mammals have considerable "tilt" to their ribs. In these species, the double-headed ribs (see later) have joints that are aligned to allow for substantial swing of the attached vertebral ribs in the plane of rotation. This extreme mobility of the rib cage can help accommodate the lung volume changes that accompany changes in depth so that ribs will not break. It may also have evolved to accommodate rib cage dynamics caused when abdominal muscle contractions prevent caudal displacement of the diaphragm during inspiration; in this case, ribs could be moved forward to increase lung volume.

Some thoracic vertebrae have ventral projections called hypapophyses—not to be confused with chevron bones, which are intervertebral and are structurally not part of the vertebrae (Figs. 3 and 4C). In the manatee, the diaphragm is firmly attached along the midline of the central tendon to hypapophyses. Hypapophyses also occur in some cetaceans (i.e., *Kogia*, the pigmy and dwarf sperm whales) in the caudal thorax and cranial lumbar regions; it is assumed that these hypapophyses increase the mechanical advantage of the hypaxial muscles.

The neural spines of thoracic vertebrae are often longer than those in any other region of the body (Figs. 3 and 5). Long neural spines provide mechanical advantage to neck muscles that support a head cantilevered in front of the body. Therefore, species with large heads tend to have long neural spines; however, the buoyancy of water negates the need for such long neural spines in permanently aquatic species.

Embryonically, ribs and transverse processes are homologous structures, but the presence of a movable joint ultimately distinguishes a rib from a transverse process in an adult. The unfinished joint may be indicative of developmental age. In some species (i.e., the manatee), there may be a movable "riblet" (pleurapophysis, *pleura* = side or rib) on one side and an attached "transverse process" on the other side of the same (typically the first lumbar) vertebra. Pleurapophyses are more common in some of the lower vertebrates (Romer and Parsons, 1986; Kardong, 1998).

A rib may attach to its respective vertebra (Fig. 4B) at one or more locations (e.g., centrum or transverse process, or both). Typically the cranialmost ribs have two distinct regions of articulation with their juxtaposed vertebrae. The cranialmost articular part of a double-headed rib is the head or capitulum (plural, capitula) and it articulates (via a synovial joint) with the body (or bodies) of one or more vertebrae. The tuberculum (plural, tubercula) is the second point of attachment of a double-headed rib; it articulates (sometimes with a synovial joint, other times by connective tissue fibers) to a transverse process of the respective vertebra. Since the capitula of some double-headed ribs touch two vertebrae, the vertebra with the transverse process attachment is used to identify the respective vertebra.

The caudalmost ribs have single attachments and are referred to as single headed. In most mammals, the single-headed ribs have lost their tubercula and are attached to their respective vertebrae by the capitulum at the centrum. In contrast, the single-headed ribs of cetaceans lose their capitula and are attached to their respective vertebrae by their tubercula at the transverse processes (as occurs in some reptiles). Thus, single-headed ribs of cetaceans attach to vertebrae farther from the midline than single-headed ribs of other mammals. Additionally, the transverse processes of the thoracic vertebrae in cetaceans can be longer than those of other mammals. The last ribs often "float" free at one or both ends, i.e., they are attached to neither their associated vertebra nor the sternum. These ribs tend to be significantly smaller than the ones cranial to them and are often lost in preparation of the skeleton.

Sternum The sternum is formed from bilaterally paired serial elements, called sternebrae (the sternal equivalent of vertebrae; Fig. 5). The paired elements fuse on the midline, occasionally imperfectly, leaving foramina in the sternum. The first and last sternebrae are called the manubrium and xiphisternum, respectively. In some species (e.g., some odontocetes, all mysticetes, and all sirenians), sternebrae fuse into a single unit. Sternal ribs extend from the sternum to join the vertebral ribs. True seals have an elongate presternal cartilage extending cranially from the manubrium. Some species, particularly the California sea lion and its close relatives, have enlarged xiphisternal cartilaginous extensions.

E. Lumbar Region

Lumbar vertebrae are trunk vertebrae that typically do not bear movable ribs (Fig. 3). Recall that ribs and transverse processes develop from the same embryonic structures. Occasionally a distinct pleurapophysis may be found in this region. As noted previously, pleurapophysis are commonly found in manatees: there will be a "normal" transverse process on one side and a movable riblet on the other side of the same vertebra. These lumbar ribs are clearly distinct from thoracic ribs (Fig. 4B).

As already noted, the number of lumbar vertebrae is usually closely linked to the number of thoracic vertebrae; an increase in number in one section typically means a reduction in the other. For example, there are 19 thoraco-lumbar vertebrae in all species of Artiodactyla, whereas there are 20 or 21 in Carnivora; compare these numbers with those of the selected marine mammals (Figs. 3 and 4B). Interestingly, the scaling of the skeletons to similar shoulder–hip joint distances helps us avoid some of the "distractions" that are inherent in the variation among species in size, number, and shape of the other regions of the body.

Typically, lumbar vertebrae are more flexible dorsoventrally than they are laterally and they may have no axial flexibility. Some of the mobility of lumbar vertebrae may be constrained

by ribs that, although not attached to these vertebrae, are angled backward and extend beyond the tips of some lumbar vertebrae (Figs. 4B and 5).

F. Sacral Region

There are at least two commonly accepted definitions for sacral vertebrae: (a) serial fusion of postlumbar vertebrae, only some of which may attach to the pelvis (the human sacrum), and (b) only those vertebrae that attach to the ileum, whether or not they are fused serially (Fig. 3). Both definitions have merit. In species in which there is contact between the vertebral column and the pelvis, it is relatively easy to define sacral vertebrae. However, it is not easy in cetaceans and sirenians (dugongs have a ligamentous attachment between the vertebral column and the pelvic vestiges) because there is no direct attachment between the pelvic vestige and the vertebral column and there is no vertebral fusion. Thus, permanently aquatic species have (by either definition) no sacral vertebrae. Within a species, the number of serially ankylosed vertebrae may vary, particularly with age. The number of sacral vertebrae is commonly two to five, but there are exceptions.

G. Caudal Region

Caudal (cauda = tail) vertebrae are found in the tail (Fig. 4C). The number of caudal vertebrae varies widely. Long tails usually require numerous caudal vertebrae (up to a maximum of 46 in one African pangolin, *Manis gigantea*). Florida manatees have between 22 and 27 caudal vertebrae, and bottlenose dolphins and right whales both have 26; for cetaceans, the minimum is 13 in *Caperea marginata* (pygmy right whale) and the maximum is 49 in *Phocoenoides dalli* (Dalls porpoise). Note that caudal vertebrae of cetaceans extend to the tip of the tail (fluke notch), whereas manatee vertebrae stop 3–9% of the total body length (as much as 17 cm in a large specimen) from the fluke tip. Caudal vertebrae range from being robust, important locomotory structures in permanently aquatic species to being relatively small, unimportant pieces in pinnipeds and the polar bear.

Chevron Bones The chevron bones or chevrons (Fig. 4C) are ventral intervertebral ossifications found only in the caudal region. They are relatively large in permanently aquatic species but can be found as small ossifications in many other species, including the dog. By definition, each is associated with the vertebra cranial to it [note that there is some controversy over which is the first caudal, see Rommel (1990)]. Pairs of chevron bones form arches, creating a ventral channel called the hemal canal. Within the hemal canal, the blood vessels (caudal arteries and veins) that supply the tail are protected from occlusion when the tail is flexed. In some cetaceans the ventral aspects of each chevron bone pair fuse and may then function to increase the mechanical advantage of the hypaxial muscles to flex the tail ventrally.

II. Appendicular Skeleton

A. Pectoral Limb Complex

The forelimb (Fig. 6) is referred to as a flipper in permanently aquatic species (in true seals and sea lions the hindlimb is also referred to as a flipper). The forelimb includes the scapula, humerus, radius and ulna, and manus.

The scapula is attached to the axial skeleton only by muscles; there is no functional clavicle in marine mammals (Klima *et al.*, 1980; Strickler, 1978). The scapula consists of an essentially flat (slightly concave medially) blade with an elongate scapular spine extending laterally from it. The scapular spine is roughly in the center of the scapular blade in most mammals. However, in cetaceans, the scapular spine is close to the cranial margin of the scapular blade, and both the acromion and the coracoid extend beyond the leading edge of the blade. The distal tip of the spine is the acromion.

The humerus has a ball-and-socket articulation in the glenoid fossa of the scapula; this is a very flexible joint. The humerus articulates distally with the radius and ulna; this is also a flexible joint in most mammals, but it is constrained in cetaceans. The olecranon is a proximal extension of the ulna that increases the mechanical advantage of the triceps muscles that extend the forelimb. In species like the polar bear and the sea lion, the olecranon is robust; however, in the Cetacea it is relatively small. The radius and ulna of manatees fuse at both ends as the animal ages. This fusion prevents axial twists that pronate and supinate the manus. The radius and ulna of Cetacea are also constrained but are not typically fused. The forelimbs of the sea otter are very mobile, allowing for the manipulation food.

The distal radius and ulna articulate with the proximal aspect of the manus. The manus includes the carpals, metacarpals, and phalanges. There are five "columns" of phalanges, each of which is called a digit. The digits are numbered, using Roman numerals, starting from the cranial aspect (the thumb; associated with the radius). Note that the longest digit may be different in different species (Fig. 6).

In many of the marine mammals, the "long" bones of the pectoral limb (humerus, radius, and ulna) are relatively short, and the phalanges are elongated. Cetaceans are unique among mammals in that they have more phalanges than any of the other mammals (Fig. 6); this condition is known as hyperphalangy (Howell, 1930). The number varies between individuals of each species: pilot whales (*Globicephala* spp.) have the most (14), the bottlenose dolphin has a maximum of 9, and the right whale has a maximum of 7.

Notice the "plane" in which each manus is oriented (Fig. 6). The sea otter's manus is much like that of humans and has similar dexterity. The polar bear manus is much like that of the dog and other terrestrial quadrupeds. Permanently aquatic species hold the manus in a plane roughly parallel to the midsagittal plane of the body or parallel to the nearest body surface.

B. Pelvic Limb Complex

The typical mammalian pelvis is made of bilaterally paired bones: ilium, ischium, and pubis (Fig. 7). Each of the halves of the pelvis attaches (via the ilium) to one or more sacral vertebrae. The crest of the ilium, which is a prominent landmark, flares forward and outward beyond the region of attachment between the sacrum and the ilium. The two halves of the pelvis join at the pubic symphysis on the ventral midline. In permanently aquatic marine mammals, there is but a vestige of a

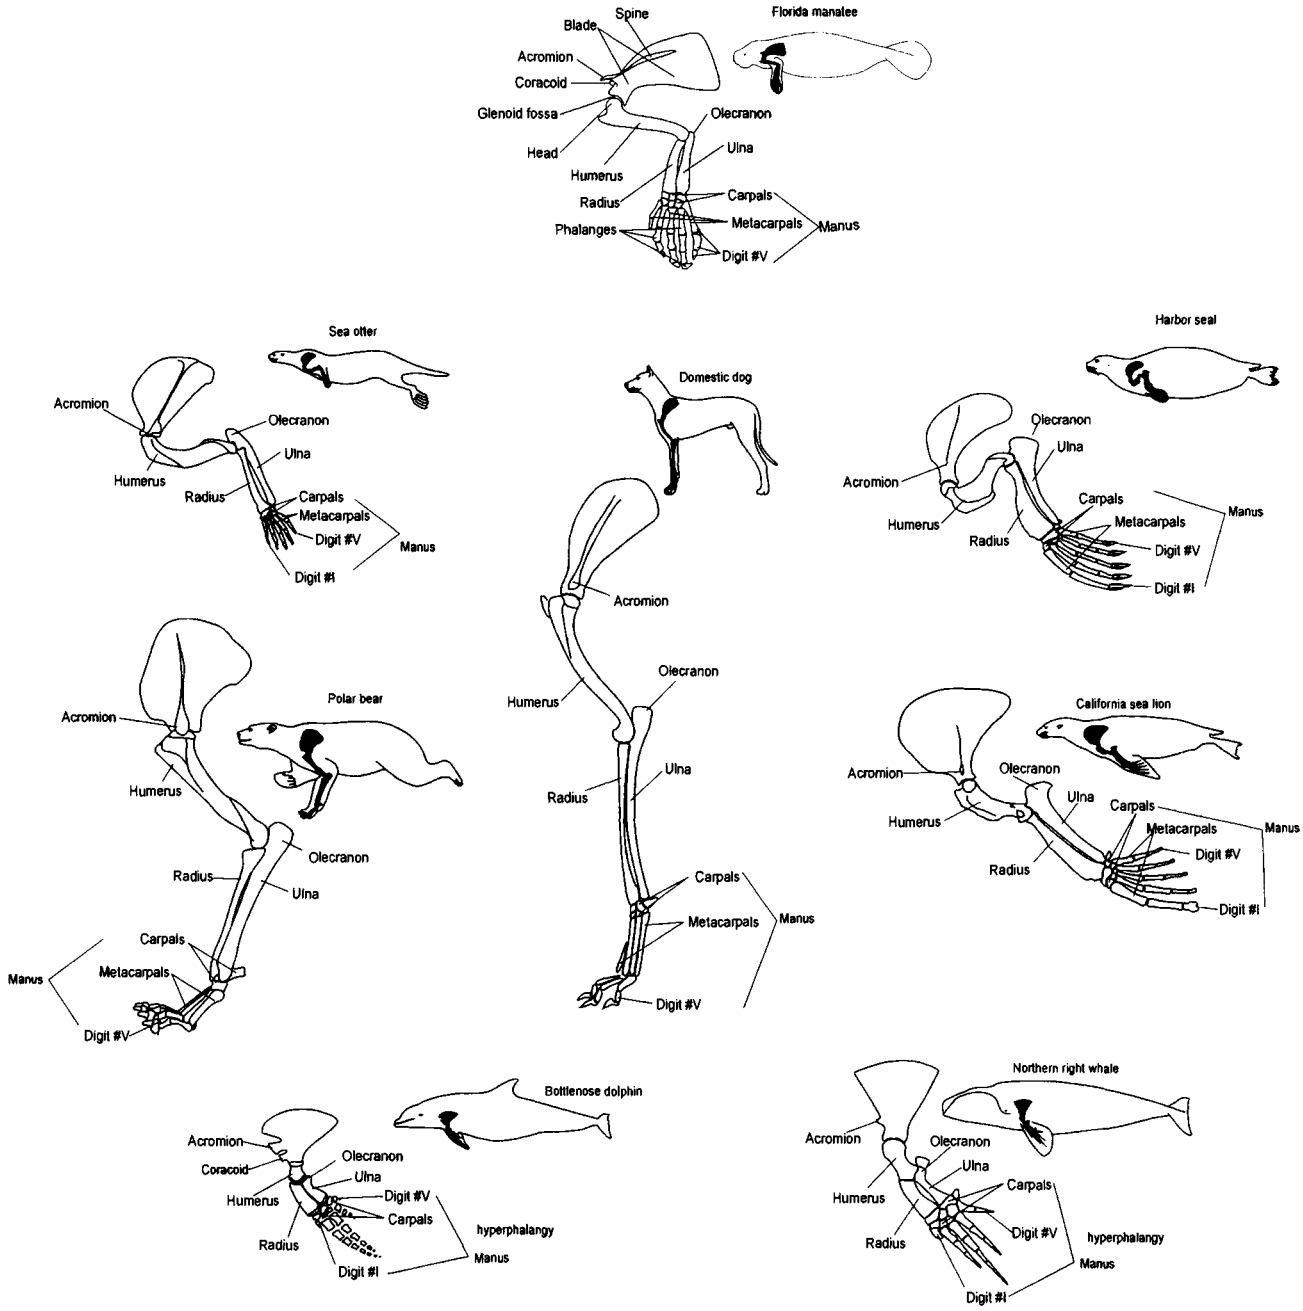

Figure 6 *The forelimb (pectoral appendage) includes the humerus, radius and ulna, and manus. The forelimb attaches to the pectoral girdle, which is made of bilaterally paired scapulae. The scapula is a flat (slightly concave medially) blade with an elongate scapular spine extending laterally from it. The distal tip of the spine is the acromion process. The humerus has a ball-and-socket articulation with the glenoid fossa of the scapula. The humerus articulates with the radius and ulna at the elbow. The radius and ulna articulate with the proximal aspect of the manus at the wrist. The manus includes the carpals, metacarpals, and phalanges. There are five "columns" of phalanges; each "column" is called a digit. The digits are numbered, using Roman numerals, starting from the cranial aspect (associated with the radius, in humans—the thumb). Copyright S. A. Rommel.*

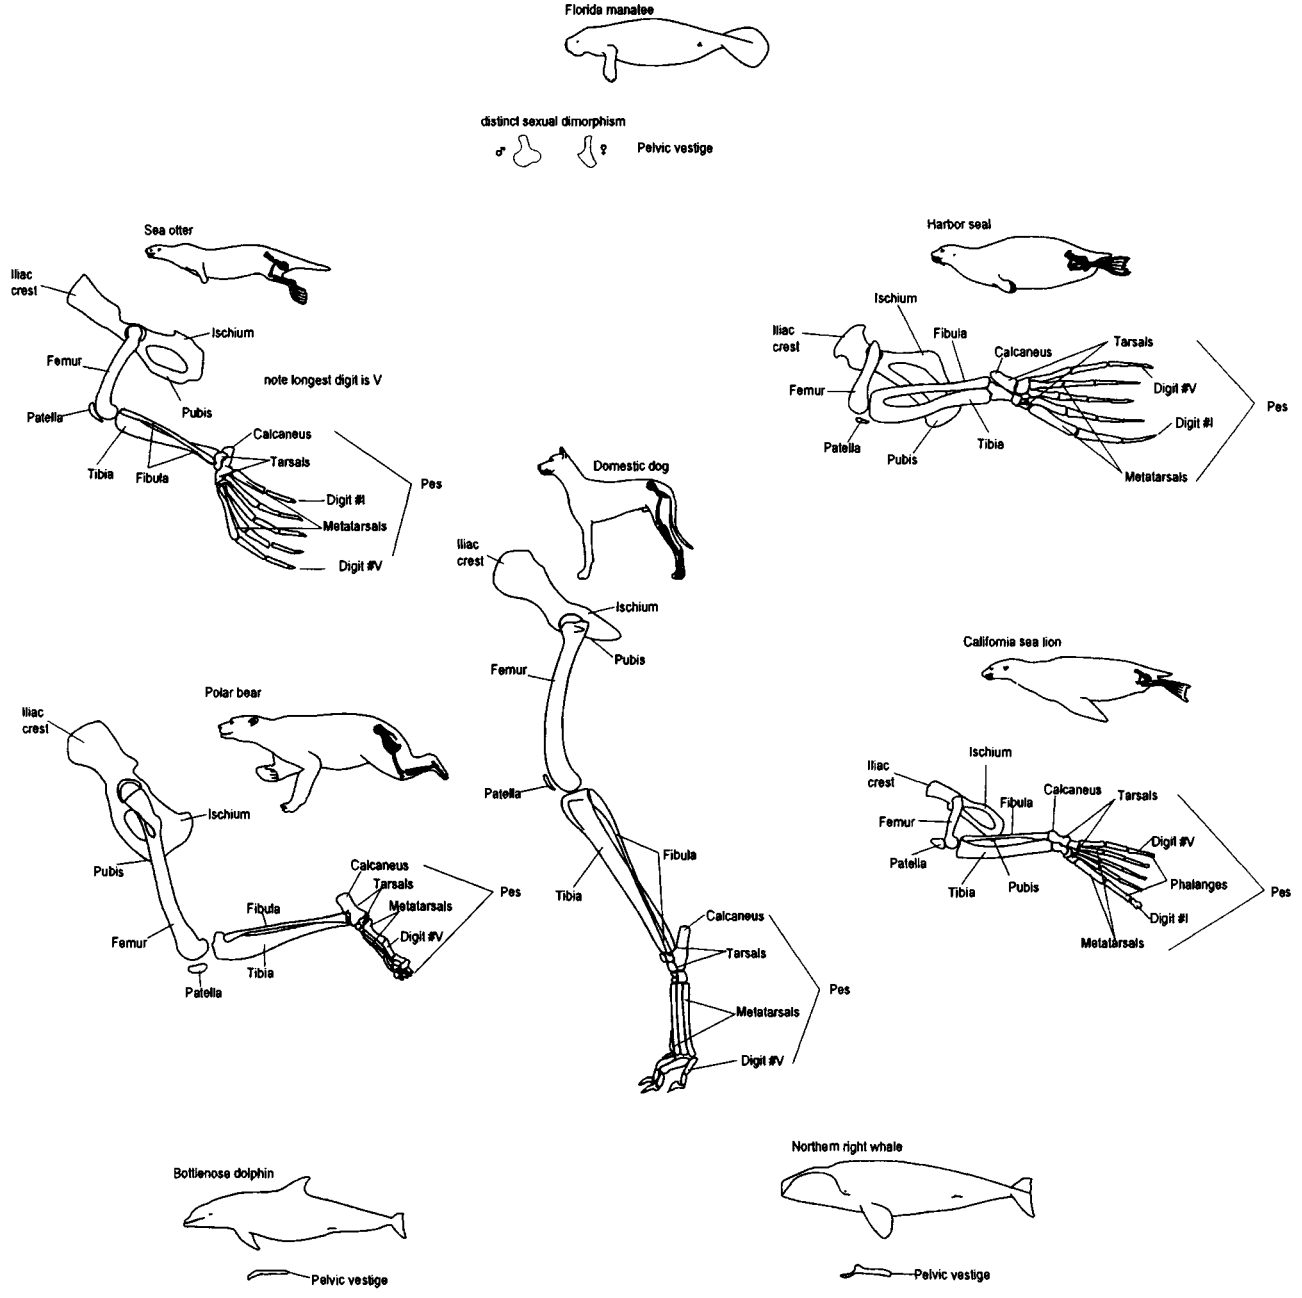

Figure 7 *The pelvic appendage (hindlimb) and pelvic girdle. The typical mammalian pelvis is made of bilaterally paired coxae attached to one or more sacral vertebrae. Each coxa is made of three elements: the ilium, ischium, and pubis. Each half of the pelvis attaches to one or more sacral vertebrae. The crest of the ilium is a prominent landmark; it flares forward and outward beyond the region of attachment between the sacrum and the ilium. The two halves of the pelvis join at the ventral midline pubic symphysis. In permanently aquatic marine mammals there is but a vestige of a pelvis. The hindlimb, if present, is attached to the pelvic girdle via a ball (femoral head)-and-socket (acetabulum) joint at the hip. The proximal limb bone is the femur. Distally, the femur articulates with the tibia and the fibula at the knee joint. The tibia and fibula distally articulate with the pes at the ankle. Note that the pes is oriented in different "planes" in some of the selected species. The pes is made of the tarsals proximally, the metatarsals medially, and the phalanges distally. Copyright S. A. Rommel.*

pelvis to which portions of the rectus muscles of the abdomen may attach. Additionally, the male reproductive organs may be supported by these vestiges. Occasionally, in some of the large whales, a hindlimb articulates with the pelvic vestige.

The hindlimb, if present, is attached to the vertebral column via a ball-and-socket joint at the hip. The proximal limb bone is the femur, whose head articulates with the socket of the pelvis, the acetabulum. Distally the femur articulates with the tibia and the fibula (at the knee joint). The tibia and fibula articulate distally with the pes or foot (Fig. 7). The pes is composed of the tarsals proximally, the metatarsals medially, and the phalanges distally. Note that the digits of the sea lion terminate a significant distance from the tips of the flipper. Of the chosen group of marine mammals, the limbs of the polar bear are closest in gross appearance to those of the terrestrial mammals. In contrast, many of the marine mammals have relatively short "long" bones (femur, tibia, and fibula) and relatively long phalanges. The femurs of some phocids (e.g., the harbor seal) are so short that the knee cannot contact the ground.

Note that the pes is oriented in different "planes" in some of the selected species (Fig. 7). The pes of the polar bear is oriented in a fashion similar to that of the dog. The sea otter, seal, and sea lion all orient the pes parallel to the sagittal plane when swimming. The sea lion can rotate its hind flippers to "walk" on land, and the sea otter can manipulate its hind flippers to hold food. Compare the positions of the first and last digits in the sea otter with those of the seal and sea lion and note how the sea otter's fibula crosses the tibia to achieve this orientation.

Sexual Dimorphisms In many mammals the adult males are larger than the adult females, and among marine mammals, this dimorphism is extremely pronounced in certain pinnipeds and the sperm whales. In contrast, the adult females of the baleen whales and some other species are larger than the adult males. In permanently aquatic marine mammals, there may be sexual dimorphisms in the pelvic vestiges (Fagone *et al.*, 2000). The penises of mammals are supported by tough fibrous structures, the crura, which attach to the pubic bones of the pelvis. The muscles that engorge the penis with blood are also attached to the pelvis, and presumably the mechanical forces associated with these muscles influence pelvic vestige size and shape, particularly in manatees. Males in some groups of mammals, particularly the carnivores, have a bone within the penis (the baculum) that helps support the penis.

III. Sutures and Epiphyses

Many bony features change as the individual develops and matures; these features can be used as milestones in life history studies, and in some cases, they can be fairly accurate estimators of age. Some postcranial elements grow from separate ossifications centers at the margins of the bones (Fig. 8A). Epiphyses (*epi-*, upon, and *physis-*, grow or generate) are regions at the ends of bones (most often at or near a joint) associated with longitudinal growth in mammals. Epiphyses allow the portion of the bone near a joint to grow at a different rate than the rest of the bone. Growth occurs at a cartilaginous plate between the epiphysis and the diaphysis (*dia-*, between; body or shaft). At the completion of growth, the epiphysis fuses with the rest of the bone, and the cartilage plate disappears. Eventually the suture between the two parts disappears. Skeletal maturity is defined (for most mammals) when the vertebral epiphyses are all fused to their respective centra. Because most marine mammals are large, their epiphyses are more evident than those of smaller terrestrial mammals.

The best-studied epiphyses are those of the long bones. There are, however, other epiphyses that are less well known. For example, the proximal finger bones may have epiphyses (Fig. 8B). The pattern of epiphysial fusion in the flipper can be used to determine the relative age of an individual when compared to the fusion pattern in other animals of a known age. Occasionally, epiphyses are found on the proximal ends of ribs, on the scapula at or near the coracoid, or at the tips of neural spines and transverse processes.

Among the epiphyses most important to mammalian osteologists are those located at each end of the vertebral centrum (Fig. 8D). Most mammals have indistinct bony plates at each end of their growing vertebrae. These plates are vertebral epiphyses. Manatees (and humans) are among the few species of mammals that have distinct or no vertebral epiphyses. In manatees, the vertebral epiphyses are delicate irregular films of bony tissue found within the cartilaginous surfaces at the ends of the centrum. After these vertebral sutures are completely fused, the skeleton cannot grow in length and the individual is considered skeletally mature. This may or may not coincide with other forms of maturity, such as reproductive maturity.

Nonepiphyseal sutures can also be used to estimate the age of parts of the postcranial skeleton (Fig. 8C). For example, the two halves of the neural arch ankylose at the dorsal midline to form the base of the neural spine. These sutures may persist well into adulthood in cetaceans.

There is much more to learn about the postcranial skeleton. See Pabst *et al.* (1999) for additional functional morphology on marine mammals. Young (1975) for information on mammals in general, and Alexander (1994) for vertebrates. For principles on size and scaling see Calder (1966) and Schmidt-Nielsen (1984).

Acknowledgments

We thank Meghan Bolen, Tim Evans, Llyn French, Judy Leiby, and James Quinn at the Florida Marine Research Institute and Lisa Johnson at Eckerd College for helpful comments on the manuscript. Anatomical illustrations were created with FastCAD (Evolution Computing, Tempe, AZ).

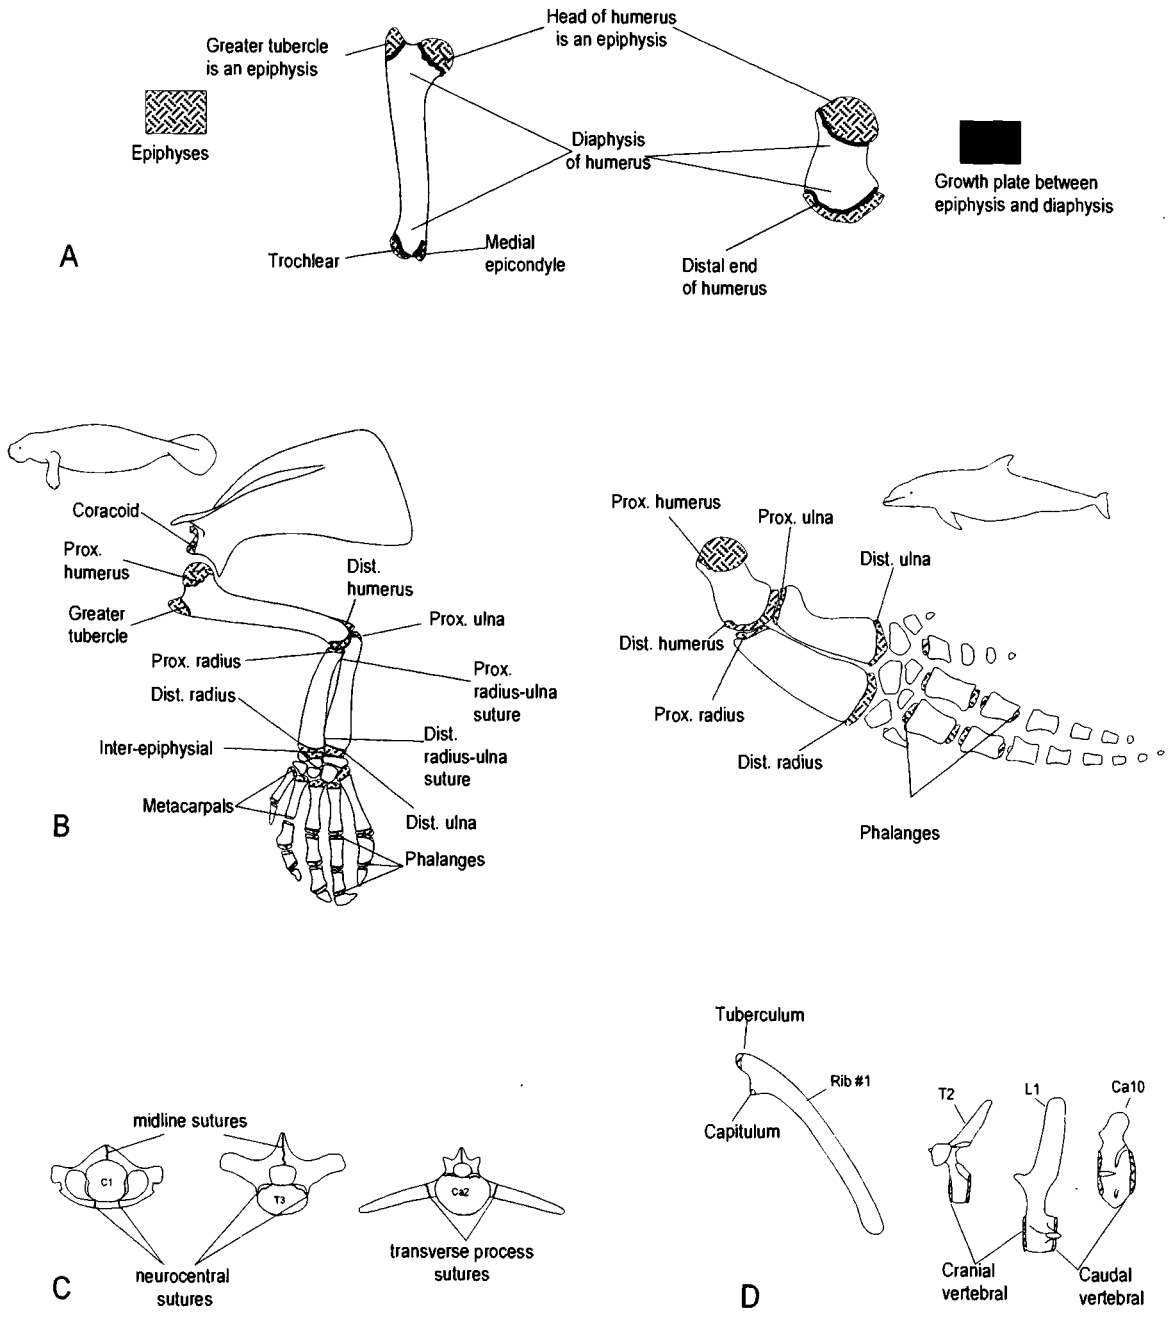

Figure 8 *(A) Postcranial features that change with age. Some postcranial elements grow in length by separate ossification centers, the epiphyses, at the margins of the bony element. The humeral head develops as an epiphysis, as does the distal humerus. A cartilaginous growth plate located between the epiphysis and the diaphysis (body or shaft) disappears when growth is completed. (B) Epiphyses are also found at the ends of the phalanges. Patterns of fusion of these epiphyses provide information about aging. The epiphyses illustrated here have been used for relative aging of manatees and dolphins. (C) Nonepiphyseal sutures can also indicate age in the postcranial skeleton. The transverse processes and the neural arches have sutures that disappear early in adolescence. Additionally, the two halves of the neural arch ankylose at the dorsal midline to the base of the neural spine. (D) Epiphyses may occur on the ends of ribs and the tips of transverse processes and neural spines. Most mammals have distinct vertebral epiphyses at each end of their growing vertebrae. Vertebral epiphyses fuse to their respective vertebral centra at physical maturity of the vertebra. Skeletal maturity is achieved when all vertebral epiphyses are fused: after this event, longitudinal growth of the vertebral column ceases. Manatees (and humans) are among the few species that have indistinct or no vertebral epiphyses. Copyright S. A. Rommel.*

Skull Anatomy

SENTIEL A. ROMMEL
Florida Marine Research Institute, St. Petersburg

D. ANN PABST AND WILLIAM A. MCLELLAN
University of North Carolina, Wilmington

To appreciate skull anatomy, take a moment and look at your own face in a mirror. The structures above the neck are designed for the acquisition and initial processing of nutrients, the exchange of respiratory gases, the acquisition of sensory information about light, sound, touch, odor, and taste, and the broadcast of information about your own thoughts and emotions. Sensory and motor information is processed and sent from here to coordinate body functions. Complex signals can be sent to others of our species via vocalizations and/or the contractions of facial muscles. The head is our window for contact, perception, and communication with our world, and the skull provides the framework, the organizing hub, for the head. Thus, the skull is interesting in itself. It is also fundamentally important in our picture of evolutionary biology. This article describes the skull morphology of the evolutionarily diverse group called marine mammals (see Reynolds *et al.*, 1999).

I. Defining the Term "Skull"

The term "skull" is inexact. It has been used to describe the entire skeleton of the head. It has also been used to refer to only the cranium (plural, crania) or housing for the brain and sense organs, and the upper jaw (the part of "poor Yorick" that Hamlet held in his hand). This article uses the word skull to refer to the *entire* head skeleton, including the cranium and the derivatives of the first two visceral arches, i.e., the lower jaw (or mandible, which is composed of right and left dentaries) and the hyoid apparatus. The mandible and hyoid apparatus of marine mammals have received less attention in the literature, but they are particularly important in adaptations for feeding (see later).

The skull acts as a foundation for the fat, muscle, skin, and vascular and sensory structures that form the head. Thus, the skull alone does not dictate the contours of the head. For example, the external profile of the manatee head differs from that of the underlying skull (Fig. 1), and the relationships between the bones and the soft tissues of the head vary among species (Fig. 2). Odontocete cetaceans have a melon, a fatty facial pad, the shape of which is only partly defined by the underlying bones (Mead 1975); the extreme difference in head and skull profiles may be found in the sperm whale (*Physeter macrocephalus*). Contrarily, the dorsal surface of the right whale's head follows closely that of the underlying skull, although the right whale also has huge lower lips that follow the contour of the upper jaw but are not predicted by the outline of the lower jaw.

The shape of the head may also influence the dynamics of LOCOMOTION and balance. The completely aquatic species (cetaceans and sirenians) have shorter necks and less need for "antigravitational" muscles that support the head than do terrestrial mammals (imagine the right whale moving its head around in the air the way a sea lion does).

II. Feeding and Swallowing

The specific characteristics of a skull (including dentition) often reflect the animal's methods of FEEDING (Fig. 3). For example, the "typical" heterodont dentition (Kardong, 1998) of terrestrial mammals such as the dog is also found to various degrees in seals, sea lions, walrus (*Odobenus rosmarus*), sea otter (*Enhydra lutris*), and polar bear (*Ursus maritimus*).

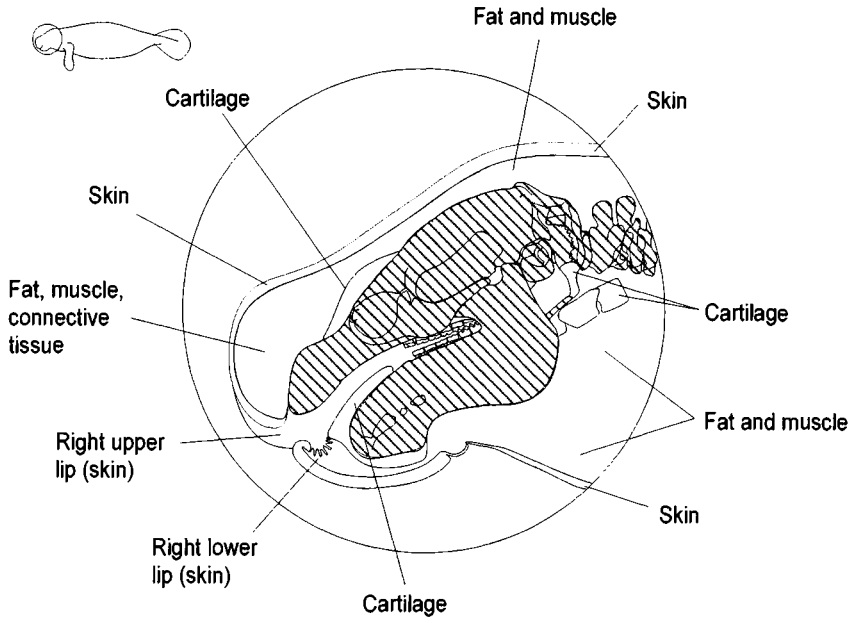

Figure 1 *Positions of skull features within the head vary among species. Here we illustrate how the midline contours of the manatee head differ from a left lateral illustration of the skull. The skeletal elements are cross-hatched to contrast them with soft tissues. Copyright S. A. Rommel.*

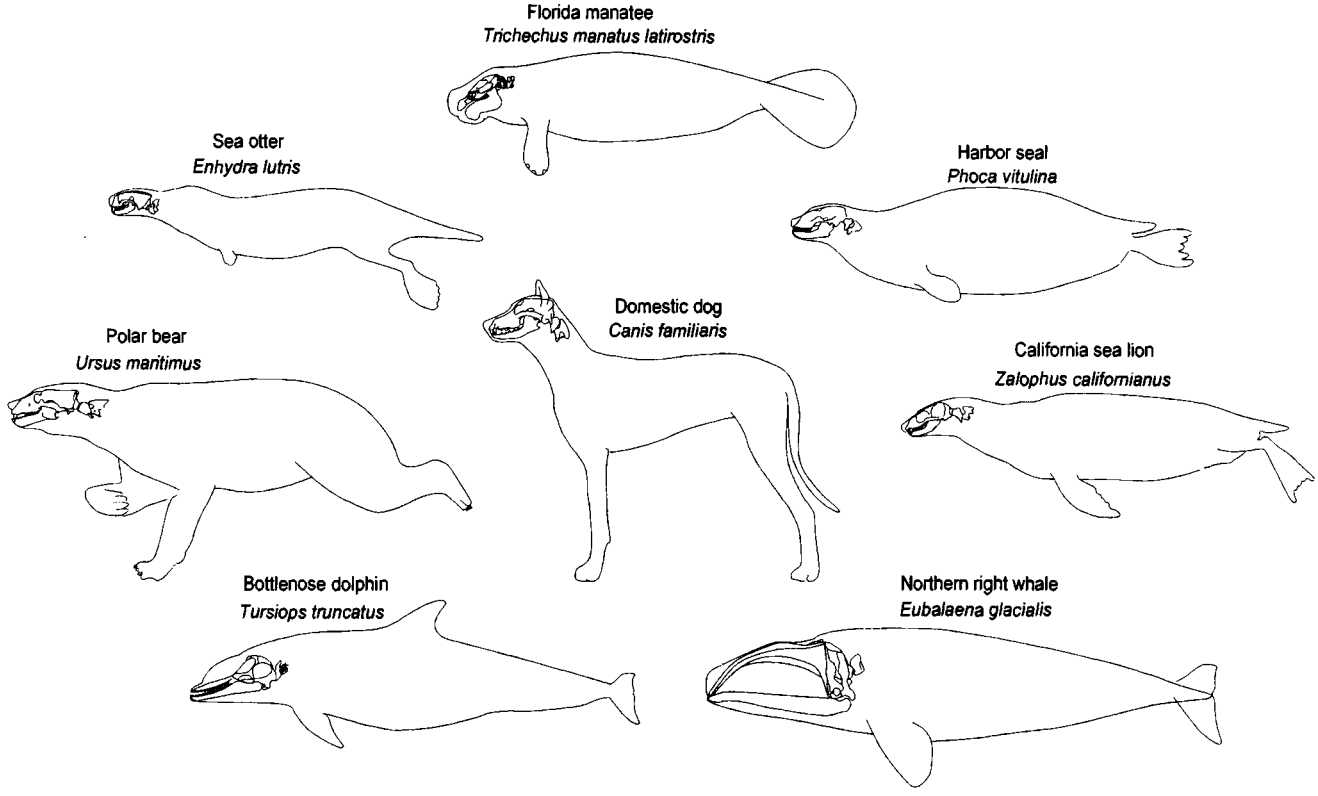

Figure 2 *Skulls and first two cervical vertebrae (unless fused, as it is in cetaceans) of a selection of marine mammals for comparison with those of the dog. Each species is scaled so that the distances between the shoulder and the pelvis are similar; body cavities are therefore roughly similar in length, allowing one to compare head sizes with visceral volumes among species. Copyright S. A. Rommel.*

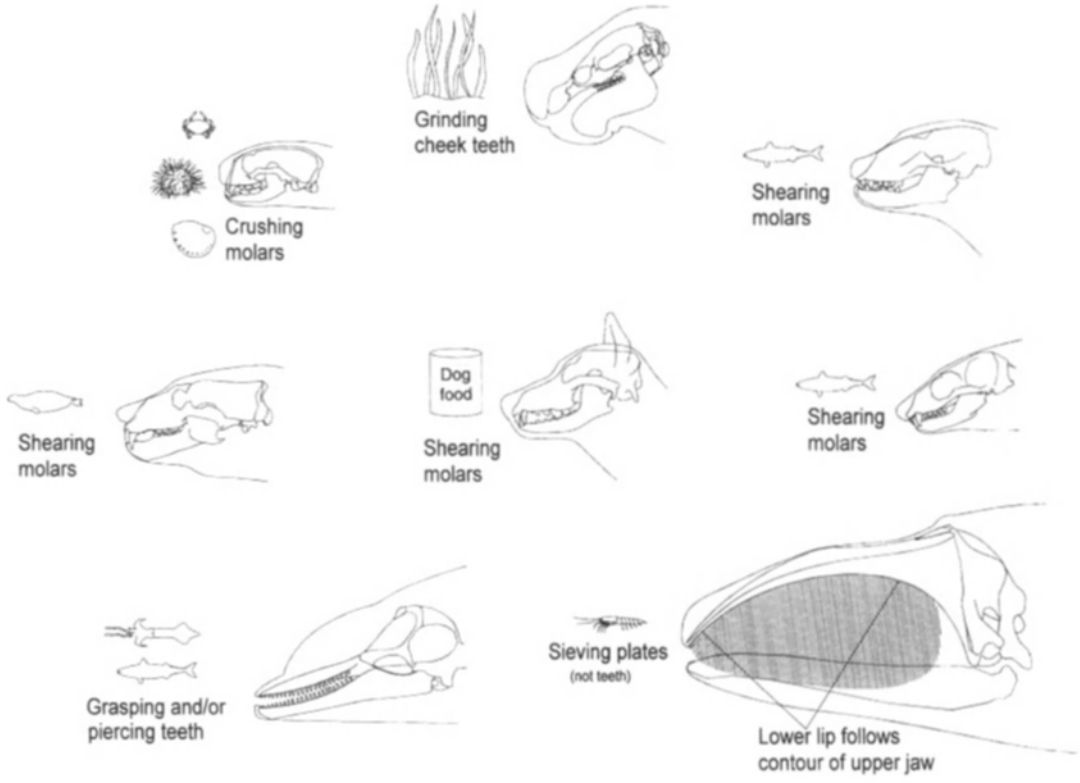

Figure 3 *Feeding apparatus and typical food. Dominant tooth type is also given. Note that the embryonic teeth of the right whale have been replaced with horny plates of baleen in the upper jaw only. Copyright S. A. Rommel.*

Heterodonty is tooth shape differences in different parts of the mouth: incisors and canines rostrally and premolars and molars caudally. Although each of these tooth types may vary in shape, the definitions are specific and are related to tooth position in the bones of the *upper* jaw (Hildebrand, 1995). Incisors are found only in the incisive or premaxillary bone; canines are found in the maxilla, in or very near the suture with the premaxilla; premolars are deciduous cheek teeth (erupting from the maxillary bones) that are found rostral to the molars; and molars are nondeciduous cheek teeth. Typically, deciduous teeth are replaced vertically as they are pushed out by the developing permanent teeth deep to them. Each tooth shape may perform a distinct function, sort of a "Swiss Army mouth" (G. Early, personal communication). Incisors, if chisel like, are for slicing and chipping and, if pointed, for piercing. Long, pointed canines are good for capturing and piercing. Relatively blunt cheek teeth are good for crushing and grinding. Manatees, unlike all other marine mammals (including the dugong, *Dugong dugon*), have continuous, horizontal tooth replacement of their molars (Domning and Hayek, 1984).

In some species, all of the teeth have the same shape—this is the homodont condition. The homodont dentitions of odontocetes and manatees differ in shape and function (they are grasping teeth for dolphins and grinding teeth for manatees).

Baleen whales lose their embryonic teeth and acquire food by sieving PLANKTON, small fish, and (in the case of gray whales, *Eschrichtius robustus*) benthic invertebrates using plates of horny (keratinized) BALEEN suspended from their upper jaws (Pivorunas 1979).

The lower jaw generally mirrors some of the features of the upper jaw, particularly dentition. Articulation of the mandible with the cranium (the temporomandibular joint or TMJ) also reflects feeding style. The lower jaws of the rorquals must support the large, pleated gular sac that fills with water and prey during lunge feeding (Lambertsen, 1983), whereas those of the skimmers, such as the right whales (*Eubalaena* spp.), support massive lower lips that guide an almost continuous stream of water past long baleen plates. Gray whales, which are bottom feeders, have relatively robust lower jaws. In addition to supporting their fish-grasping teeth, the lower jaws of odontocetes are fat filled and perform the acoustic function of receiving and guiding sound energy to the earbones (Norris and Harvey, 1974). The lower jaws of the herbivorous manatees (*Trichechus* spp.) support grinding cheek teeth. The mandible of the manatee also has large mental foramina to transmit the large nerves associated with the vibrissae (see later).

Feeding style may also be reflected in the shape of the rostrum, the zygomatic arch, and the temporal fossa. Relatively

large temporal muscles and their fossae are typical of carnivorous mammals that tear or shear flesh without finely dividing that prey in the mouth and/or have teeth for killing and temporarily holding prey (Hildebrand, 1995). Carnivorous mammals have upper and lower tooth rows that do not slide horizontally but rather occlude with a chopping motion, using a hinge joint that is roughly in line with the tooth row (Fig. 3). In contrast, the TMJ in herbivores is typically above the tooth line (Fig. 3). Relatively large masseters and the robust zygomatic arches that support them are more typical of herbivorous mammals that use a crushing and rolling action to chew. This feeding style requires a TMJ that can slide and a large masseter to apply force along the extent of the cheek tooth row. TMJs of the mysticetes accommodate complex axial rotations of the individual dentary bones and absorb shock in lunge feeding of rorquals (Lambertsen, 1983), whereas the two dentaries of the odontocetes tend to fuse with age into a single compound bone.

Feeding includes swallowing. How do the bones of the head accommodate swallowing? Hyoid bones provide the mechanical support of many of the muscles that act upon the tongue and the larynx. Swallowing requires the coordinated action of these muscles as food leaves the oral cavity and moves through the pharynx. The dorsal hyoid bones (epihyoids) are attached by the stylohyoid cartilage to the base of the skull at a position immediately caudal to the tympanic bones (Fig. 4A). They provide the primary hinge to depress and move the tongue caudad. The ventral hyoid bones (basihyoids) form a secondary hinge that allows sternohyoid (sternum to hyoid) and mylohyoid (mandible to hyoid) muscles to move the basihyoid bones forward and back (Fig. 4B). In suction feeders, such as the squid-eating beaked whales and pilot whales (*Globicephala* spp.), the hyoid apparatus and its associated muscles are massive.

The soft and hard palates that separate the respiratory system from the digestive system are almost unique to mammals and allow extended chewing time or suckling while breathing. The fleshy soft palate extends the bony margin of the nasal cavity (Fig. 5) and makes a very important contribution to the evolutionary forces that shaped mammal skulls. Prolonged chewing, while breathing, means there is additional time for food processing in the mouth. Teeth of mammals are more indicative of food type than is the case for most other vertebrates. The specificity of dentition and the hardness of teeth, which increase preservation in the fossil record, contribute significantly to our current understanding of the ecology and evolution of extinct species.

III. Bony Features vs Bones

One approach to studying the skull is to focus on bony features (Fig. 6). Bony features are morphological characters or landmarks of the skull that are formed by one or more bony elements (individual elements or bones may develop from one or more ossification centers). Bony features reflect evolutionary,

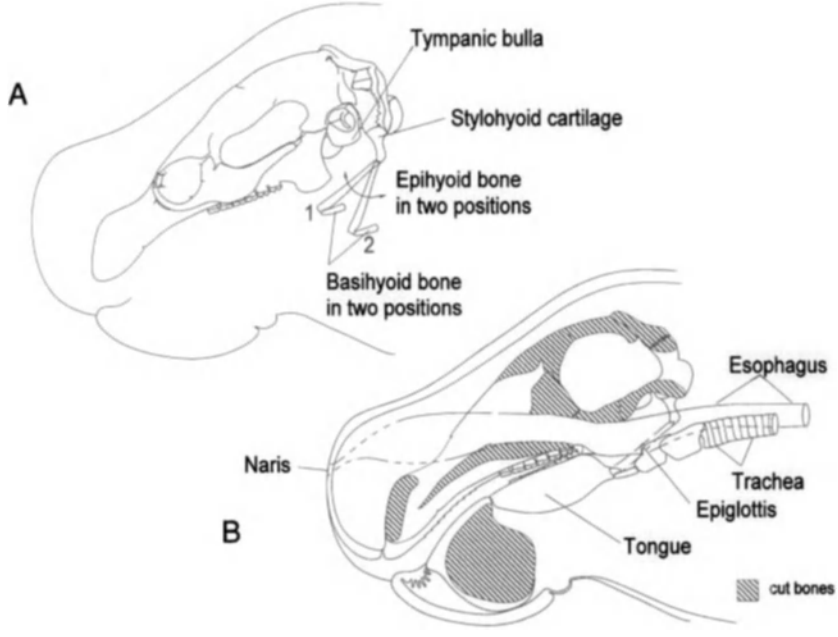

Figure 4 *(A) Lateral view of the manatee cranium with the hyoid apparatus in two positions to illustrate its range of motions. Muscles between the basihyoid and the sternum move the hyoid apparatus down and back. Muscles between the tongue and basihyoid move the hyoid apparatus up and forward. (B) Left midsaggital section of the manatee head. Movements of the hyoid apparatus influence the trajectories of air and food through the head and into the trachea and esophagus, respectively. Copyright S. A. Rommel.*

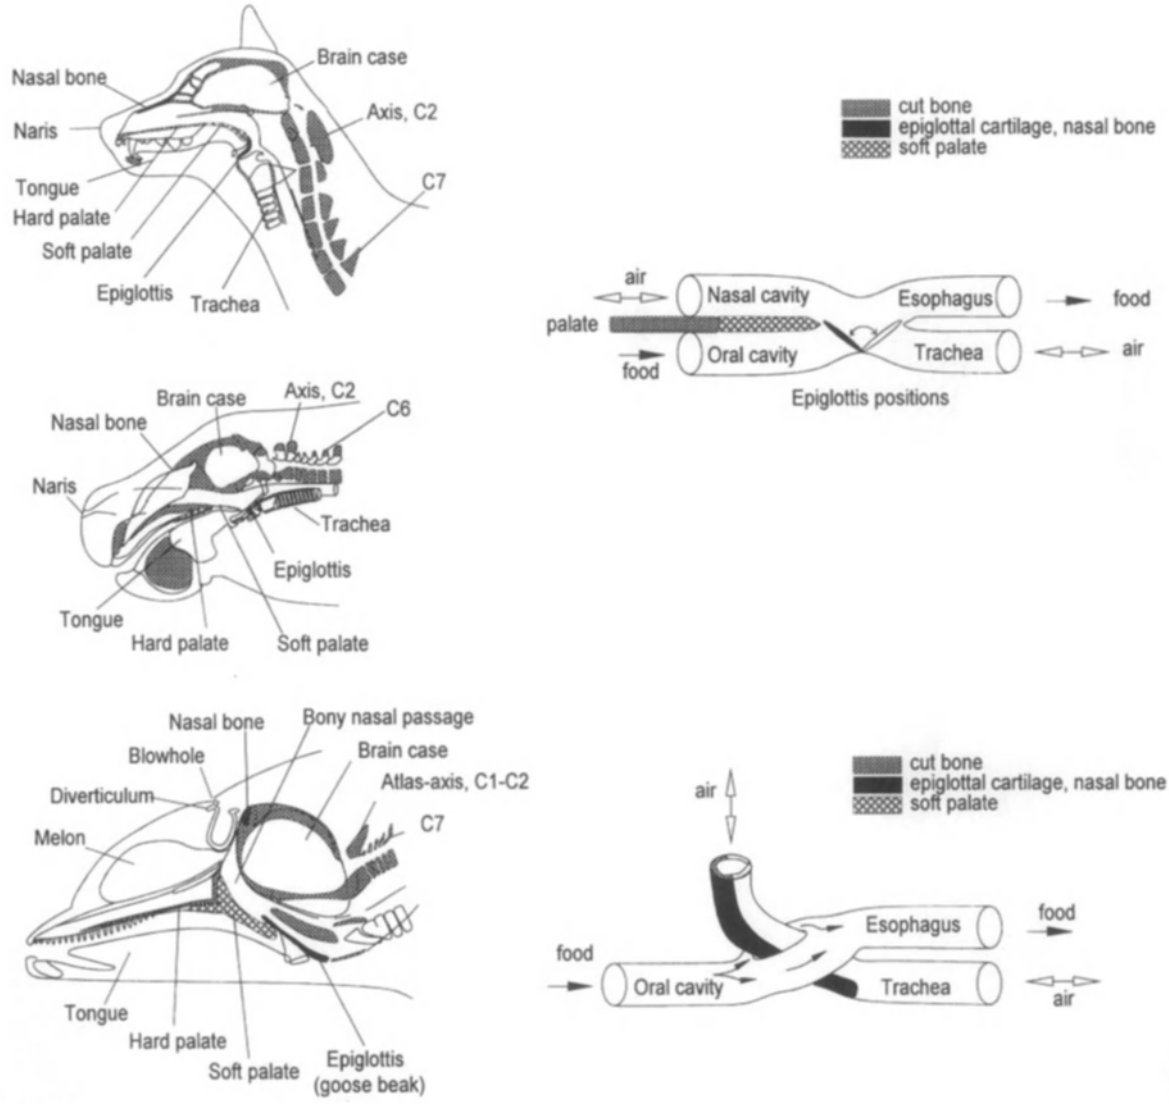

Figure 5 *Comparisons of the morphological adaptations of the mammalian head that allow respiration while food is in the mouth. Separation of oral and nasal cavities accommodates prolonged chewing and allows teeth to be modified accordingly. The dog and manatee (upper two on the left) are represented schematically in the upper right. In the dolphin (lower left and right), further modification is shown to accommodate the migration of the respiratory opening to the top of the head. Copyright S. A. Rommel.*

developmental, and mechanical pressures in a grossly visible manner. In contrast to bony elements or skull bones, bony features are structures that incorporate one or more parts of individual bones. For example, the zygomatic arch, which supports the masseter muscle and helps close the jaws, may be composed of one, two, or three bones. The rostrum or muzzle may be elongate and may include the nasal bones. Thus, to characterize individual skulls without having to identify individual bones, biologists can use the morphology of bony features such as zygomatic arch shape and composition; rostrum length; orbit size, shape, and position; and jaw articulation.

Take, for example, the small zygomatic arch of the right whale and the relatively delicate one of the dolphin. In these species the masseter muscles are relatively small and the temporal muscles are relatively massive. Compare these zygomatic arches with the massive ones in the manatee and polar bear.

In general, large, forward-facing orbits are characteristic of predators that rely on vision as their primary sensory modality, whereas laterally facing orbits are more typical of nonpredatory species. Also note how the orbits of most species in Fig. 6 are open caudally, in contrast to those of the fully aquatic mammals. In species in which the orbit is open, there is a postorbital ligament caudal to the eye that extends between the postorbital process of the frontal bone and zygomatic arch; these postorbital processes, most evident in the polar bear, serve as sites for muscle attachment.

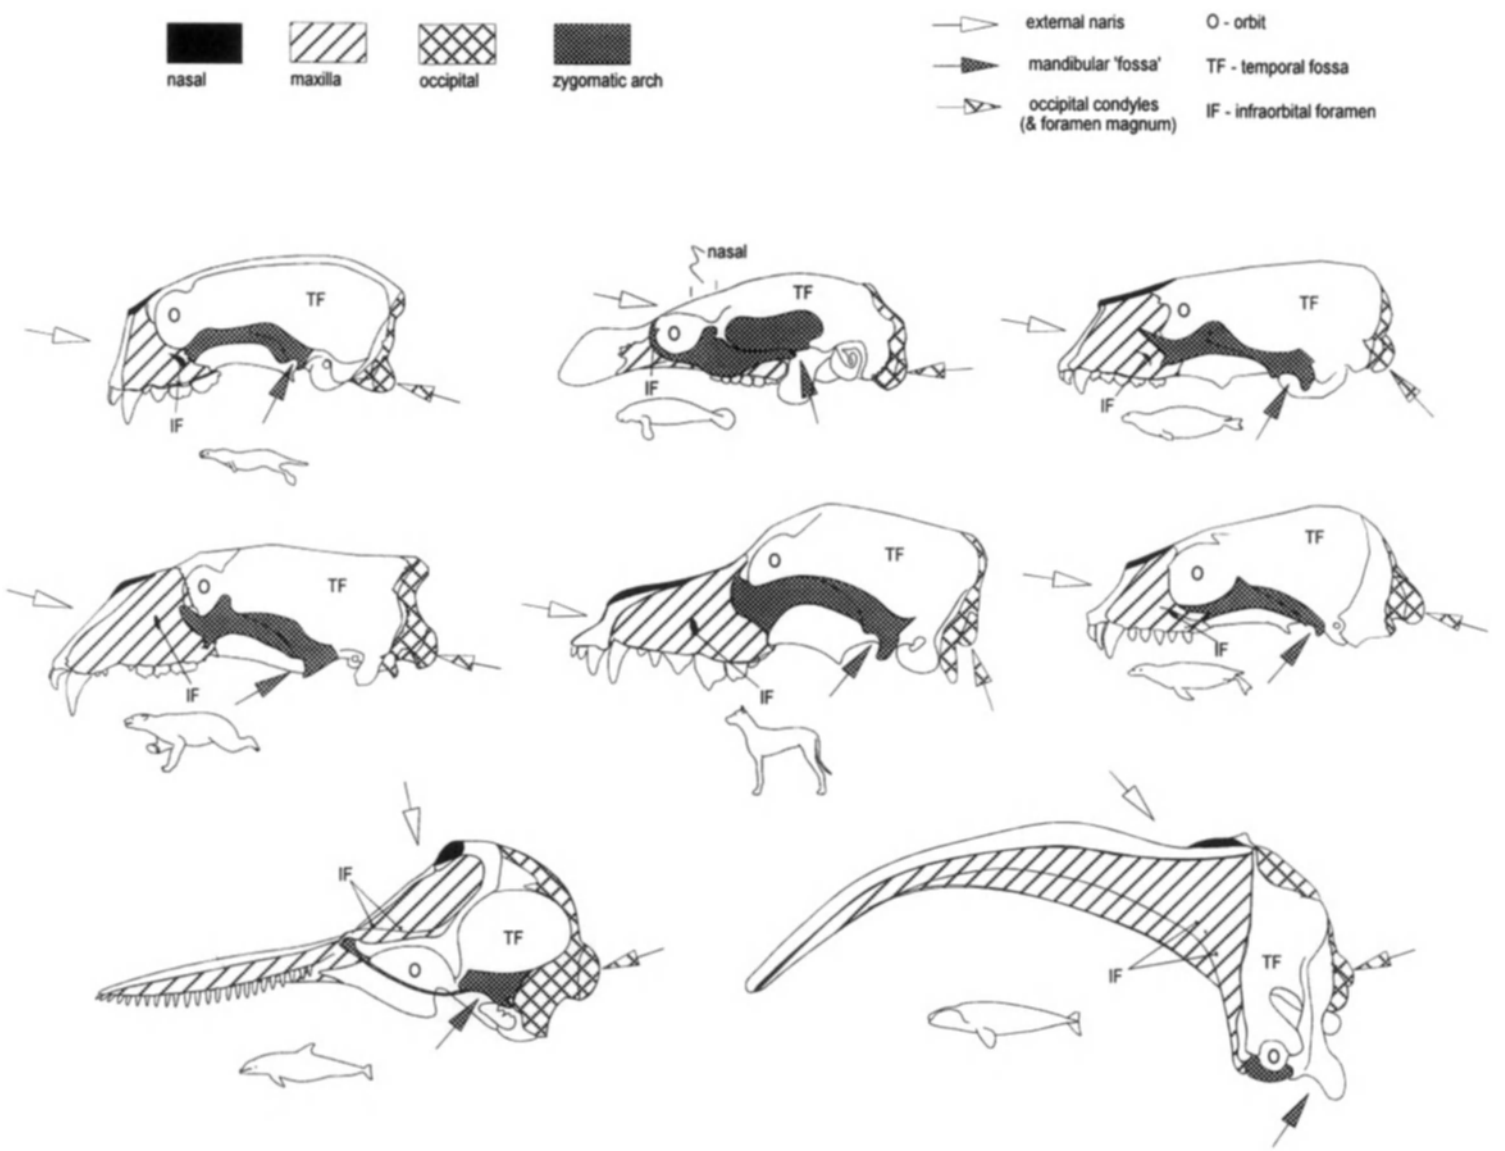

Figure 6 *Selected bony features are emphasized. The rostrum, composed of the premaxilla, maxilla, and occasionally the nasal bone, forms the "face" of each species. The zygomatic arch, which supports the masseter muscle, may be composed of a single bone, the jugal, or parts of as many as three bones in some species. Arrows indicate directions of air flow at the external naris, vertebral column articulation at the occipital condyle, and lower jaw articulation at the mandibular fossa. Processes extending from the frontal may be present to help form the dorsocaudal aspect of the orbit, referred to as postorbital processes of the frontal: absent in the seal, small in the otter, and relatively large in the dolphin. Copyright S. A. Rommel.*

The positions (on the top of the skull) of the external nares may reflect respiratory adaptations to diving, feeding, and locomotion. Note the positions of the external nares in fully aquatic species. The internal nares or passageways for air through the cranium are bordered by the nasal bones in all species.

The occipital condyles position the head on the neck and influence the flexibility at the terminal end of the neck (Figs. 2 and 6). Some of the species with short necks have two or more fusions of cervical vertebral (Flower, 1885; Slijper, 1979; Rommel, 1990), placing the base of the skull very near the shoulder joint and the thoracic cavity. Species with long necks may have a wide range of neutral head positions and may also have a greater range of movement than fully aquatic species (King, 1983).

IV. Ground Plan of Skull Bones

What other factors shape the skull? In all vertebrates, the skull bones develop from ossification centers in a basic pattern that partially or completely encloses the brain plus the sensory organs of olfaction, vision, HEARING, and balance (Fig. 7). Bones that are preformed in cartilage are referred to as endochondral or replacement bones; those deposited directly as bone within tough connective tissue membranes are referred to as dermal or membrane bones. The distinction between endochondral and dermal bones is valuable in establishing homologies with skull bones of the lower vertebrates.

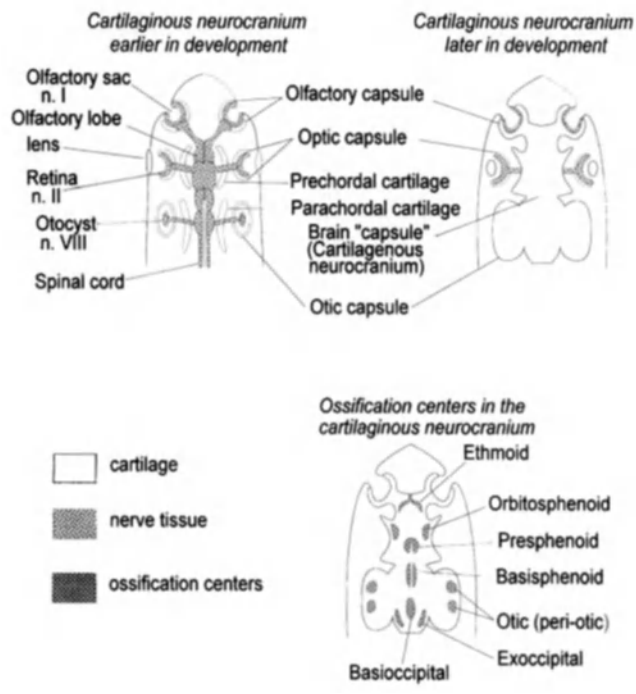

Figure 7 *Schematic illustration of ventral views of the developing vertebrate skull (modified after Kent and Miller, 1997). The basic plan of encapsulation of the senses and brain is illustrated in the top two drawings. The lower drawing illustrates the ossification centers that will eventually become the replacement bones of the cranium. Copyright S. A. Rommel.*

How does one determine which elements of the skull, i.e., which of the 40-some bony elements, are homologous between species? A systematic approach that allows one to compare homologous elements (Fig. 8) is a particularly useful way to avoid the "mental indigestion" (Romer and Parsons, 1977) of having to memorize all the individual bones.

In some species, individual bones fuse (ankylose) to form compound bones;[1] these include the occipital, temporal, and sphenoid "bones." Of particular interest is the temporal "bone," which is a compound bone made up of many separate bony elements and/or ossification centers (see Kent and Miller, 1997). In many mammals, the bulk of the temporal is a single unit with no visible sutures between the bony elements once skeletal maturity is reached. Thus, it is common to refer to the temporal as a bone, but this is not the case in several of the marine mammals, particularly cetaceans and sirenians.

The exploded diagram of the cranium of the Florida manatee illustrates the overlapping and/or abutting margins that make up the skull sutures (Fig. 9). Note that the ear bone complex—made up of the periotic and tympanic bones plus the middle ear ossicles (only the malleus is visible in this figure)—is illustrated as a single unit. Another compound bone is the occipital, which in some species is composed of the basioccipital, exoccipitals, supraoccipital, and inter(post) parietal (Jollie, 1973; Kellogg, 1928).

Figure 10 is a left lateral view of the individual cranial bones for our representative marine mammals. Contrast this illustration with Fig. 6 to reinforce the distinction between bones and bony features; see Fig. 2 to compare skull size to total body size. The abbreviations are the same as in the schematic generic cranium (Fig. 8) and the exploded manatee cranium (Fig. 9). Pick any one bone and compare it with the homologous structures in all of the crania.

V. Sutures

The regions between adjacent bones are referred to as sutures. In the exploded illustration of the manatee skull (Fig. 9), the hatched regions represent sutures or regions of overlap; skull bones can meet in several ways and attach by more than one type of material (e.g., cartilage and connective tissue).

In Fig. 11, the sutures of the dog skull are compared with those of the manatee skull. Note that different types of sutures may be found between the same bones in different species. The type of suture generally reflects the mechanical forces necessary to accommodate whatever biological constraints are

[1]We have used three different terms incorporating the word "bone." Bones or bony elements are discrete ossifications that can be traced phylogenetically. Compound bones are structures that appear to be single units in adults because the sutures between the component bones have been resorbed or are not apparent. Bony features are gross features, such as the zygomatic arch, that are made up of discrete and distinct bones or parts of bones (e.g., the zygomatic process of the squamosal bone).

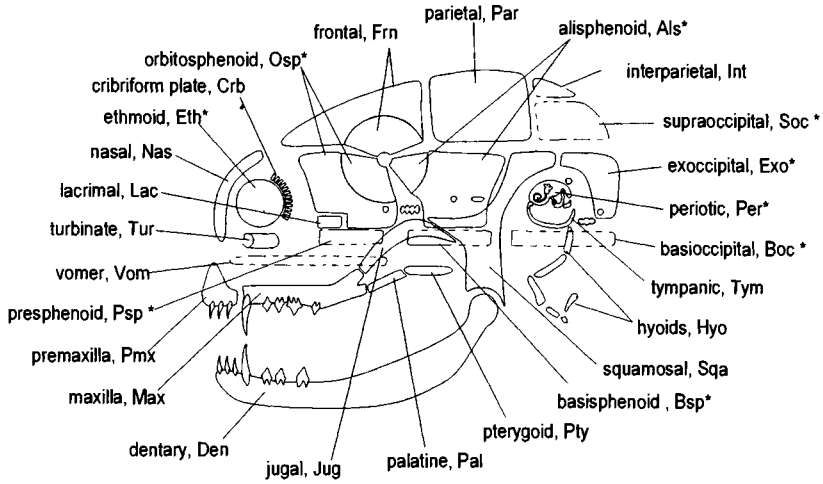

Figure 8 *Left lateral schematic of the mammalian skull illustrating relative bone positions. Most skull bones are bilaterally paired—the unpaired skull bones are positioned along the midline and are dotted in this illustration. This schematic approach has been used for more than 100 years and provides a framework in which to compare a wide variety of mammalian skulls (modified after Flower, 1885; Kent and Miller, 1997; Evans, 1993). Recall that the nose, eyes, and ears are encapsulated early in development; these three sensory areas are represented by circular regions in the schematic. Endochondral bones (first laid down as cartilage) are marked with an asterisk. Copyright S. A. Rommel.*

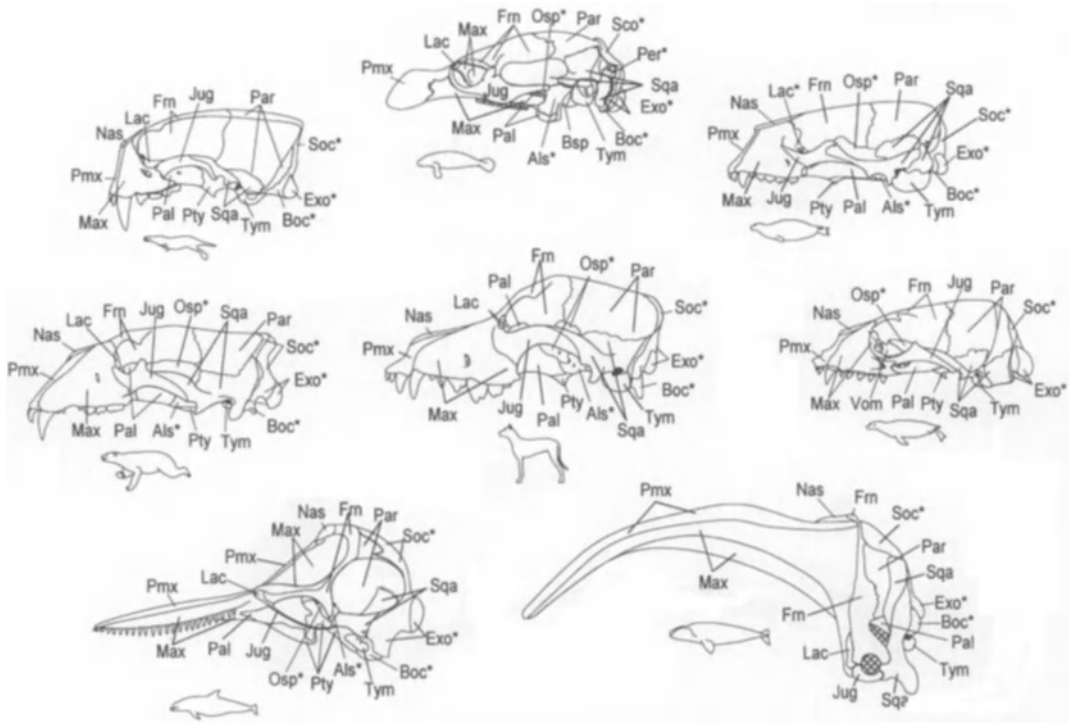

Figure 10 *Left lateral illustrations of individual cranial bones of selected marine mammals and the dog. Abbreviations are the same as in Fig. 8. Use Fig. 8 to help visualize how each species has modified the basic plan of mammalian skull morphology. Copyright S. A. Rommel.*

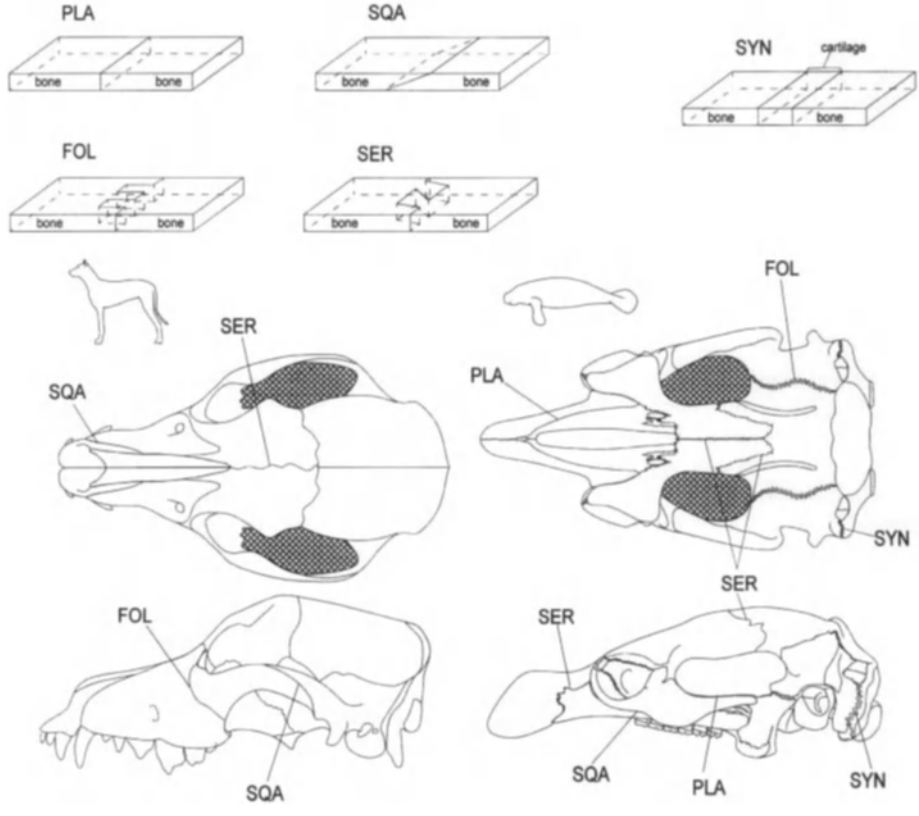

Figure 11 *Suture types in the dog and manatee. Definitions are from a variety of sources, and names in parentheses are from Schaller (1992). Suture types are defined by their shape. PLA, plane or butt joint (harmonious, sutura plana); an approximately straight suture with nearly squared-off margins. SQA, squamous or scarf joint (sutura squamosa); a suture with tapered overlapping margins. FOL, foliate joint (sutura foliata); a regular suture in which adjoining bones interleave. SER, serrate joint (sutura serrata); an irregular suture in which adjoining bones interlock. SYN, synchondrosis; a joint that has persistent cartilage between bones (synchondroses cranii). Copyright S. A. Rommel.*

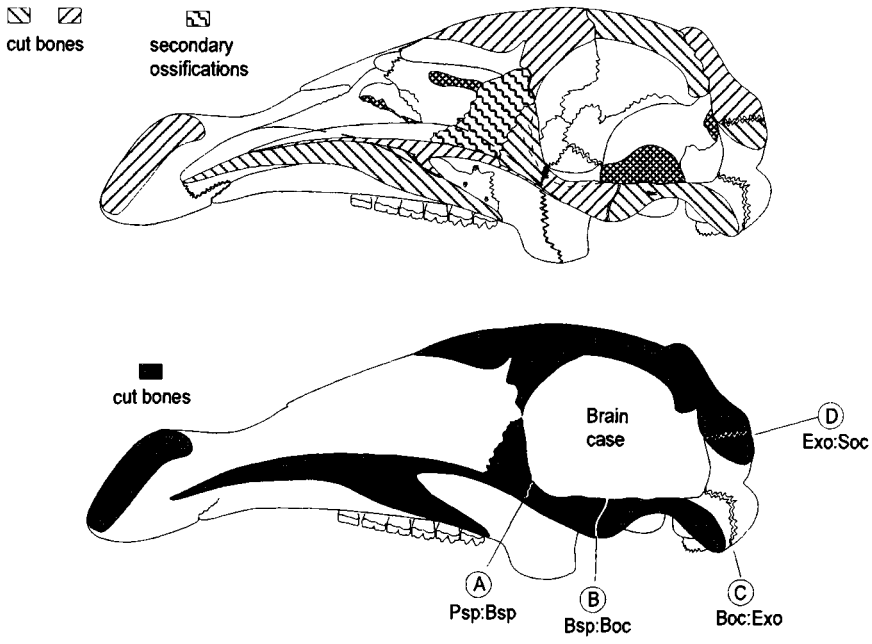

Figure 12 *Sagittally sectioned crania of the manatee. The upper illustration shows the number and complexity of individual bones. The lower drawing is simplified to illustrate four sutures that give some indication of relative age in the manatee. (A) Between the presphenoid bone and the basisphenoid bone. (B) Between the basisphenoid bone and basioccipital bone. Sutures labeled A and B are the first to close and may reflect growth of the braincase. (C) Between the basioccipital bone and the two exoccipital bones (bilaterally paired sutures). (D) Between the two exoccipital bones and the supraoccipital bone. Sutures labeled C and D ankylose later in life and probably reflect changes in the mechanics of head and neck morphology as the animal matures. Copyright S. A. Rommel.*

imposed upon the bones—these constraints include muscle attachments, size and shape of nerves and sensory capsules; and mechanical attachments for feeding, display, locomotion, and social interaction. Interlocking joints can absorb energy. Movable joints eliminate shearing forces. Butt joints can support little shear but are strong in compression. Squamosal or scarf joints allow more surface contact between adjacent bones and are stronger than simple butt joints. Some configurations affect the complexity of joints, and this complexity, in turn, affects the action and strength of the joints.

Relative aging in cetaceans was pioneered by Perrin (1975). He established principles that allow one to use changes in the skeleton that occur during an animal's life to estimate the age of a specimen by comparing it to others. The sutures of a skull can be used for relative aging in some species, e.g., the sutures that allow brain growth ankylose after the brain stops growing. In the manatee, five skull sutures (two associated with the occipital are bilaterally paired) are used to estimate relative age (Fig. 12). The first two (A and B) appear to reflect the changes in brain size and ankylose within the first few years. The three associated with the occipital bone appear to be more related to musculoskeletal changes that occur during juvenile and adult life.

Development of the skull bones proceeds at a pace different from the development of the soft tissues of the head. Bone is constantly being remodeled and thus it can indicate aspects of the evolutionary forces that work to separate species. This plasticity is reflected in the way individual skull bones form around vessels and nerves. The resulting openings, or foramina (singular, foramen), are often phylogenetically conserved and so can be used to establish homologies of the same bones in very different species. An individual nerve or vessel may be completely surrounded by a bone or bones of the skull, resulting in a specific foramen. Because this process occurs early in the development of the individual and appears to have the same essentials in all vertebrates, we use these cranial nerve foramina to help identify the cranial bones (Fig. 13).

VI. Telescoping

Telescoping is a process often cited describing the skulls of cetaceans. The term, coined by Miller (1923), refers to the elongation of the rostral elements and the dorsorostral movement of caudal elements (Kellogg, 1928; Miller, 1923; Rommel, 1990). The relative movement of skull bones in cetaceans

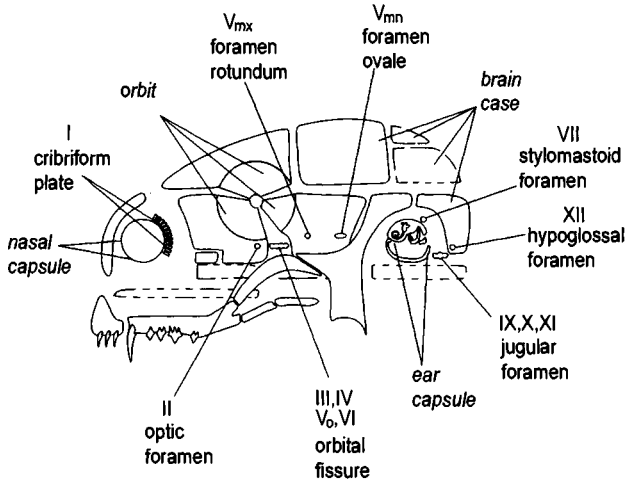

Figure 13 *Openings, or foramina, of the skull. Foramina can be used to establish homologies of the same bones in different species; each foramen (or foramina) associated with 1 or more of the 12 cranial nerves (labeled I through XII) has a name that is used (fairly) consistently by vertebrate morphologists. Thus the cribriform plate, found at the anterior margin of the braincase, is associated with the olfactory nerves (this will be referred to parenthetically as I—olfactory n.) in all of the species that have a sense of smell [even odontocetes, which do not have olfactory nerves as adults, have these perforations (Rommel, 1990)]. The second cranial nerve, associated with the optic nerve, passes through the optic foramen and usually perforates the orbitosphenoid bone (II—optic n.). The orbital fissure is usually at the orbitosphenoid bone–alisphenoid bone suture (also anterior lacerate foramen; III—oculomotor n., IV—trochlear n., V_0—ophthalmic branch of trigeminal n., VI—abducens n.). The foramen rotundum (V_{mx}—maxillary branch of the trigeminal n.) and the foramen ovale (V_{mn}—mandibular branch of the trigeminal n.) perforate the alisphenoid bone. The stylomastoid foramen is located at the tympanic bone–basioccipital bone suture (VII—facial n.). (Nerve VIII—vestibulocochlear n. is not shown; it perforates the periotic bone through its internal auditory meatus.) The jugular foramen (also posterior lacerate foramen) is at the exoccipital bone–basioccipital bone suture (IX—glossopharyngeal n., X—vagus n., XI—accessory n.). The hypoglossal foramen usually perforates the exoccipital (XII—hypoglossal n.). An additional cranial nerve (O—terminal n.) was discovered after the numbering system was developed. This nerve is found rostral to the olfactory nerve of the species illustrated; it has been described only in odontocetes and is not illustrated here. Copyright S. A. Rommel.*

creates sutures with considerable overlap of adjacent bones. If the skull were sectioned, one could observe as many as four different bones overlapping each other; this overlap resembles old-fashioned collapsible telescopes. In dolphins, the external nares have been displaced to the dorsal apex of the skull so the nasal bones are located just caudal to the external nares but dorsal to the braincase. The premaxillary and maxillary bones have been extended at the rostral tip and also pulled up and back over the frontal bones to maintain their relative positions with the nasal bones. The narial passages are essentially vertical in cetaceans, which eliminates the nasal bones as roofing bones of the nasal passages. The nasal bones are, instead, relatively small vestiges that lie in depressions of the frontal bones; the roof of the cetacean mouth is not the floor of the nasal passages as it is in most other mammals. Telescoping is different in odontocete and mysticete cetaceans (Fig. 14). Changes in the mysticetes are dominated by a ventrocaudal extension of the maxillary bones, whereas in the odontocetes, the premaxillary and maxillary bones are shifted more dorsocaudally (Kellogg, 1928). Interestingly, whereas the odontocete facial muscles have moved up and back over the eye, the temporal muscles of the mysticetes have moved up and forward over the eye. Thus, the temporal fossae of mysticetes are very different from those of odontocetes. Contrast the morphological differences associated with telescoping in cetaceans (Fig. 14) with the homologous structures illustrated in Fig. 6.

Additionally, the remodeling associated with telescoping is reflected in the number and positions of the cranial nerve foramina in the maxilla. Consider the nerves that are associated with the muscles of the face: the (sensory) trigeminal nerve (V) and the (motor) facial nerve (VII). The right and left facial nerves control such muscle activity as facial expression in the dog, feeding in the manatee, and focusing of sonar pulses in the dolphin. The trigeminal nerves signal the brain to coordinate the muscular activities in the same region. The relatively large sizes of these two nerves in the dolphin and manatee reflect the importance of these neuromuscular actions. The nerve diameters are reflected by the size of the foramina (the infraorbital foramina) through which the trigeminal nerve pierces the maxilla (Fig. 15). As the bones and muscles of the face are reshaped to accommodate the evolution of a melon and its need for complex mechanical manipulation, the sensory and motor nerves are moved up and over the orbit. The homologous (and thus same-named) opening, which is *infra*orbital in most species, is now actually above (or *supra*orbital) the orbit in cetaceans!

VII. Additional Influence of Central Nervous System Morphology on the Skull

The shape and dimensions of the central nervous system strongly influence skull morphology. Consider the shape of the brain (Fig. 16) and how it might influence the shape of the braincase (region enclosing the brain). Note the arrangement and sizes of the cranial nerves and envision how the skull foramina would reflect these and their accompanying vessels. In some species, additional vascular adaptations for diving have influenced the development of foramina to excessive proportions (e.g., the *foramen magnum* is a relatively close fit to the spinal cord; but enlarged arteries and veins surrounding the central nervous system in cetaceans, phocids, and manatees have necessitated enlargement of the openings).

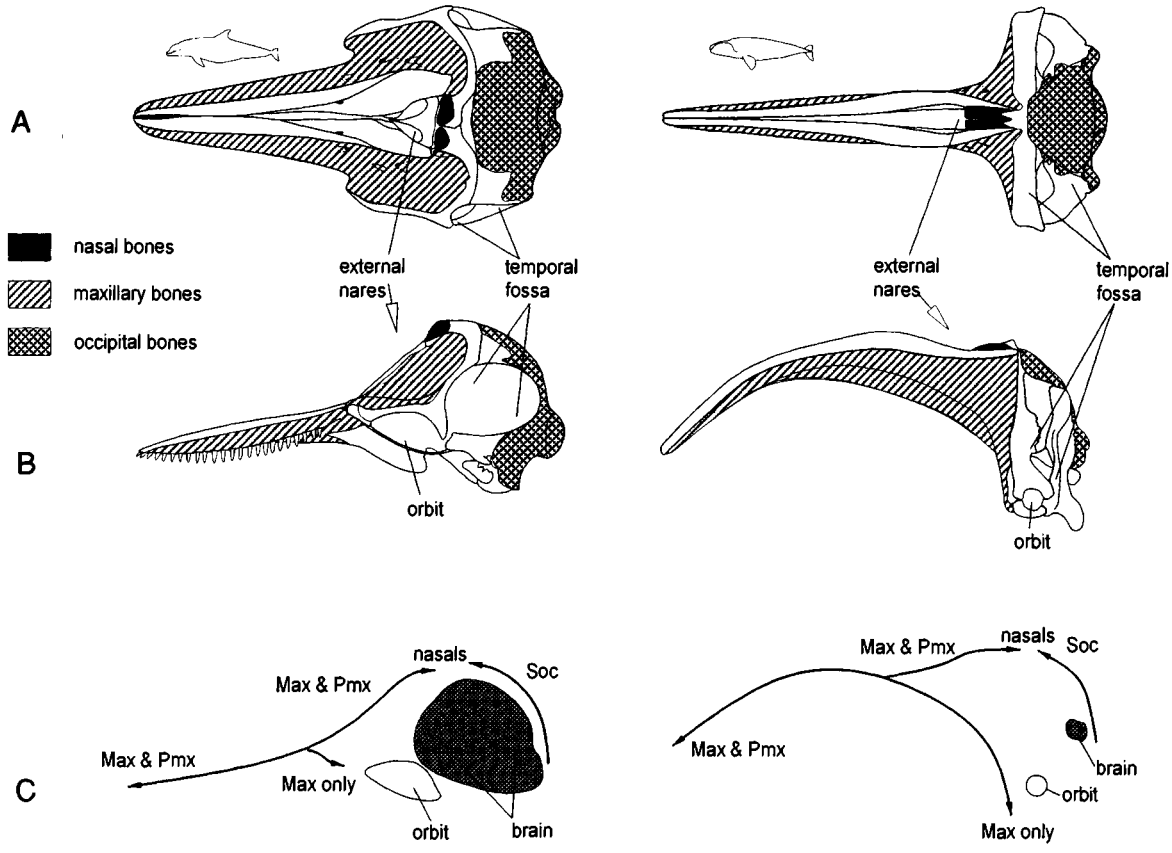

Figure 14 *Dorsal (A) and lateral (B) views illustrating telescoping in odontocetes (left, e.g.,* Tursiops*) and mysticetes (right, e.g.,* Eubalaena*). Telescoping refers to the elongation of the rostral elements [both fore and aft in the case of the premaxillary and maxillary bones (Pmx and Max), the vomer, and mesorostral cartilage], the dorsorostral movement of the caudal elements [particularly the supraoccipital bone (Soc)], and the overlapping of the margins of several bones. This overlap or sliding over each other of these elements resembles old-fashioned telescopes. One result of telescoping is the displacement of the external nares (and the associated nasal bones) toward the dorsal apex of the skull—up and over the rostral margin of the brain! Telescoping is actually quite different in odontocete and mysticete cetaceans; in most odontocetes the rostrum is dorsally concave, whereas in mysticetes the rostrum is ventrally concave. The temporal fossae of the mysticetes have moved up and forward over the eye; the temporal fossae in odontocetes are in a more typical mammalian position. Relatively more bone mass is moved up and over the orbit in odontocetes, whereas relatively more bone mass is moved down and under the orbit in mysticetes. In the lower schematic (C), arrows indicate the directions of relative movement as each skull is remodeled to accommodate the brain and the respiratory, feeding, and acoustic apparatus of the two types of cetaceans. Note that the odontocete brain makes up a larger percentage of the cranial volume than the brain of the mysticete; in C the brains are scaled to fit in the lateral views of the crania in B above them. Copyright S. A. Rommel.*

In conclusion, we can state that a glance at a skull tells a lot about an organism: how it senses its environment, how it feeds, how big its brain is, and so on. Instead of becoming bogged down in trying to memorize names, study a skull with an open mind (pun intended) about adaptations and function.

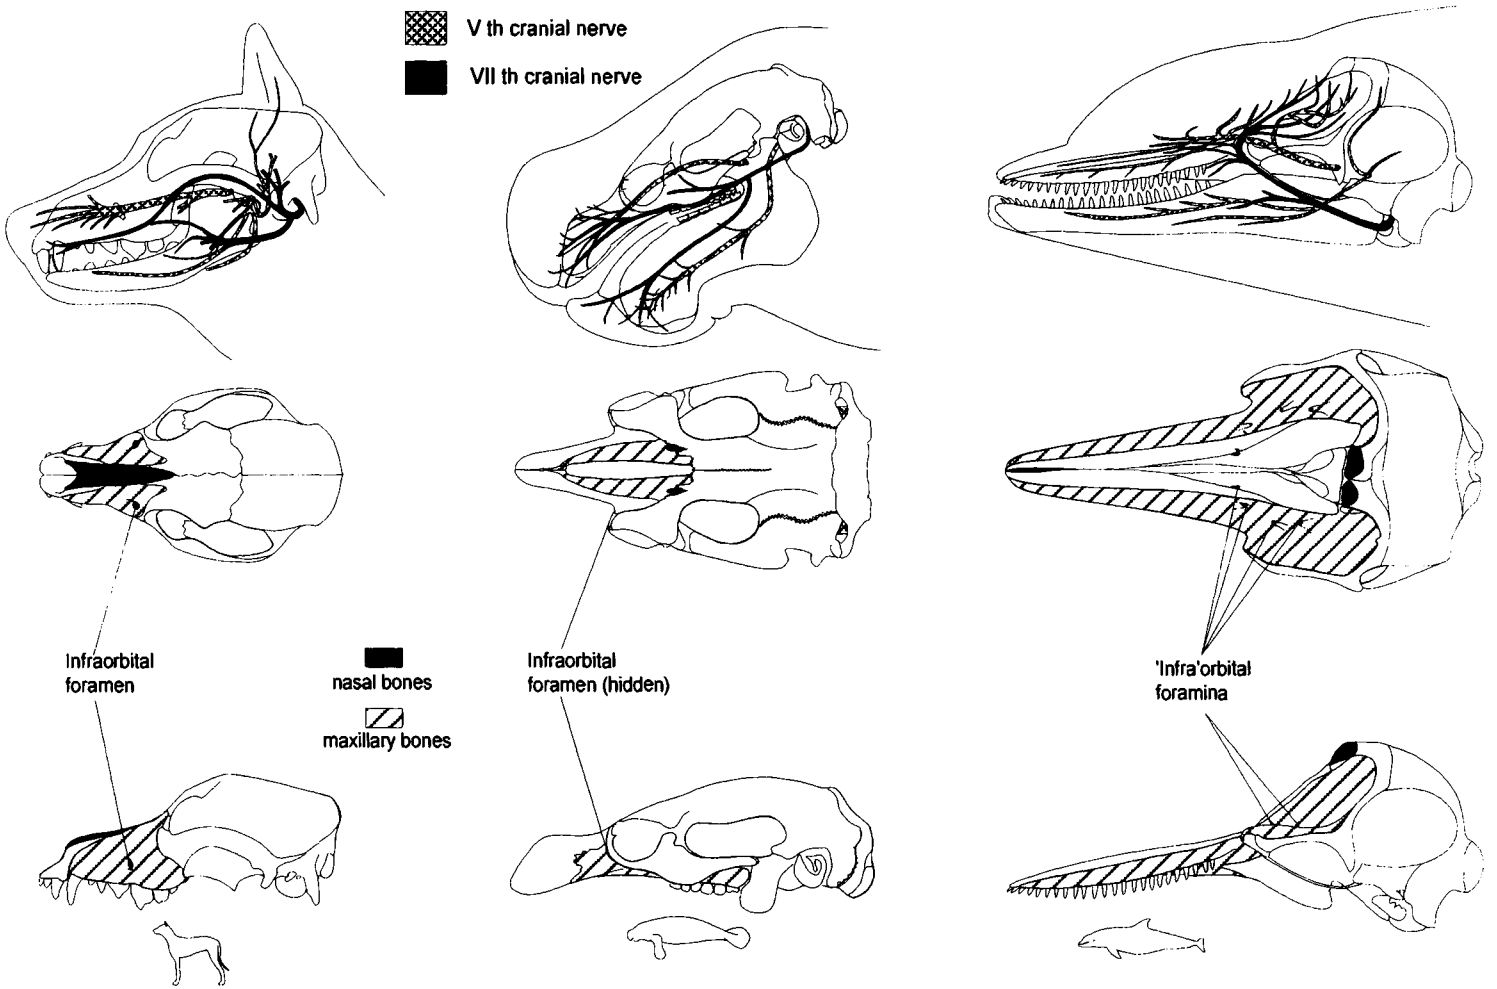

Figure 15 *Nerves associated with the facial muscles also reflect telescoping. These are the trigeminal, or Vth, cranial nerve (a sensory nerve) and the facial, or VIIth, cranial nerve (a motor nerve). Here the dog is compared with the manatee and the dolphin. The relatively large sizes of the Vth nerves are reflected in the relatively large foramina through the maxillae (infraorbital foramina); the larger the nerve, the more information it can carry. The process of telescoping has remodeled the bones of the rostrum, and included in this process are the reshaping of the muscles of the face and the nerves that enervate them. Also note that some odontocete cetaceans have notable bilateral asymmetry in the dorsal elements of the skull. Copyright S. A. Rommel.*

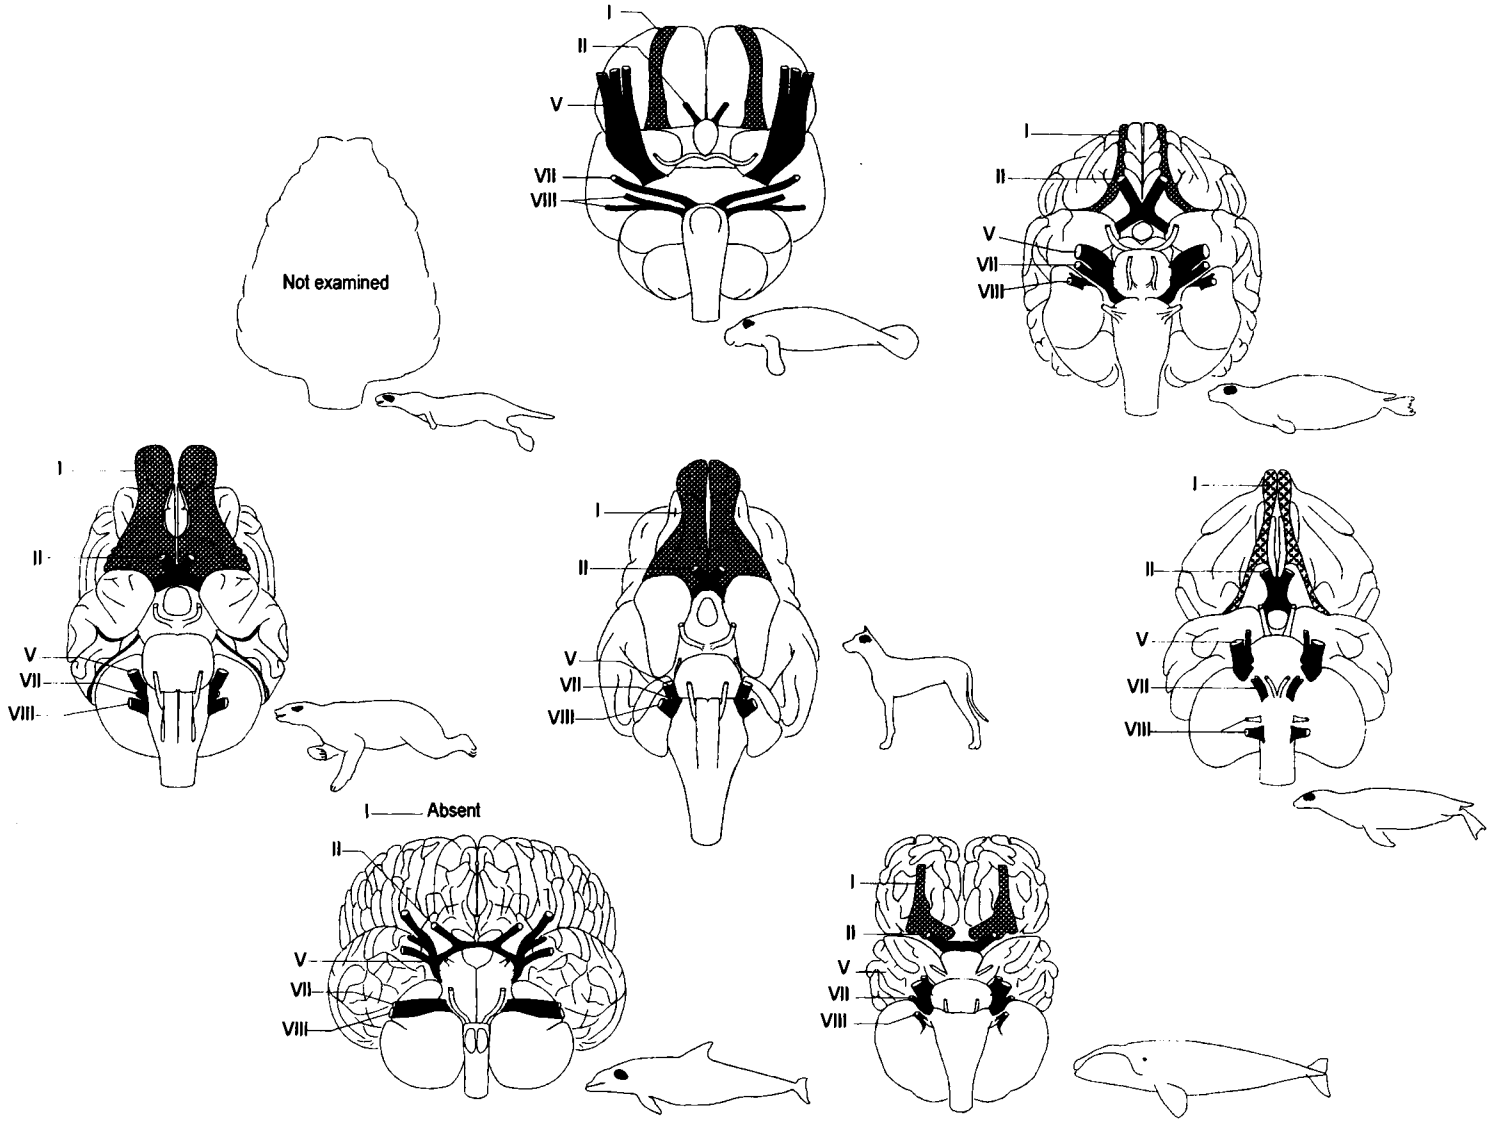

Figure 16 *Ventral views of selected marine mammal brains and of the dog brain. Inserts show lateral views of the brain positioned within the body to illustrate brain size relative to body size; note how relatively tiny the brain of the right whale is. Selected cranial nerves, indicated by Roman numerals, are labeled. Compare the trigeminal (V) and facial (VII) nerves illustrated in Fig. 15 to see the relative importance of the sensory and motor nerves from and to the facial muscles, respectively. Also note the relative sizes of the olfactory (I), optic (II), and acoustic (VIII) nerves; sizes reflect the relative importance of smell, vision, and hearing in the different species. Copyright S. Sociobiology

FRITZ TRILLMICH

University of Bielefeld, Germany

I. The Nature of Sociobiological Inquiry

Sociobiology is the study of social behavior and social evolution based on the theory of adaptation through selection. As such it is primarily concerned with the adaptiveness of social behavior and the selective processes producing and maintaining adaptiveness. Understanding the selective processes involved includes studying the ecology, physiology, and behavior, as well as the population genetics of the species in question. Sociobiological investigation increasingly attempts to characterize the genetic breeding system, as well as the population structure, both of which importantly influence the effectiveness of evolutionary processes in molding the characteristics of species.

The sociobiological approach assumes that selection at the individual level is the predominant force producing adaptation. A proper understanding of social phenomena, therefore, needs an understanding of the benefits and costs that the individual derives from its interaction with the social environment. Explicitly, group selection is relegated to a secondary position, as in most circumstances, selection operates more strongly at the individual than at the group level because fertility, dispersal, and mortality events are more frequent and act much more forceful on individuals than on groups. Explanation at the level of the individual of social phenomena such as group formation, parental care, and mating systems form the core of sociobiological inquiry.

As the majority of sociobiological inquiry in the field of marine mammals has been done on whales and pinnipeds, these two groups form the focus of the following sections. Relevant information on sea otters (*Enhydra lutris*) and manatees (*Trichechus* spp.) is mentioned briefly in Section IV.

II. Group Formation

The most obvious phenomenon of social life is group formation. Suitable feeding or breeding habitat may initially lead to an aggregation of individuals, thus setting the stage for selective processes moulding the evolution of elaborate social interactions. In contrast to aggregations, groups imply that individuals of a species come together to derive benefits from interactions that follow from this proximity. Such a grouping may serve social foraging, predator avoidance, or defense against predators. Groups may also be established for mating and to share parental care. These kinds of advantages constitute the selective processes that promote group formation in a wide variety of animals. Sociobiology tries to explain groupings from the advantages and disadvantages incurred by the individuals.

A. Whales

The open ocean habitat offers few options for hiding from predators. Consequently, predation by large sharks and killer whales (*Orcinus orca*), particularly on newborns, is one important factor selecting for group formation in whales and dolphins. Direct observational evidence for this hypothesis is scarce, but signs of scarring provide ample evidence of frequent encounters with predators. For example, about one-third of all humpback whale (*Megaptera novaeangliae*) calves carry tooth marks on their flukes when arriving in the foraging areas, presumably from encounters with killer whales or sharks during migration to the feeding grounds. The most spectacular groupings are found in open ocean species such as spotted dolphins (*Stenella* spp.), which benefit the most from the advantages of grouping as protection against predators, but these species may also benefit from group foraging, as may many others.

Several effects play a role in the protection offered an individual by a group. The "dilution effect" acts by reducing the chances of an individual to be attacked by a predator who has noticed the group (to 1/group size, if a predator takes only one individual out of the group). This effect thus dilutes the chances of an attack on a given individual dramatically. The "confusion effect," many individuals rushing back and forth through the visual field of an attacking predator, makes it more complicated for the predator to concentrate on one prey to catch. Finally, animals in the middle of a group can in effect use other individuals around them as shields against predatory attack, as there will always be other individuals geometrically closer to the predator attacking from the edge of a group. This is the so-called "geometry of the selfish herd," which allows an individual to use other group members as protection. These effects may also partly protect individuals in groups against PARASITES, such as the cookie-cutter shark, which takes little bites out of the side of its victim. The advantages of grouping using dilution, confusion, or cover against predation do not depend on individual recognition or social bonds among the animals joining such a group, but also function perfectly well in a totally anonymous group.

Eventually, the advantage of gaining protection in the group will be counteracted by increasing food competition among individuals in a large group, which will determine the upper size of groups. Because food competition depends on abundance, distribution, and behavior of food organisms, which are little known for whale prey, the importance of food competition is also largely unknown. However, signs of territorial behavior between killer whale groups provide at least some direct evidence for the role of food competition in limiting group size.

For more powerful animals such as killer and sperm whales (*Physeter macrocephalus*), grouping offers the additional option to defend smaller, more vulnerable individuals against predators by taking them into the middle of the group. This kind of group action has a completely different quality than the examples given earlier because it involves bonds among the individuals in the group, which are presumably well cemented by individual recognition. Individuals in these groups actively take some risk to defend others (mostly calves) against predators. This can be understood by the fact that the individuals involved in such cooperative behaviors are kin to each other or it may represent mutualistic cooperation. The evolution of such mutualism would be eased in kin groups through kin selection.

However, grouping can also be of advantage for a predator. Foraging groups have perhaps been best analyzed for killer whales. For the mammal-hunting so-called *transient* killer whales in British Columbia, groups of three individuals proved most efficient in terms of energy intake per unit time when hunting harbor seals (*Phoca vitulina*). Optimal efficiency of this group size results because a group of three cooperatively hunting whales seems to be better detecting and catching prey than single animals or duos. However, competition in such a small group is less than in larger group once it comes to sharing a harbor seal carcass. For more evasive prey such as Dall's porpoise (*Phocoenoides dalli*), larger groups may be more successful because more animals are better at intercepting fleeing prey.

Dusky dolphins (*Lagenorhynchus obscurus*) herd schools of fish cooperatively toward the surface and presumably thereby increase food intake. Such activities have also been observed in other dolphins that herded fish schools into bays or against fishing nets and thus may increase food intake for all individuals in the group.

Social systems in whales differ widely between mysticetes and odontocetes. Mysticetes often live solitarily and, except for the mother–calf association during the rearing period, show little evidence of long-term social bonds. This is most likely caused by the nature of their food resources and the fact that due to their body size they have largely escaped PREDATION. They may, however, aggregate during feeding in particularly productive areas and during the mating season (see later).

In contrast, almost all odontocetes are quite social. The social groupings of sperm whales, killer whales, pilot whales (*Globicephala* spp.), and bottlenose dolphins (*Tursiops* spp.) are best documented. In whales, groupings represent matrilines in which male offspring may (in killer and pilot whales) or may not (sperm whales) remain for life. In sperm whales, the grouping of kin serves protection of offspring. During foraging, these animals routinely dive to 400 m depth and stay at depth for 40–60 min. During this period, young would be unprotected, waiting at the surface. This can be and is avoided by adults in a group staggering their diving in such a way that one or more adults almost always attend the calves at the surface. Clearly, such behavior provides indirect fitness gains if the individuals in a group are relatives (such as mother, daughter, granddaughter). Kin selection effects may also explain the lack of dispersal of young in killer whales (in this case of both sexes). In resident, fish-eating groups, male offspring in a matrilineal group may offer protection to relatives as well as help in the defense of foraging areas. Females that stay with their mother may likewise gain fitness from cooperation with close relatives. The size of the group will be limited by food competition, and indeed large groups split up when they have grown too much into smaller units along matrilineal kinship lines. Limitation of group size by the potential for food competition is particularly evident, as the so-called *transient*, mammal-eating groups are much smaller (no more than three to five animals) than those of fish-eating *residents*, presumably because otherwise the disadvantage of food competition would offset the advantage of close cooperation with kin. Pilot whales show a similar social structure where male and female offspring stay with mothers. Advantages and disadvantages of this social structure are less understood for the pilot whale than for the other species mentioned previously.

Bottlenose dolphins and some other inshore odontocetes live in quite open fission–fusion societies in which females associate frequently with many different partners. These associations may be useful in foraging or vigilance and defense against predators, but this hypothesis seems less likely because females with calves tend to be less gregarious. Whether this is due to food competition is unclear. Females may also sometimes group to avoid harassement by males (see later). Male associations vary between study sites and seem to serve mating purposes.

B. Pinnipeds

As a group, pinnipeds are characterized by an amphibious lifestyle. They forage at sea but females need to return to a firm

substrate, land or ice, for parturition. A strong selective force during this period of birth and subsequent pup rearing is to avoid predation on mother and pup. In land-breeding pinnipeds, mostly otariids but also elephant seals (*Mirounga* spp.), monk seals (*Monachus* spp.), and the largest populations of gray seals (*Halichoerus grypus*), predator avoidance has led to the choice of oceanic islands for breeding. In comparison to the ocean used for foraging, these islands are limited in area, automatically leading to high densities of females on land. Otariid females come into estrus shortly after parturition, which sets the stage for sexual selection on males trying to station themselves in these female aggregations to breed (see later).

Primarily, the concentration of females on land has all the characteristics of an aggregation, but females of most land-breeding species stay closer together than necessitated by available habitat. One reason for such active groupings may be to avoid harassment by ardent males trying to mate with females. In addition, subadult males of some species of otariid abduct and herd pups, molesting them to the extent that they may die. In this dangerous situation, grouped pups profit from the dilution effect, which might select for tighter grouping of females.

Thermoregulation may also further grouping: Sea lions and the South African and Australian fur seal (*Arctocephaus pusillus*) tend to clump together as soon as they leave the water, which may serve to keep the body shell warm at minimal metabolic cost to the individual. This is not necessary for a fur seal with its highly insulating, air-trapping fur, and the function of clumping in the South African and Australian fur seal is therefore doubtful.

In contrast, ice-breeding seals tend to be much wider dispersed, be it on pack ice or fast ice. In these species, different factors select for some gregariousness. Most important for many species is predation: in the Arctic by polar bears (*Ursus maritimus*) and in the Antarctic by leopard seals (*Hydrurga leptonyx*) and killer whales. Some kind of a grouping advantage is perhaps operating that might equally benefit animals resting between foraging excursions and animals breeding on the ice. Indeed, harp seals (*Pagophilus groenlandicus*) are well known for breeding—even if dispersed—in well-defined local concentrations. It is not certain whether these concentrations are true social groupings or could also be induced by the characteristics of the ice in combination with the food resources below it, i.e., are aggregations due to resource distribution. It may actually be a combination of both. Weddell seals (*Leptonychotes weddellii*) group around tide cracks in fast ice, which offer holes for entry into the water where the seals forage under the ice. Because suitable holes are limited, this leads to a concentration of animals around entry holes and importantly influences the mating system.

Principally, pinnipeds are solitary foragers. There is little evidence for social foraging except occasional observations of sea lions herding fish into bays and communally preying on the trapped schools of fish. Aggregations of foraging sea lions and fur seals occur quite frequently near large fish schools where pinnipeds, birds, and whales may gather in so-called feeding frenzies. True cooperativity in these aggregations has not been demonstrated. This does not exclude that loose groups of pinnipeds may be more likely to locate food and through signs of foraging activity attract other animals to the site, an advantage frequently exploited by group-foraging birds.

III. Parental Investment Strategies

There is no convincing evidence of paternal investment in the rearing of young in any whale or pinniped. Lack of paternal care is typical for the majority of mammals and reflects that females alone provide for offspring during pregnancy and lactation, which frees males of parental duties. Only in a few whale societies, e.g., the killer whale matrilineal groups, do males act as helpers in defense and perhaps feeding of young. Maternal strategies in whales and pinnipeds are characterized by massive energetic investment in young through the production of large precocial young and extremely lipid-rich milk. However, parental investment is measured not by energy expenditure, but rather by a reduction in future fitness, a cost incurred by the mother through a loss in subsequent fertility or an increase in mortality due to a expenditure that benefits the offspring by increasing its fitness. Evidence of parental investment, so defined, is rare in whales and pinnipeds.

A. Whales

The patterning of parental effort differs widely between mysticetes whales and odontocetes. Mysticete females gather the material and energy for pregnancy (lasting about 1 year) and lactation during a feeding season of about half a year when food is plentiful and starve for the other half-year. Extraordinary fast fetal growth rates (in blue whales, *Balaenoptera musculus*, 27 mm/day) permit even the largest mysticete whale—with the exception of the bowhead (*Balaena mysticetus*), sei (*Balaenoptera borealis*), and gray (*Eschrichtius robustus*) whale—to produce a calf within 1 year. By migrating to warmer oceans in the nonfeeding period, mysticete whale females seem to minimize the metabolic overhead for themselves and newborn and sucking calves. Females suckle their young for a short period of 6–8 months on very lipid-rich milk, which is produced from maternal body stores, and wean abruptly. After lactation, mothers need to replenish body reserves, which usually takes a year. Females, therefore, generally breed every other or every third year. Females of the tropical Bryde's whale (*Balaenaptera edeni*) have similar gestation and lactation lengths but show much less of a seasonal breeding pattern. Despite the impressive energy flux involved in pregnancy and lactation in mysticetes, there is no evidence that this reproductive effort incurs clear fitness costs, i.e., really constitutes parental investment, for example, by systematically reducing the probability of a successful pregnancy in the year following lactation.

Large odontocetes have pregnancy periods lasting longer than 1 year and take 8–36 months to wean their young (but reports on 13-year-old sperm whales with milk in their stomachs also exist). All larger odontocetes need more than a year to wean. Females consequently need much longer than 2 years to complete one reproductive cycle. The long period of nursing, even in dolphins, allows young to profit from the milk supply while gradually developing independent hunting skills.

It is presently speculated that the difference in rearing strategy between the two groups depends largely on the difference

in hunting strategy. Mysticetes prey on small schooling prey, which are supposedly easy to catch for recently weaned young, particularly since weaning seems to coincide with the annual peak abundance of prey. In contrast, odontocetes eat large prey singly, which forces them to use more complex prey-hunting tactics. They may need to learn a lot more about prey distribution and behavior before young can feed successfully themselves. This may even involve teaching by mothers as suspected for the technique of beaching themselves used by southern killer whales hunting pinnipeds, e.g., on the breeding beaches of Argentina.

Another peculiar feature of some odontocetes is the occurrence of menopause. This phenomenon was documented for short-finned pilot whales (*Globicephala macrorhynchus*) and killer whales. One idea about the functional significance of menopause, which finds some support in studies on humans, is that menopausal females may help their last born and previous daughters in the group through prolonged maternal and allomaternal care, respectively, and by representing a living memory of how to deal with scarce resources and rare ecological disturbances. In matrilineal societies, menopause could be selected through indirect effects on the fitness of kin if the benefit to kin was larger than the benefit an old female could gain through further reproduction.

Sperm whales, long-finned pilot whales (*Globicephala melas*), false killer whales (*Pseudorca crassidens*), and bottlenose dolphins show evidence of reduced fertility with age, perhaps caused by extended periods of lactation. This change in maternal strategy might be expected from the life history theory because old females have a lower reproductive value and may therefore invest more in current offspring than young females. Alternatively, prolonged lactation in older mothers might be caused by a reduction in condition through previous parental care episodes and could then be considered a cost of reproduction.

Despite marked sexual size dimorphism in many species, there is little evidence for a sex-biased investment in sons vs daughters. Data on short-finned pilot whales suggest that sons are suckled for longer than daughters based on milk in the stomachs of caught individuals. Males had milk in their stomachs up to an age of 15 years, but females only up to an age of 7 years. This fits with the observation that males grow faster than females and are consistently larger at weaning than female juveniles. Similar observations have been reported for sperm whales. If such a difference in effort expended on the two sexes were consistent in the population, one would predict from Fisher's model of sex allocation that the sex ratio at birth or at weaning should be strongly biased toward females. There is as yet no evidence for such a sex ratio bias.

B. Pinnipeds

Pinniped females produce one pup per year (instances of twinning are exceptional). They have a postpartum estrus (otariids) or copulate around the time of or after the weaning of young (phocids). Implantation is delayed and followed, after 3–4 months, by an 8- to 9-month pregnancy. The young are reared on lipid-rich milk and are usually weaned at an age less than 1 year, thus allowing an annual cycle of reproduction. Pinnipeds follow one of two alternative pup-rearing strategies. Females may nurse pups for a short time (a few weeks) from body reserves and then wean abruptly. This is termed the *fasting strategy* and is typical for larger phocids. Smaller phocids and otariids combine nursing from body reserves for a short (in otariids, 1 week) phase after parturition with regular cycles of alternate foraging close to the colony and nursing ashore (the *foraging cycle strategy* of pup rearing). Phocids wean pups after a shorter duration of lactation (4–65 days) at a smaller mass relative to maternal mass (about 25–35%) the otariids (after 120 days to 3 years, at 35–55% of maternal mass).

Contrary to earlier beliefs, the rearing strategy depends more on female body mass than on phylogenetic grouping. The larger a female, the richer a food resource she needs to support pup rearing by foraging during lactation. This is because the energetic costs of traveling to and from the food resource and maintaining the metabolism of mother and pup during the foraging sojourn become too high for large pinnipeds to make foraging during lactation a feasible strategy. Therefore, large species separate foraging completely from lactation, store massive energy reserves during a long foraging period in rich feeding areas often far away from breeding sites, and then fuel lactation out of body reserves. Because phocid females are on average larger (median maternal mass for all species 140 kg) than otariid females (median 55 kg), this can explain why phocids usually follow a fasting strategy and otariids a foraging cycle strategy. The largest otariid, the Steller sea lion (*Eumetopias jubatus*), with a female mass around 250 kg, needs to take its unweaned young close to the foraging areas to maintain lactation by alternate foraging and suckling. Similarly, walrus (*Odobenus rosmarus*) females take their young to foraging areas where they are suckled while the mother can forage nearby. Ecological constraints thus play an important role in shaping maternal strategy.

Evidence is mixed that the energetic effort expended on pup rearing induces fitness costs of reproduction. In the Northern elephant seal (*Mirounga angustirostris*), primiparous (giving birth for the first time) young females are less likely to bear a pup in the year following birth than older females, thus suffering reduced fertility as a consequence of early onset of reproduction. Also, survival seems to be reduced when females first reproduce at 3 rather than 4 years of age, implying a mortality cost. However, these results were obtained at one but not another site on the Californian islands and the interpretation is not entirely clear. In otariids, Galápagos fur seal (*Arctocephalus galapagoensis*) females incur fitness costs of reproduction in terms of reduced fertility because they frequently lose a newborn pup when still accompanied by their previous young, be it a yearling or a 2 year old, by the time the next pup is born. This arises because young Galápagos fur seals grow extremely slowly and therefore take unusually long (up to 3 years) to become independent of their mothers. They may suckle for a second or third year if environmental conditions are poor, and thus preclude rearing of another pup by their mother. Clear evidence for a fertility cost of reproduction was also found for Antarctic fur seals (*A. gazella*). Parturient females of all ages were significantly less likely to reproduce in the subsequent year than nonparturient females. In addition, females that reproduce in a given year are less likely to survive to the follow-

ing year than nonreproducing females, a clear mortality cost of reproduction. In this species and the northern fur seal (*Callorhinus ursinus*), females older than about 13 years appear to show reproductive senescence. These old females are less fertile and produce smaller newborns than prime-age females. Particularly for otariids, there is thus evidence that the high energetic effort expended by females on pup rearing indeed constitutes maternal investment because it produces fitness costs to the mother.

It has been claimed repeatedly that female pinnipeds of highly polygynous species invest differentially in male and female offspring. Following sociobiological arguments, this would be expected if an increased investment in males (the larger sex showing greater variance in reproductive success) would lead to a greater expected reproductive success of such males. In many polygynous pinnipeds, males are born heavier and grow faster than females. This was taken as evidence for greater maternal investment in sons. However, this is no proof of greater investment in male offspring because male pups of some otariids store less fat and produce more lean body mass than female pups. Fat has a higher energy density than lean body mass, and consequently smaller female pups may have taken as much energy from their mothers as the larger, leaner male pups. Also, the most important growth spurt determining later male adult size and probably reproductive success occurs generally after weaning, thus making it less likely that male offspring derive direct benefits for their future reproductive success from increased maternal investment.

IV. Mating Systems

Females are producers that are limited, in mammalian reproduction, by the time and resources needed for pregnancy and lactation, as well as by the recovery of condition after a reproductive cycle. This constitutes strong selection to optimize acquisition and efficiency of use of resources for reproduction. Because the maximal reproductive rate of female mammals is necessarily much lower than that of males, which in the extreme need only the time of one copulation to produce offspring, females become a limiting resource for the reproduction of males. This leads to selection on males for an increased ability to get access to and breed with as many females as possible, which is the essence of sexual selection. In mammals such as whales and pinnipeds, where males do not contribute to the care of offspring, males are expected to conform to the description of "ardent" males, eagerly searching for females and even harassing them for copulation. Females distribute themselves in relation to the distribution of resources (food and adequate habitat for reproduction), and males map onto this distribution of females. This difference in the selection on reproductive strategies of males and females leads to the phenomenon that quite often the sexes behave and morphologically look as if they belonged to different, competing species.

Sociobiological reasoning therefore leads to the expectation that observed mating systems represent the compromise emanating from the conflict of the sexes. Competition among males for access to females can take the form of aggressive competition, but can also occur via sperm competition when several males copulate with one female, as demonstrated for northern elephant seals. Such sperm competition, if occurring regularly, is expected to lead to the evolution of large testis mass, as larger testes produce more sperm and thus increase a male's chances to fertilize the ova of females in competition with sperm of other males. Such an increase in relative testis mass was documented in other mammalian orders where species in which multiple copulation is frequent have larger testes than species where only one male copulates with a given female, whether the social system is monogamous or polygynous.

A. Whales

Whale mating systems are still largely unknown partly due to the problem that copulations are hard to observe. Except for a few particularly observable species, this leaves only indirect methods of investigation, such as genetic analyses, to determine the mating pattern in the more elusive species.

Among mysticete whales, much is known about the humpback whale, so well known for its spectacular songs. During the mating season, males station themselves well spaced out and advertise their position. This is very similar to the lek structures observed in many birds. This song may attract females and keep competing males away, but there is presently no firm evidence for this inference. Alternatively, males follow females, and several males may be doing this simultaneously, leading to competition for proximity to the female. Apparently these males compete over mating access to a female. Because humpback whales have small testes for their size, it is unlikely that females will copulate with several males, thus inducing sperm competition. Such sperm competition is likely to occur regularly in right whales (*Eubalaena* spp.), which—weighing about 50 tons—have testes weighing 1 ton, in strong contrast to blue whales, which weigh about 100 tons but have a testis mass of only about 70 kg. Copulation is observed frequently in right whales but has never been described convincingly in humpbacks, despite much more study of the latter.

Mating patterns in odontocetes are somewhat better known from a few species. Male strategies vary from singly roving males in the sperm whale via mating groups in killer and pilot whales to males that cooperate to herd and perhaps force females into copulation in the bottlenose dolphins. Sperm whales show a pattern similar to elephant mating patterns in which single fully adult, highly aggressive males rove among female groups in search of receptive females. They stay only briefly with each one of the female groups and then go on. Presumably, the long intervals between estrus in females make it unprofitable for these males to stay with any one group of females waiting for one of the females to get into estrous condition. Only fully adult males appear able to compete in this system, and subadult males as well as nonroving males stay at higher latitudes, often in small schools, feeding and maximizing energy intake in this way to grow to a competitive size. It is unclear why these males might stay in small groups as bachelors because they are certainly not endangered by predation and it is unknown which foraging advantages they might derive from grouping.

The killer and pilot whale mating system is the most surprising, least understood of the whale mating systems and has

no parallel in terrestrial mammals. Genetic evidence shows that males who remain philopatrically in their maternal group never father offspring in their own group but apparently in other groups. Some evidence suggests that several related males of one group may mate with several females in another group, presumably during repeated encounters of these pods. This was concluded from the genetic observation that offspring in a group seem to be paternally related.

B. Pinnipeds

The pattern of mating interactions among individuals depends greatly on the dispersion of females during the breeding season, which in turn reflects the availability of a suitable habitat for pupping and foraging. In pinnipeds, pack ice, fast ice, and land-breeding species differ widely in this respect.

Phocids breeding on ice floes seem to have a mating system best described as serial monogamy in which a male stays with a female that has recently pupped until she comes in estrus. He then leaves after copulation to search for another female. The reproductive success for males in such a mating system depends more on their aptness to locate females ready to mate than on fighting abilities. In such species, sexual dimorphism tends to be small, slightly reversed (males smaller than females), or nonexistent.

Some fast-ice breeding species also show reversed sexual dimorphism, which is best analyzed in the mating system of the Weddell seal. Females gather around cracks in the fast ice where they dive for food from holes in the ice. During the reproductive season, they pup near these holes and males claim territories under the ice and defend the holes against other males. Under these conditions, maneuverability is considered more important than sheer size in male–male competition. This may be the reason for the observed reverse sexual size dimorphism. Alternatively, females may be selected for larger size, enabling the production of larger young or the storage of more massive fat reserves for lactation, and males may have remained smaller for lack of such selection. Copulation is underwater and consequently little is known about the reproductive success of males in this mating system.

Phocid seals, such as the harbor seal, which breed in the water close to land areas where females loosely aggregate frequently, seem to engage in fights for the best stations where females have to pass by, and such males are often wounded. Fighting males seem to have the highest reproductive success and, in some places, the mating system of this species may be similar in structure to a lek.

When female otariids or land-breeding phocids come together on predator-free islands, the resulting high female density permits males to station themselves among females and attempt to monopolize access to females. This competitive situation sets up sexual selection for an ever increasing male size, leading to impressive sexual size dimorphism in a few phocid and many otariid species, such as the northern fur seal in which males weigh six times as much as females. In addition, a larger size also enables males of these species to remain fasting on territory for long periods, thus increasing their chances to mate with females.

Otariid mating systems have been described as resource defense, female defense, or leks. The presence of resources important to females with pups, such as shade or access to tide pools, on male territories was demonstrated experimentally for a few species. However, resource distribution is not sufficient to predict the exact location of female aggregations nor does it explain female gregariousness, i.e., an active tendency of females to approach each other. Because high female density correlates with increased pup mortality in breeding colonies, there is a marked cost to female gregariousness, which must be compensated by comparable benefits. Bartholomew (1970) suggested that female choice of genetically superior males was responsible for female gregariousness, but little evidence supporting this view has come forward. New studies suggest a strong selection of female gregariousness through avoidance of interaction with large males, whether territorial or not. In many otariid species and in elephant seals, interactions with a much larger male can be dangerous or even deadly to a female. Females can minimize the probability of interaction with territorial males by aggregating into a "selfish herd." Through this effect and by avoidance of dangerous and sometimes directly fatal harassment of females and pups by marginal males, females are selected to group much more closely than can be explained by resource distribution. Thus, the stationing of large adult males on clustered territories among parturient and estrous females creates a resource "peace from marginal male harassment." Except for this socially created resource, the system could also be described as one in which males are lekking on areas where females are forced to stay for a while because they spend the period between parturition and postpartum estrus near-stationary on land. Males may benefit from clustered territories by the reduced chances of losing females when disturbed by marginal subadult or adult males. Within this system, the male defense of access to females varies intra- and interspecifically with habitat and female density from female defense to territorial site defense with larger or smaller territories reminiscent, respectively, of a resource defense or a lekking system.

Dominating males in these land-based breeding systems gain most copulations and can reach quite extreme reproductive success, sometimes up to 100 copulations in one breeding season. However, genetic studies have shown that observed number of copulations does not always correlate well with actual paternity, suggesting that peripheral, apparently "excluded" males may also gain some reproductive success by keeping close to female groups. There is no evidence of female choice beyond the mechanism that females in dense groups attract the strongest males in the best condition because only these are competitive enough to station themselves in the middle of female groups. Female elephant seals protest when they are attacked and forced into copulation by subadult or peripheral males, thereby attracting the attention of the dominant male who will often chase off the smaller male and copulate with the female. In this way females indirectly choose dominant males as copulation partners.

Gray seal mating systems on land strongly resemble the otariid system. Whether female choice plays a more important role in gray seal colonies remains to be seen. Genetic analysis of subsequent offspring of individual females suggests that females copulate year after year with the same male, even though they may stay in the territories of different males. This would

suggest that they actively choose a particular male or, in case of multiple copulations, have mechanisms to choose among sperm of several males. In more dispersed breeding species, such as harbor seals, males have no chance to defend access to females as these are too mobile and not available continually in the same areas, depending on tide level and sea conditions. In situations in which females breed on sandbanks, harbor seal males were observed to station themselves in areas where females are likely to pass by and make themselves obvious through vocal display. Whether this and similar observations on walrus males that station themselves near females and produce bell-like sounds can be considered a lek display need further investigation.

V. Sirenians and Sea Otters

Much less is known about the social life of sirenians and sea otters and, therefore, these two groups are only treated briefly here.

The only clearly recognizable social structure in sirenians is the mother–offspring bond, which may last for up to 3 or 4 years. Other than that, it appears that the dispersion of most sirenians relates directly to the distribution pattern of food, aquatic macrophytes, fresh water for drinking (in the Florida manatee, *Trichechus manatus*), and, particularly in winter, warm water areas. Animals may migrate for large distances between such resources. However, it seems possible that underlying the apparent asocial pattern may be a subtle pattern of individualized relationships. This might be hypothesized from "greeting" displays exchanged between individuals that meet only occasionally at widely distant sites.

Cows in estrus seem to induce male scramble competition. In Florida, manatee herds of up to 20 males may follow an estrous female and compete by pushing to get into a favorable position for mating. In dugong males, competition may take a more aggressive form in which males may wound each other with their tusks. For West Australian dugongs, mating competition may lead to a form of lekking. However, the evidence is largely circumstantial.

Sea otter spatial dispersion also related to the need to live close to the coast where they forage relatively shallowly for macroinvertebrates. Females claim often overlapping foraging territories year-round along the coastline. They sometimes aggregate in small groups, so-called "rafts." Young males, and fully adult males outside the reproductive season, also frequently form rafts close to areas of rich feeding resources. Such rafting is presumably related to the reduction of predation risk.

During the reproductive period, fully adult males establish territories that may overlap more than one female territory. This presumably provides males with a chance for a mild form of polygyny, but hard evidence for paternity of such males is at present missing.

VI. Concluding Remarks

Much of the sociobiological interpretation of observations on marine mammals is still in a speculative stage. This situation reflects our lack of detailed knowledge about the marine environment and in particular the macro- and microdistribution of resources vital to marine mammals. Clearly, more observation, more comparative studies, and especially more experimental work are urgently needed to understand the sociobiology of these magnificent animals. Obviously, experimental work will be particularly challenging and can only be successful if built on the thorough knowledge of marine mammal natural history. However, a well-founded functional understanding of the social behavior of marine mammals cannot be achieved without experimental tests of our many assumptions. Ingenious instrumentation and molecular genetic tools, developed during the last decade, should prove most helpful in making this summary of marine mammal sociobiology soon outdated.

Song

JIM DARLING
West Coast Whale Research Foundation, Tofino, British Columbia, Canada

Humpback whales (*Megaptera novaeangliae*) produce a complex sequence of sounds ranging from 5 to 30 min in duration and then repeat it with precision. The nonstop repetition of this sequence is called the "song." The song is produced by males during the breeding season: in late fall on the feeding grounds, during MIGRATIONS, and on the winter breeding grounds. The song has a standard structure: several sounds termed *units* are associated to make a *phrase*. A repetition of the phrase composes a *theme*, and several different themes make up the *song*. The composition of the song changes or progresses slowly over time, and the majority of singers in a population sing fundamentally the same version in any season. The songs of humpbacks may be similar across entire ocean basins such as the Pacific, yet different in separate oceans. On the winter breeding grounds singers are usually lone adult males, which may be stationary just beneath the surface or slowly traveling. The singing usually ends with an interaction with other whales. The specific function of the song is not known, but it is clearly a key communication of humpback whales during the breeding season.

Our understanding of the song is in early stages, with aspects of it based on just one or a few studies. The following summarizes the working knowledge of the song, but new findings may change the emphasis substantially.

I. Characteristics

A. First Descriptions

Although likely heard by sailors for centuries, the first recordings of humpback songs were made via U.S. Navy hydrophones in the 1950s off Hawaii and Bermuda. Scientists first recognized these sounds as coming from humpback whales in the 1960s. The first technical description was published in *Science* in 1971 by Roger Payne and Scott McVay with the revealing subheading, "Humpbacks emit sounds in long, predictable patterns ranging over frequencies audible to humans." Their analysis led to a structural context in which to view the sounds introducing the terms units, phrases, themes, and song. With the observation that humpback whales "produce a series of varied sounds then repeat the same series with considerably precision" these authors called the performance "singing" and the repeated series of sounds the "song."

B. Song Structure

The song is composed of a sequence of highly varied sounds ranging from high-pitched squeaks to midrange trumpeting and screeches to lower frequency ratchets and roars, and combinations of all these. This sequence is typically about 10–15 min in duration, although it may range from 5 to 30 min. It is then repeated without a break.

The song has a predictable structure or framework. Discrete sounds are termed *units*. Several different sounds or units in a sequence compose a *phrase*. A phrase is repeated some variable number of times (e.g., 10 times), and this series of the same phrase is called a *theme*, say, "theme 1." After several minutes of singing theme 1 the singer changes to a different set of phrases (composed of different units or sounds) and repeats it a number of times. This might be called "theme 2." This pattern repeats until the whale cycles back to its theme 1. A typical song may contain six themes. A singer may sing in order themes 1-2-3-4-5-6 and then start at 1 again. The number of themes in a song varies from population to population and from year to year. A song session may continue without a break for hours.

Several characteristics of this song display are notable. First is the precision by which a singer repeats its complex song in any song session. An undisturbed singer may repeat the same themes, phrases, and units faithfully for hours as if on a continuous tape. The second characteristic is that all the singers in a humpback assembly, and there may be hundreds, follow the same structural rules and broadcast essentially the same song. At the same time, however, there is some variation in song presentation and some songs are exceptional to the point that they have been termed "aberrant" by investigators. The significance of this variability is not yet understood.

C. Song Progression

One of the more unique characteristics of the humpback song is that it gradually changes over time. Different sounds, and arrangements of sounds, form to create new phrases and themes. These are incorporated into the song gradually, while older patterns are lost. After a period of several years the song my bear little resemblance to the original version. This is a rare, although not unique, characteristic of biological songs. Several bird species are known to vary their song over time.

The song apparently changes as it is being sung; i.e., the progressive changes occur during the singing or breeding season, not during the off-season. For example, as winter progresses, one unit in a particular phrase may be heard less and less while another becomes more common, or two units in one phrase that had been separate may become joined as one sound. These small changes may eventually lead to new phrases and themes. During the nonsinging or summer season, the song appears to remain relatively stable, to begin to progress again once singing begins the following season. The biological forces or mechanism behind the progression of the song is not known.

The change in the song display occurs in a collective or common way throughout a population of humpback whales; i.e., at any one time all the singers in a population produce fundamentally the same version of the gradually changing song. This is a generalization in that there is certainly some range in when individuals incorporate new elements into their song. However, the majority of singers produce many if not all the same clearly recognizable units, phrases, and themes in the same general order in any one season. Changes in the song are apparently incorporated throughout the population. The mechanism by which this occurs is not known. Some researchers speculate that the changes are learned, with some whales making changes and others learning them; others suspect a genetic component to this phenomenon.

The similarity and collective change of the song may occur not only within one population of humpbacks, but between

populations separated by thousands of kilometers. For example, humpback populations that winter in Japan, Hawaii, and Mexico sing similar versions of the song at any one time. In contrast, the Atlantic humpback song would be substantially different. The means by which this occurs is not known. Some degree of mixing occurs among all populations in the North Pacific in that individual whales may visit the different winter assembly areas over several years or even in 1 year. Perhaps this mixing is reflected in the similarity of songs. It is important to emphasize that whereas the generalities described here are striking, much further research is required to conclude on the relationship of songs, singers, and populations. This is emphasized by a discovery that over a 2-year period the humpbacks off eastern Australia essentially adopted the western Australian humpback song, apparently introduced to that region by the mixing of whales.

II. Singing Behavior

A. Seasonality

Singing is a seasonal behavior pattern. It occurs primarily during the winter half of the year, throughout the peak of the humpback breeding season. Although a few songs have been recorded during midsummer, they are rare. Songs become increasingly common on the feeding grounds as fall progresses into winter; they are heard regularly during migrations and predominate on the warm water winter breeding grounds. It is not clear when the singing activity declines in the spring, but the decline has occurred by the time the migrant whales reach their summer feeding grounds.

B. A Male Display

The evidence to date indicates that only male humpbacks sing. The gender of a sample of singers has been determined both by photographs of the genital region and by genetic analysis of skin samples, and so far all were males. Also, singing is a behavior pattern common to individual whales that may escort a cow with calf or compete in mating groups—both distinct male behavior patterns. Because there are no confirmed observations of female humpback whales singing, the song may be a male secondary sexual characteristic or display that functions during the breeding season.

A singer on the breeding ground is typically a lone adult male. Also, it is not unusual for an "escort," the adult male accompanying a cow with calf, to be singing. Occasionally a singer has a companion adult or juvenile in the close vicinity. Often the singer is stationary, remaining in one geographic location for many hours while singing. In these situations the singer generally adopts a motionless, head-down, tail-up posture approximately 50–100 feet beneath the surface. It maintains this posture until it surfaces to breathe and then immediately after diving resumes it. At other times a singer travels steadily as it is singing and may move tens if not hundreds of kilometers during a song session.

C. Interactions with Singers

Humpback songs are loud and can be heard underwater for at least several kilometers and, in some circumstances in deep ocean basins, possibly hundreds or even thousands of kilometers. A collection of dozens of singing humpbacks produce a substantial noise, clearly designating the location—on an oceanic scale—of an assembly of humpback whales during the breeding season. It is likely that individual humpbacks interact with the collective singing herd over extensive oceanic distances.

On a smaller scale, several studies have focused on the interaction of individual singers with other whales. Generally, singers sing until one of two things happen: (1) They are joined by other single adults, the singing stops, and the two interact in some way, ranging from a single pass to rolling, tail lobs, or breaches by one or both animals. Often the interactions are very short, with the pair splitting after a few minutes. One or the other may start singing again shortly after the interaction. There is increasing evidence that the lone adults that join male singers are also males. (2) The singer stops singing without any close approach by another whale and then rushes to approach or join a passing group of whales—often a surface active or competitive group; at times a cow with calf. In these cases, the singer joints a group that includes a potentially breeding female.

III. Function

The function of the song has been the subject of much speculation. Much of this has revolved around proposals of the song as a male display that functions to (1) attract females, (2) signal status to other males, or (3) a combination of these. However, other suggestions include that the songs serve as a means to synchronize ESTRUS, a spacing mechanism between males, a migratory beacon, and as sonar by males to find females. Recent research has widened the basis for the speculation but is far from resolving it.

Conservatively, the song is a communication from male humpbacks during the breeding season. It almost certainly serves to provide the location of the singer, and by association the entire herd, and signals that breeding activity is underway. The song also likely broadcasts information about the individual singer, but what information and who the recipient(s) is remain speculative. The collective, gradual change of the song seems to confound many simple explanations as to its function.

Several early investigations proposed that the song by males serves to attract females and went further to suggest that changes in the song are driven by female choice. This notion has persisted and predominates in the popular literature; however, there no data to support it. There is little question that singers join and accompany females, but no evidence that females are attracted by, and voluntarily join, individual singers.

In a related idea, several researchers have proposed that the humpback song functions as part of an aquatic lekking behavior. A lek, as generally defined for land animals, is a seasonal assembly where males display their attributes to attract females for the purpose of mating. This seems to describe the overall breeding assembly of humpbacks, including the male song display; however, if, when, or how females choose a mate is unclear.

Another proposal suggests that the song is a display of males aimed primarily at other males—perhaps signaling social status or position. In this view the song may enable the male–male interactions that are integral to the establishment and maintenance of the dominance-ordered, polygynous mating system that has been hypothesized for humpback whales. Alternatively, it may facilitate temporary male associations on the breeding grounds. This proposal accounts for the common interactions between

male singers and male joiners, and the lack of evidence that females approach, choose, or join singers.

Regardless of whether the song display is directed at females, males, or both, these potential explanations suggest that song displays should vary with some attribute of the singer. That is, the song should reflect dominance class, fighting ability, or some other measure of the "fitness" of the male. At this stage, research has not revealed any evidence that this is the case.

In summary, at this time the function(s) of the song is not clearly understood. The notion that it is a sexual display is attractive as it accounts for many of the observations and characteristics of the song, and does so within the larger mammalian context. However, this is far from established, leaving other speculative ideas that do not presume the song to be a sexual display as open possibilities.

Sound Production

ADAM S. FRANKEL

Marine Acoustics, Inc., Arlington, Virginia

Most terrestrial mammals rely heavily on vision and smell. These senses are limited in water by the absorption of light and the slow physical movement of water, respectively. As a result, marine mammals have evolved to use sound and hearing as their primary means of communication and sensing their world.

This article briefly reviews basics of sound and the physical ways in which sounds are produced by marine mammals. The main focus is on characteristics of sounds made internally by marine mammals. Certain species stand out as particularly unusual or particularly well studied, and these get special attention. Other species are treated in taxonomic groups, when their acoustic characteristics are similar or less well known. Especially whales and dolphins often leap clear of the water or slap tail or flippers onto the water surface, creating percussive sounds. These sounds are variably thought to be expressions of playing, socializing, or aggressiveness. They are not treated in detail here.

I. Fundamentals of Sound

Imagine throwing a rock into a calm lake. You can easily picture the ripples, or water waves, that move out in an expanding circle. In these ripples, the water's surface moves up and down, in a smooth progression from crest to trough. Sound waves are similar to these water waves. The "crests" of a sound wave are areas of high pressure, and the "troughs" are areas of low pressure. Like the water wave, there is a smooth progression between these areas of high and low pressure. A sound wave is a propagating (moving forward) alternation of these areas of high and low pressure. The wave is formed by a structure that vibrates, such as a radio loudspeaker or our larynx.

Several major terms are used to describe the characteristics of sound. The amount of time it takes for a complete cycle between the highest pressure to the lowest, and back to the highest, is referred to as the period of the wave and is measured in seconds. The reciprocal of that time measurement, the period, is called the frequency of the wave, measured in seconds^{-1}, or more commonly hertz (Hz). The longer the period, the fewer number of cycles will occur in a fixed amount of time, and the lower the frequency of the sound. In music, this low frequency is called one with low pitch, or a bass sound. High-pitched sounds of a flute or violin are high in frequency. Frequency is a physical characteristic of sound, whereas pitch is our perception of sound. Humans hear from about 18 to 20,000 Hz (or 20 kHz). Therefore, sounds below 18 Hz are termed "infrasound," whereas those above 20 kHz are termed "ultrasound."

Marine mammalogists often want to know the loudness of a sound, whether produced by a whale, dolphin, ship, or oil rig. The loudness, or amplitude, of a sound is described in decibels (dB), but "in-air" decibels and "in-water" decibels are different from each other. In water, sound amplitude is measured and referred to as a certain number of dB references to one micropascal. This is usually written XX dB re 1 μPa. Because sound amplitude decreases with distance, the standard of describing amplitude is usually referred to as 1 m from the sound source, or XX dB re 1 μPa at 1 m. Sounds that are not very loud tend to be below 100 dB, and very loud sounds are above 160 to 180 dB.

A signal is said to be frequency modulated (FM) when its frequency changes over time. Dolphin whistles are usually frequency modulated. Amplitude-modulated (AM) signals are

those where the amplitude changes over time. Many mysticete calls are amplitude modulated and sound like "growls."

When one examines a display of sound waves per time, or a spectrogram, one often sees "extra lines" above the main "line" of the spectrogram. The "main line" of the spectrogram is the lowest frequency contour, termed the fundamental frequency. Additional "lines" about the fundamental frequency represent the harmonics. Harmonics are integer multiples (e.g., 2×, 3×, 4×) of the fundamental frequency. They are the result of the physical characteristics of the sound-producing structure, and they alter the sound. Harmonics occur with frequency-modulated calls and are strictly integer multiples of the fundamental frequency. Amplitude-modulated calls frequently have a stack of closely spaced bands that look like harmonics, but are side bands that are the product of the rate of amplitude (loudness) modulation (Fig. 1).

II. Sound Production Mechanisms

A. Humans

Unlike most marine mammals, humans exhale to vocalize. The energy for vocalization comes from exhaling. The lungs force air through the larynx. The vocal cords in the larynx open and close as the air rushes past them, breaking the exhalation up into a series of air puffs, or an undifferentiated sound. These air pulses then pass through the vocal tract of the throat, tongue, mouth, and lips. All of these structures move during speech to change the shape of vocal tract, literally shaping the buzzing sound from the larynx into speech.

B. Dolphins

There has been considerable debate over the sound production mechanism in toothed whales, or odontocetes. Only recent work has begun to clarify the issue. As in humans, the energy for vocalizations comes from pushing air. The similarity ends there, as odontocetes lack vocal cords. Odontocetes have a structure in the upper portion of their heads called dorsal bursae that have structures protruding into the nasal passage called phonic lips. Air appears to be pushed past these phonic lips, and the result is that they slap together and send the neighboring tissue into vibration. Once past the phonic lips, the air enters the vestibular sac, just below the blowhole. The air can either be pushed back into the lower nasal passage or it may be released into the water. Whistling dolphins sometimes emit bubble streams. All odontocetes, except the sperm whale (*Physeter macrocephalus*), have two of these dorsal bursae/phonic lip structures. It appears that they can operate the two structures independently, creating two different sounds simultaneously. Toothed whales produce clicks, click trains (often so rapid as to be heard as a "buzz"), and—especially many species of dolphins—whistles. Some but not all click types are used for echolocation to scan the environment, as also in bats.

Once the sound is produced, it is directed out into the water through a structure called the melon. The melon sits on top of the skull, behind the rostrum of dolphins. The melon is a complex structure that couples the vibrations produced by the dorsal bursae/phonic lips complex to the water. It also functions as an acoustic lens to "focus" clicks into a beam. This is similar in function to the focusing of light into a beam by the lens and reflector of a flashlight (Fig. 2).

C. Baleen Whales

There is no equivalent in mysticetes to the dorsal bursae/phonic lip structure found in odontocetes. Mysticetes have a larynx, but it lacks the vocal cords found in humans. It is likely that the larynx does have a sound production function, but it remains undetermined. Cranial sinuses are also suspected to play a part in vocal production, but the details remain uncertain. Visual observations of singing humpbacks reveal that they do not exhale, even while singing for 20 min or longer.

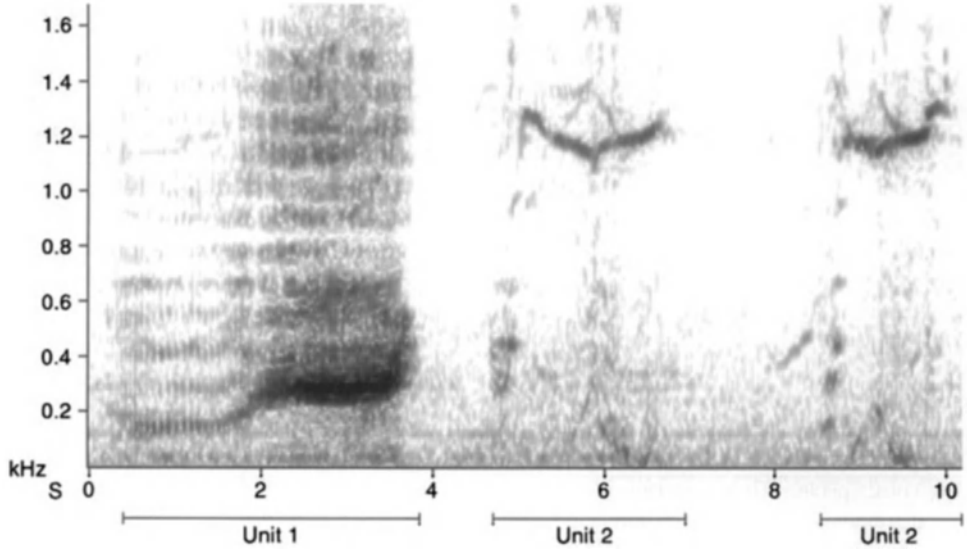

Figure 1 *Spectrogram of part of a humpback whale* (Megaptera novaeangliae) *song. The first sound is shown as a broad, fuzzy structure, typical of amplitude modulated sounds. The second sound, the "V"-shaped structure, is a frequency modulated sound.*

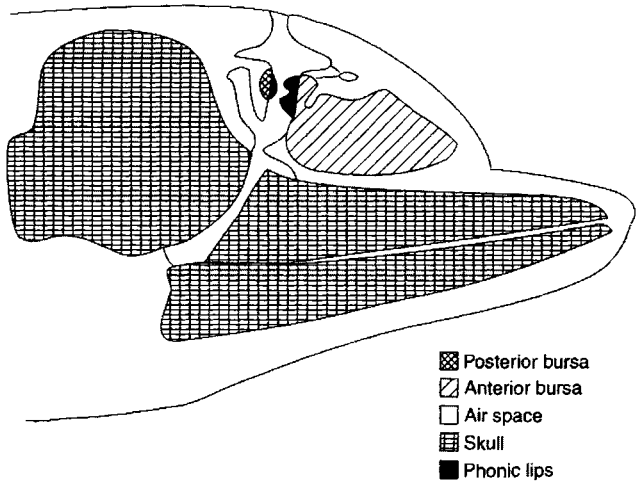

Figure 2 *Diagram of sound production structures in the head of a dolphin. Redrawn from Cranford (2000).*

This indicates that they are recycling air within their body to vocalize.

D. Sirenians and Carnivores (Pinnipeds, Polar Bear, and Sea/Marine Otters)

Noncetacean marine mammals appear to make sounds similar to those of their terrestrial relatives, generally by vibrations in the throat. Sea lions (Otariidae) bark underwater, and manatees (*Trichechus* spp.) and dugongs (*Dugong dugon*) have a rich repertoire of sounds. Underwater, these sounds are generally made without air being released from the mouth, and it is surmised that air is shunted between the lungs and mouth/nasal structures.

III. Characteristics of Vocalizations by Group and Selected Species

A. Pinnipeds

1. Phocid Seals Phocid, or true, seals live in a wide variety of environments, from tropical islands to the ice packs of the Arctic and Antarctic. While the underwater sounds of all species have not been described in detail, it is likely that all make underwater sounds. In-air sounds tend to consist of barks or growls, sometimes produced at the surface but more usually produced while mating and pupping on land or ice. Such sounds are often aggressive or warning signals, as when, for example, a human approaches an animal too closely. Pups tend to have higher frequency in-air "mew" sounds, apparently useful for mother/pup interactions and potential pup recognition. Underwater sounds are described in more detail later.

A. WEDDELL SEALS (*LEPTONYCHOTES WEDDELLII*) Weddell seals are a very vocal species. Their repertoire has been categorized into 12 calls, labeled by letters, and subdivided into 34 types. These calls range between 100 Hz and 12.8 kHz. The function of some of these calls has been suggested. T calls are long downsweeps and are thought to function in territorial advertisement. C calls are pulses of intermediate frequency, which appear to be used as an aggressive display. M calls are a long low-frequency tone, and H calls are low-frequency pulses. Both M and H calls are thought to be used as a high-intensity threat. G and L calls are both low-frequency-modulated sweeps, thought to be used as a low-intensity threat. Functions have not been proposed in similar detail for other phocid species.

Calling rates are lowest in winter and highest in spring. It has been suggested that calls produced from the pupping season through the mating period function as male advertisement "song." Weddell seals also make numerous in-air vocalizations during this time period that sound similar to those produced underwater, a richer in-air repertoire than produced by most (and possibly all) other phocid seals. Recordings of Weddell seals at different locations indicate that there are geographic differences in calls between breeding populations.

B. LEOPARD SEALS (*HYDRURGA LEPTONYX*) Recordings of a captive leopard seal included vocalizations reaching as high as 164 kHz. These included frequency-modulated chirps, buzzes, and a click train. The presence of ultrasonic clicks suggested a possible echolocation function, but no data support echolocation in leopard or any other seals.

As in Weddell seals, recordings of leopard seals made in distant locations showed differences in the calls between the two areas. The repertoire of leopard seals shows considerable variability. Their calls range from low-frequency tonal calls, both narrowband and wideband high-frequency pulses, and frequency-modulated calls ranging from 500 Hz to 8 kHz. The most frequent calls of leopard seals are surprisingly soft, given its role as a top-level predator. Many other seals, including the Weddell seal, produce harsh calls during aggressive interactions. It has been suggested that the leopard seal's solitary existence reduced the need for territorial calls. However, when hauled out on ice or land, leopard seals that were approached by a researcher made explosive, broadband vocalizations termed "blasts" and "roars."

C. BEARDED SEALS (*ERIGNATHUS BARBATUS*) Like Weddell seals, bearded seals are well known for their long calls and songs. Bearded seals produce distinctive trills, which typically consist of a series of discrete frequency sweeps. Trills can begin at 2.5 kHz and gradually sweep down in frequency to a few hundred hertz. Most trills are characterized by decreasing frequency, but some variations can have near constant frequency or even alternations of frequency increases and decreases. Trills last from 4 to 16 sec. In some populations, the long trill is followed by a rapid upsweep to 3 kHz and lasts 1–2 sec. The vocalizations of bearded seals are thought to function as male advertisement displays during the mating season (Fig. 3).

D. RINGED SEALS (*PUSA HISPIDA*) Ringed seals, like many seals, were long thought to be silent. However, they are now known to produce at least four types of calls. These are low- and high-frequency barks, frequency-modulated tones between 2 and 4 kHz, broadband growls that range up to 6 kHz, and frequency-modulated chirps. It is likely that ringed seals produce higher frequency calls that have not been recorded, as their best hearing sensitivity is at 45 kHz. Animals usually have their best hearing in the same frequency range in which they vocalize. Source levels for all of the recorded ringed seals are relatively low, between 95 and 130 dB re 1 μPa. None of

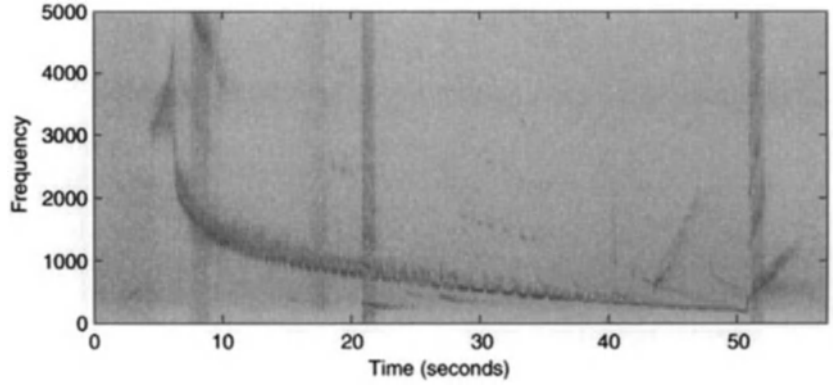

Figure 3 *The long downward trill and rapid upsweep of a bearded seal from Alaska is shown in this spectrogram.*

the recorded calls occurred exclusively within the breeding season. The proportion of calls produced did vary with season, however.

E. HOODED SEALS (*CYSTOPHORA CRISTATA*) The acoustic repertoire of hooded seals can be grouped into three major classes. Class A and B signals are produced by normal vocal mechanisms, whereas class C signals are produced by the hood and septum, a set of specialized anatomical structures in this species. Class A calls tend to be the most common vocalization and are produced both in air and underwater. All of these calls are pulsed and rarely frequency modulated, with energy ranging from 500 Hz to 6 kHz. Class A calls are used in a variety of circumstances, including female responses to displaying males, who also make a variety of A calls. Female and pup interactions also use A calls. Class B calls are described as growls or roars. These growls tend to be made by females fighting with males and by males fighting with other males. Other variants of B calls are used as low-level threats. Class C signals are produced by the inflation and deflation of the hood and septum. They are short-duration, broadband with rapid onsets, and little or no frequency modulation. These calls have been described as "bloops," "wooshes," and metallic "pings," clicks, and "knocking" sounds. It is possible that only males make class C sounds.

F. HARP SEALS (*PAGOPHILUS GROENLANDICUS*) Harp seals aggregate at the ice edge in March in the northwest Atlantic. At least 19 different call types have been described for the species. The call types range from a nearly pure sine wave to pulsed sounds, high-frequency chirps, broadband "warbles," trills, squeaks, and grunts. The maximum source level of these calls is between 135 and 140 dB re 1 μPa. Harp seals also produce clicks that are about 25 dB louder than their other calls. A long-term observation has shown that within one breeding area these call types are stable over a period of tens of years. The calls may help individuals locate the herd; harp seal aggregations can be heard from 30 to 60 km away. Once in the aggregation, calls may be used to find a mate. Comparisons of different breeding aggregations found many shared calls and some that were unique to the breeding areas, again suggesting that there may be distinct breeding populations. In-air recordings revealed that harp seal pups have an unusually wide variety of vocalizations. These tend to be longer than calls from other phocids and are very complex, showing a wide variety of frequency and amplitude modulation.

G. ELEPHANT SEALS (*MIROUNGA* SPP.) Elephant seals mate on land and males compete for dominance, and thereby access to females. Males use threat displays and actual fights to establish dominance. Male elephant seals make three main types of calls during AGGRESSION: "snoring," "snorting," and "clap threatening." "Snoring" is used as a low-intensity threat, and dominant males "snort" more aggressively when approached by a challenging male. Snorts range between 200 and 600 Hz. The "clap threat" ranges up to 2.5 kHz. It is thought that in-air threat calls produced by males are also transmitted through the ground, and these seismic signals can produce responses from other elephant seals. Females produce a low-frequency "belch roar" in aggressive situations and a 500 Hz to 1 kHz bark to attract the pup. Pups produced a higher frequency, up to 1.4 kHz, call that is used to maintain contact with the mother or to elicit attention. As in other seal species, both the mother's and the pup's call have individual characteristics that are used to recognize each other acoustically.

Underwater sounds have been recorded, but only described cursorily as sounding like a bell, cymbal, or guitar.

H. WALRUSES (*ODOBENUS ROSMARUS*) Social interactions between walruses hauled out on the ice often include vocalizations. Adults use roars, grunts, and guttural sounds as threats. Roars are long, loud calls that last a second or more and have most of their energy at low frequency. Grunts are brief calls lasting between 100 and 400 msec and vary greatly in amplitude. Grunts range from 50 to 250 Hz. Guttural sounds are the most common threat vocalization, consisting of a series of low-frequency, wideband pulses. These can range from 13 Hz to 4 kHz. Barks are short, frequency-modulated calls that range from 90 to 260 msec in length and between 300 and 500 Hz. They are frequently given as a series. Barks are used by adults to indicate submission, and louder barking may indicate more submission. Calves bark in a wider variety of situations. Calves separated from their mother bark loudly and then may continue to bark softly once they are rejoined. The structure of the

bark changes as the calf matures, gradually becoming a longer single call, with both frequency and amplitude modulation. Females produce a soft short call between 0.3 and 1.0 sec long. The call is usually frequency modulated, either as a downsweep or as an alternation of up-and-down sweeps. This call serves as a female contact call, produced when female and pup are in close proximity to each other. Females do not have a loud contact call to attract the calf, as in some other phocid species.

Males on the mating grounds produce a gong-like sound as a courting display, both in air and underwater. This sound is produced by inflated throat pouches, at times augmented by flippers striking the throat. Male walruses also make aggressive clacking sounds with their teeth.

2. Otariid Seals: Sea Lions and Fur Seals While a considerable detail of sounds for several select phocids has been presented, relatively little time has been spent on eared seals. Most of them are known to make bark-like sounds or other "groans and grunts" in air, and the barks of a group of hauled-out California sea lions (*Zalophus californianus*) are loud and far-reaching (to at least 3 km on a still night). Barks tend to have most energy below 2 kHz. These sounds and other interactions result in a physical structuring of the society on a beach or headland. Sea lions also bark underwater, in similar fashion as in air, but otariids tend not to have the complex social signals of many phocids. This is probably because those phocids tend to mate in the water, and sounds are often, although not always, related to social/sexual interaction. Otariids, however, tend to mate on land, and they are in large part relatively quiet in the sea.

Nevertheless, there are sets of clicks, snorts, bleats, and growls produced underwater by Steller sea lions (*Eumetopias jubatus*), and clicks and high-frequency "sheep-like" bleating sounds by northern fur seals (*Callorhinus ursinus*). The clicks of some species have led some researchers to postulate that otariid seals might echolocate, but repeated investigations in captivity have not shed light on this possibility. If they do use echoes for environmental information (and they are likely to do so at a very basic level, at least), this is not nearly as sophisticated as the echolocation capability of many dolphins and bats.

B. Carnivores

1. Sea Otters (Enhydra lutris) Sea otters produce airborne sounds that have been described as whines, whistles, growls, cooing sounds, chuckles, and snarls. They may produce harsh screams when stressed. Airborne vocalizations serve to maintain the mother–pup bond. When a mother dives, the pup at the surface often vocalizes continuously until the mother resurfaces. If the mother does not find the pup upon surfacing, she vocalizes and the pup responds. Pups also vocalize to elicit nursing or grooming. The frequencies of these calls lie between 3 and 5 kHz. No underwater vocalizations have been recorded, although they may exist.

2. Polar Bears (Ursus maritimus) Polar bears may not be quite as vocal as many other carnivores. Males chuff and snort, with powerful rapid exhalations, especially in competitive interactions with other males. Females produce low mew-like calls that may be used for mother/pup recognition.

C. Cetaceans

1. Baleen Whales

A. GRAY WHALES (*ESCHRICHTIUS ROBUSTUS*) Gray whales most frequently produce sounds referred to as "knocks" and pulses. These range in frequency from < 100 Hz to 2 kHz. A series 2–30 pulses last an average of 1.8 sec. Knocks are most common when gray whales are feeding. They are fairly vocal while feeding, relatively quiet while migrating, and most vocal during mating activities in Mexican waters. The source levels of gray whale vocalizations range between 167 and 188 dB re 1 μPa.

Four major signal types have been recorded from migrating gray whales. The first is composed of clicks and metallic-sounding "boings." Boings consist of 8–14 pulses in bursts of up to 2 sec. The frequencies range from below 100 Hz to above 10 kHz. The second sound is a continuous low-frequency moan, ranging between 100 and 200 Hz. The third is another moan with a pulsed structure. The fourth is a pulsed "grunt," a broadband noise, produced by underwater exhalations. The first two types have been recorded predominantly from whales migrating offshore, in deeper water. Whales migrating nearer to shore in shallower water predominantly make the latter two sounds.

Click trains have been recorded from gray whales in Mexico, off Vancouver Island, and from the captive gray whale "Gigi." The click trains range from 2 to 6 kHz and last between 1 and 2 msec. Between 9.5 and 36 clicks/sec are produced.

B. FIN AND BLUE WHALES (*BALAENOPTERA PHYSALUS* AND *B. MUSCULUS*) Fin and blue whales are the two largest species of extant cetaceans. These two species share the common characteristic of producing very low-frequency sounds. Both of these species are well known as sources of "20-Hz" sounds. In fact, both of these species do make calls in this extremely low-frequency region, but their range is wider than initially thought.

While fin and blue whales share their low-frequency characteristics, their calls differ in length. Fin whales produce primarily low-frequency downsweeps that are about 1 sec in length, whereas 20-Hz blue whale calls are typically 20 sec in length. Calls from both of these species generally occur in long, regularly spaced patterns. Sometimes the pattern includes "doublets," i.e., a double pulse with a longer interval between successive doublets.

The frequency range of these calls varies in different ocean basins. Most fin whale calls from the Atlantic are 1-sec downsweeps from ~23 to ~18 Hz. These "20-Hz" pulses regularly occur as a long, regular patterned series of calls. The interval between pulses typically ranges from 6 to 37 sec.

These calls are so low in frequency that they are detected on seismic equipment (geophones). It has been suggested that low-frequency sounds occur predominantly in winter and spring, during the mating time. However, fin whales are known to produce 20-Hz signals year-around, and if their calls are used as a reproductive display, then fin whales may be advertising constantly.

Atlantic fin whales also produce higher frequency calls, usually downsweeps, from 100 to 30 Hz. None of these appear to be produced in a regular manner of the 20-Hz pulses. It has been suggested that these calls are used for social communica-

tion. Fin whales also produce low-frequency broadband rumbles, centered around 30 Hz. It has been suggested that these calls indicate that the whale has been "surprised," as it was recorded when whales were near drifting ships or other objects. The 30-Hz rumble has also been recorded during social interactions between fin whales. Impulsive sounds have been associated with feeding and may be the result of biomechanical action rather than vocalization.

Blue whale calls are much longer than fin whale calls. Blue whale calls share two common characteristics: a fundamental frequency between about 10 and 40 Hz and a long duration between 10 and 30 sec. Variations on this theme are found. Calls recorded off Chile had fundamentals as low as 12.5 Hz and the harmonics ranged up to 200 Hz. These three-part calls lasted an average of 36.5 sec. All three parts of the call were amplitude modulated. These low-frequency moans were accompanied by short 390-Hz pulses.

Blue whales in the Indian Ocean are reported to produce a song, or repeated sets of sounds. These songs consist of four distinct notes. The first, second, and fourth notes are pulsive while the third is a pure tone. The total length of the four notes is approximately 2 min. Song has not been reported for any other population, and it is possible that song may have been recorded from pygmy blue whales (*B. m. brevicauda*).

Blue and fin whale calls are loud and of generally low frequency. These characteristics allow the calls to travel over great distances, and the sounds of these whales have been recorded to be heard at least several hundred kilometers away. It has been hypothesized that whales may hear each other over extents of ocean basins, especially if sounds are channeled into depths of water where characteristics of temperature and pressure interact to "carry" the sounds efficiently. Even if this occurs infrequently, the normally long distances of communication capability indicate that these whales may be considering themselves as parts of an "acoustic herd" over at least 100 or 200 km and may be exchanging basic information about the whereabouts of food or mating opportunities from afar. Research is only now delving into this possibility, although it was presented as a hypothesis by Roger Payne and Douglas Webb in the 1970s.

C. MINKE WHALES (*B. ACUTOROSTRATA* AND *B. BONAERENSIS*) Minke whales are known to produce a variety of different calls and show significant geographic variation in their call structure. Minke whales are difficult to observe in the wild and therefore it has taken many years to even associate some call types with minke whales. Others have only been described in recent years and others almost certainly remain undiscovered. The one seemingly consistent feature of their vocalizations is a low-frequency, short-duration downsweep. This downsweep generally descends from about 250 to 50 Hz and lasts between 0.2 and 0.3 sec. Australian minke whales (*B. acutorostrata* unnamed subsp.) make a vocalization so unusual that it has been termed the "star wars" call. This call consists of a series of three 100-msec pulses ranging between 50 Hz and 9.4 kHz. These pulses are produced simultaneously with harmonically unrelated low-frequency, amplitude-modulated pulses between 50 and 750 Hz. Following the pulses, the whale produces a pulsed tone at 1.8 kHz along with a tonal call at 80 Hz. The tonal call shifts up to 140 Hz as the final component of the complex set of vocalizations. The communicative purpose is unknown.

D. HUMPBACK WHALES (*MEGAPTERA NOVAEANGLIAE*) Two baleen whales are known to repeat sets of notes in predictable fashion, or sing. There may be others. The four-note song of Indian Ocean blue whales was mentioned earlier. However, humpback and bowhead whales (discussed later) are well known for their wide vocal repertoires.

Roger Payne and Scott McVay first described the songs of humpback whales in 1971. Only males sing, almost exclusively on the mating grounds in winter, and it is surmised that song is a mating display; intersexual, for males to attract females; intrasexual, as a male dominance display; or both. Humpback whale songs have a hierarchical structure, from the shortest utterance to long bouts of singing that can last for days. Individual calls (somewhat analogous to musical notes) are referred to as song units. These units are repeated and combined to form phrases. These phrases are repeated to form longer themes. A song is typically composed of between 4 and 12 themes. Songs can last from 5 to 30 min in length before beginning again. Individual humpbacks are known to sing for as short as a few minutes and for 48 hr or longer. There is a tremendous variety of song units, including upsweeps, downsweeps, and complex FM sweeps. Numerous types of amplitude-modulated signals are produced, sometimes described as moans, grunts, rumbles, and ratchets (Fig. 4).

Song units range widely in frequency, from about 20 Hz all the way up to 10 kHz. Individual units can range from fractions of a second to several seconds in length.

Individual whales slowly change the structure of their songs over time. To illustrate this, consider a theme with two upsweeps and a growl. One type of change would be the addition of a third and then a fourth upsweep. Alternatively, the FM upsweeps might exhibit less and less change in frequency until they become pure (constant frequency) tones. These could then actually reverse their frequency modulation and gradually become downsweeps. These changes typically occur gradually, over a period of about 1 month. However, the pace of change in song structure is variable as well. In some years the song changes slowly and in other years it evolves rapidly. It is not known what is responsible for this variation in rate. Whales of an area pay attention to and copy each other so that all whales of a population sing essentially the same song, with only minor variations.

Once they have evolved, individual themes do not appear to be reused. All of the themes are created *de novo*. A comparison of 19 years of songs recorded from the west Atlantic found that while general types of song units do reoccur, none of the same combinations ever reappeared.

Humpback whales also produce a rich repertoire of nonsong vocalizations, generally termed social sounds. Social sounds can be thought of a subset of the song units, uttered in a nonpatterned fashion. On the mating grounds, these sounds appear to be used as acoustic threat displays in conjunction with visual displays and direct physical contact.

Finally, humpbacks produce a third class of calls, known as feeding calls. Humpbacks feed through a variety of lunges through the water at different orientations. Their mouth is held

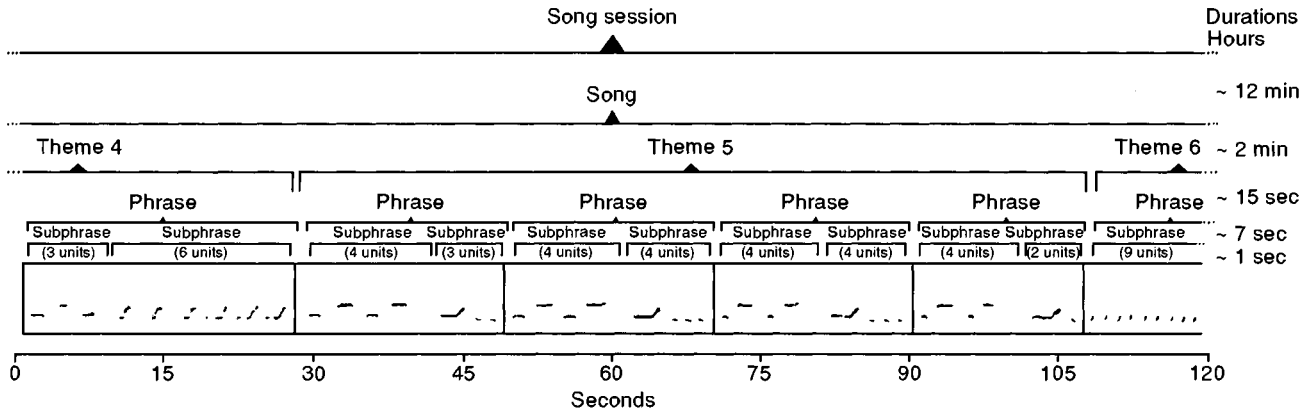

Figure 4 *The hierarchical structure of humpback whale song. Redrawn from Payne* et al. *(1983).*

open during these lunges, and the ventral pleats expand and fill with water and prey. When humpbacks feed on small fish, they may use a cooperative feeding strategy. This entails a group of 6–12 or more humpbacks all vertically lunging through the surface of the water in a coordinated fashion. Humpbacks produce the feeding call while they are maneuvering underwater. The call has been suggested to either coordinate the movements of the whales or manipulate prey. Recent experiments played back feeding calls to herring, which responded by fleeing from the call. These observations suggest that prey manipulation is the most likely function of this call.

The feeding call is a nearly constant frequency tone lasting between 5 and 10 sec. It has been compared to the sound of a train whistle. It is often repeated in a series of calls, and there is sometimes a shift of frequency at the end of the series of calls. There is variation in the frequency of the call, but most are between 500 and 550 Hz.

E. BOWHEAD WHALES (*BALAENA MYSTICETUS*) Humpbacks were the first whale to be recognized as a singer. However, extensive acoustic recording during the population census of bowhead whales off the North Slope of Alaska revealed that bowheads sing as well. Songs have been recorded during the spring migration from the Bering Sea to the Chukchi Sea. Songs are usually heard at the beginning of the migration and less at the end, suggesting that most of the singing occurs in the Bering Sea in the winter.

Song notes are usually longer than nonsong moan and grunt-like calls. Bowheads sing between one and three themes, most often two. Unlike humpback whales, bowhead songs regularly show substantial change in structure in successive years. Within a year, all whales sing the same basic version of song, but there is considerable inter- and intraindividual variation. Most of the sound energy of bowhead calls and song sequences is below 1000 Hz. The songs are frequently composed of both AM and FM components. Bowhead whales produce fewer units and in a narrower frequency range than humpbacks, yet bowheads have an unusually large variation in the tone of their songs, producing a wide variety of different sounding song notes.

In addition to songs, bowheads produce a wide range of calls. There are two main groups, the simple, low-frequency FM calls and complex calls. The FM calls can be categorized by their FM contours, i.e., upsweeps, downsweeps, constant tones, and inflected (change in contour). FM calls are almost always under 400 Hz in frequency. The complex calls have been described as pulsive, pulsed tonal, and high. High calls have frequencies above 400 Hz and sound like a whine. The pulsed tonal is a combination of both frequency and amplitude modulation. Pulsive calls are a mixture of pulses, with both frequency and amplitude modulations. Pulsed tonal calls are often below 400 Hz, but pulsive calls can exceed 1000 Hz.

Because observation conditions are often limited in the Arctic, it has been difficult to associate behaviors with these vocalizations. However, some observations have provided information on some calls. A mother and calf were separated and as they approached each other, loud FM calls were heard. Once they were rejoined, the calling stopped. Migrating bowheads will sometimes produce "signature calls" for a period of minutes up to at least 5 hr (or longer). These signature calls are often made in the context of whales countercalling with each other. Thus it has been suggested that these calls are used to maintain group cohesion. Unlike signature whistles of dolphins, the signature calls of bowheads do not appear to be specific to individuals, and individuals will switch signature call types. These signature calls may also be used to help orient in the ice field. A group of whales has been observed approaching a large block of ice. The early arriving whales only swam around the ice when they were very close. The following whales deflected much earlier, suggesting that they were listening to the echoes of the early whales and using the acoustic information to avoid the ice. Certainly one can imagine that swimming toward quiet areas (where there is no ice to reflect sound) is preferable to swimming toward an area with a strong echo (which could be caused by a large vertical piece of ice).

F. THE REST OF THE BALAENOPTERIDS: SEI AND BRYDE'S WHALES (*B. BOREALIS* AND *B. EDENI/BRYDEI*) Sei whales have been recorded only several times in the northwestern Atlantic. Sei whales produce two phrases each 0.5 to 0.8 sec long. The phrases are composed of 10–20 FM sweeps between 1.5 and 3.5 kHz, each 30–40 msec in duration. There was an interval of 0.4 and 1 sec between the two phrases.

Recordings off California have revealed that Bryde's whales make short low-frequency moans. Moans are between 70 and

245 Hz and last between 0.2 and 1.5 sec. Source levels range between 152 and 174 dB re 1 μPa. Bryde's whales also make a pulsed moan, which ranges between 100 and 900 Hz and between 0.5 and 51 sec in duration. The pulse rate varies between adults and calves. Finally, calves have been recorded making a series of discrete pulses between 700 and 900 Hz. These were recorded from calves when the adult was diving and from a captive juvenile.

Low-frequency moans have been recorded from Bryde's whales in the Caribbean, the eastern tropical Pacific, and off New Zealand. Caribbean whales produced 45-Hz calls that had harmonics and were between 1 and 4 sec long. Whales in the tropical Pacific produced calls of 35 and 42 Hz without harmonics and a call of 52 Hz that did have harmonics. Calls from New Zealand were centered on 22–28 Hz and 70 Hz; these calls did have harmonics.

G. RIGHT WHALES (*CAPEREA MARGINATA* AND *EUBALAENA* SPP.) Calls from pygmy right whales have only recently been recorded. A juvenile was recorded in a harbor and produced only one sound type. It was a short tonal downsweep that began between 90 and 135 Hz and swept down to 60 Hz. Pulses lasted between 140 and 225 msec in duration and were separated by intervals of 430 to 510 msec. Source levels were estimated between 153 and 167 dB re 1 μPa. These calls were very simple and their function is unknown.

The northern (*E. glacialis* and *E. japonica*) and southern (*E. australis*) species of right whales have generally similar calls, but only those of the South Atlantic have been described in some detail. Southern right whale calls have been described in terms of their frequency sweep or structure. They produce an "up" call, an upsweep from 50 to 200 Hz that lasts for about a second. This call appears to be used to bring individuals together, because calling stops once the whales join. "Down" calls are downsweeps from 200 to 100 Hz that are also about a second in length. They may serve to maintain acoustic contact, if not physical proximity. "Constant" calls range between 50 and 500 Hz and are 0.5 to 6 sec in duration. The frequency of these calls remains nearly constant.

Southern right whales make a variety of other sounds, such as high-frequency FM sweeps, amplitude-modulated pulses, and mixed pulses with both amplitude and frequency modulation. Blows (breaths) and slapping body parts on the surface also make sounds. The group type and behavioral context affect the mix of these sounds that are produced. Simple calls were usually used at long ranges and more complex vocalizations were used at shorter ranges.

Baleen rattle is a sound thought to be produced when right whales engage in surface feeding and the upper jaw and the upper portion of the baleen plates are out of the water and the lower portions of the baleen are in the water. As water flows through the baleen plates, they apparently rattle together, producing a series of short broadband pulses between 1 and 9 kHz, with most of the energy between 2 and 4 kHz. This sound is audible both in air and underwater, and may be simply a byproduct of feeding.

2. Toothed Whales The toothed whales, or odontocetes, are all vocal animals *par excellence*. They probably all produce clicks for echolocation, and many produce complicated sets of rapid click trains and whistles, the latter two for communication. This article summarizes sperm whale clicks and the known or believed communication sounds of other odontocetes. Even though toothed whales may be thought of as the most vocally active of all marine mammals, relatively little is known about the details of most species in sound production variability, especially in potential use of meaning of sound. This lack of detail of understanding may, of course, be because of the richness of the repertoires. A school of 500 socializing or feeding dusky dolphins, for example, produces a cacophony of sounds out of which it may be impossible for us to distinguish a particular individual or subgroup. It is likely that the dolphins themselves find meaning in this richness, but then they have evolved into this society, both genetically and behaviorally.

A. SPERM WHALES (*PHYSETER MACROCEPHALUS*) Sperm whales are the largest toothed mammals on earth and have a disproportionately huge head. It is likely that the evolution of that head has in large part been driven by the loud and complicated structure of their clicks, used certainly for communication and probably (although there is some argument on this point) for echolocation as well.

Sperm whales produce a variety of clicks in a variety of contexts. Clicks can occur singly at various intervals, in a short pattern of distinct clicks called a coda, or in a long sequence of tightly spaced clicks known as a creak. The frequency content of clicks differs between sexes. Large males have lower frequency content in their clicks than females and young males.

"Usual" clicks are produced in a regular sequence of clicks at intervals of 0.025 to 1.25 sec and have a duration between 2 and 24 msec. The click interval varies greatly between individuals, but appears to be stable within the click trains of an individual whale (Fig. 5).

Codas are stereotyped, repetitive patterns of clicks. They were originally suggested to serve the function of individual identification, analogous to signature whistles in bottlenose dolphins. Later work, however, has shown that a population of hundreds of sperm whales shared only 13 coda types. This contradicted the individual identification hypothesis, but they do appear to play a role in social communication.

"Creaks" are produced when clicks are produced at a high repetition rate. Creaks sound more like a continuous buzzing sound than individual clicks.

Mature males produce another type of click, called a "slow click" for its low repetition rate. these clicks also have a longer duration, with a mean of 72 msec compared to a 24-msec mean for "usual clicks." Slow clicks have consistent energy concentrations at 1.8 and 2.8 kHz, whereas the energy distribution in the spectra of usual clicks is much more variable.

There are competing hypotheses to explain the unique head of the sperm whale. Malcolm Clarke has pointed out that the spermaceti tissue that occurs in the head is a special lipid that changes density, and therefore buoyancy, based on its temperature. He holds that a sperm whale cools the spermaceti organ to make it denser than water, thus aiding diving. When the whale wants to surface, it warms the spermaceti, thereby decreasing its density and making it buoyant.

The more traditional theory holds that the spermaceti organ is the analogue of the melon in dolphins, and it is used to

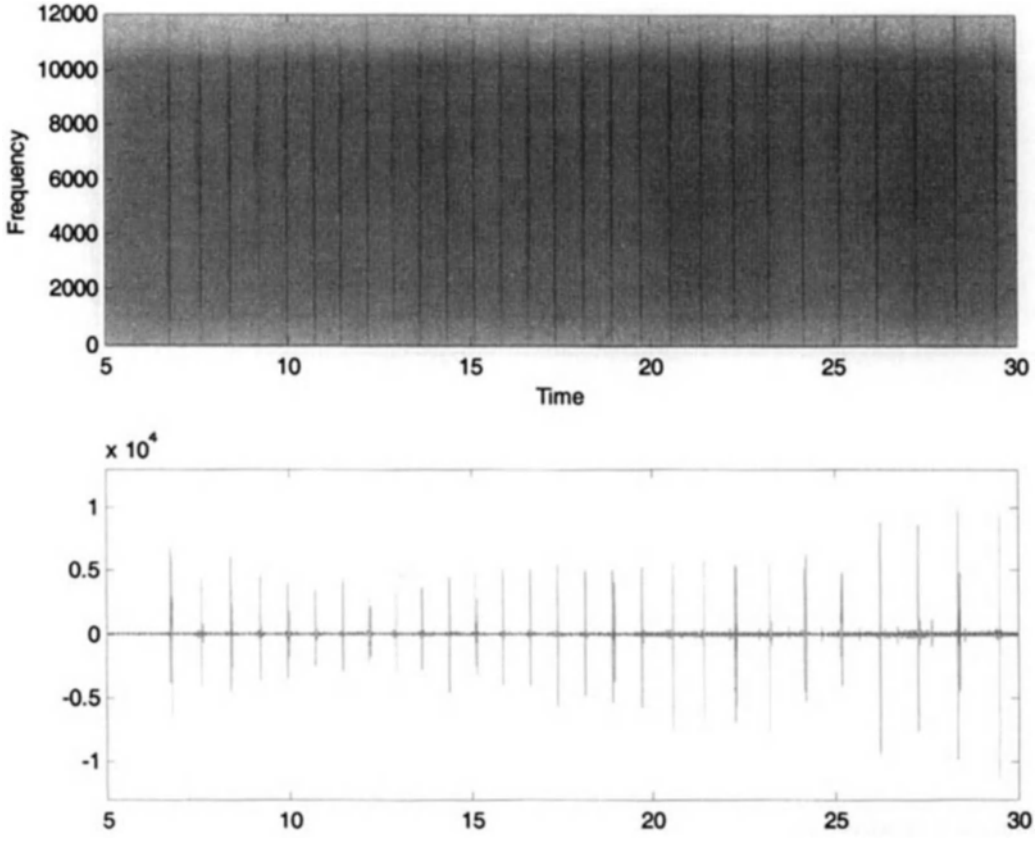

Figure 5 *The spectrogram and waveform of "usual" sperm whale clicks.*

transmit and focus the sound energy of the sperm whale. While there is no doubt that the sperm whale does produce clicks, their functions are still being determined. It is most probable that some sperm whale vocalizations are used for social communication. Differences in structure reveal some information about the sender. However, whether or not clicks are used for echolocation remains unclear. The issue is based on the dual questions of how loud sperm whales are and how much sound is reflected by squid. Squid make up the majority of the diet of the majority of sperm whales. However, squid do not have the bones and air spaces found in bony fish and therefore reflect much less sound than fish. If a sperm whale is going to obtain an echo from a target that reflects little sound, it will have to produce a tremendous amount of sound to get even a weak echo. The question of whether sperm whales can echolocate squid remains unresolved. It is possible that they may be visual predators on squid and acoustic predators on fish. It appears even more likely with relatively recent research findings that sperm whales can at least echolocate onto the surface of the water from below and to the bottom. They therefore can probably place themselves accurately at depth and may even be able to make out details of bottom topography by listening to their click echoes.

Although a detailed description of probable click production is beyond the scope of this article, it is likely that clicks are made near the front of the huge head. A part of a click's energy moves toward the rear of the head, bounces off the upward curving skull of the whale, and is reflected forward. Part of that bounced sound can be reflected backward again because of the placement of an air sac near the front of the head, and thereby one click package can be composed of the main click and a series of tightly spaced intrahead echoes. It is unknown to what degree this complex click package may help in possible echolocation or provide certain information, perhaps size due to differences in click structure by size of head. At any rate, the major sounds of sperm whales are sets of clicks, and these are likely to be critically important in communication among group members. They may also be important for males to gauge each other on the mating grounds and perhaps for females to gauge males. Sperm whale sounds provide a rich set of unanswered questions and potential for further research.

B. KILLER WHALES (*ORCINUS ORCA*) Killer whales that feed on fish in the northeast Pacific tend to live in stable societies of matriarchies that change only by birth, death, and rare splitting, generally when the group or pod becomes very large. Even males born into a pod tend to stay with the pod for life, a condition unusual for any mammalian species. It is not known whether this great stability is a general characteristic for killer whale pods worldwide simply because other groups have not been studied in as much detail (Fig. 6).

On the early 1980s, researcher John Ford discovered that killer whales, who make echolocation clicks, other clicks likely used for communication, pulsed calls of a very rapid click-like structure, and whistles, have different dialects per pod. The

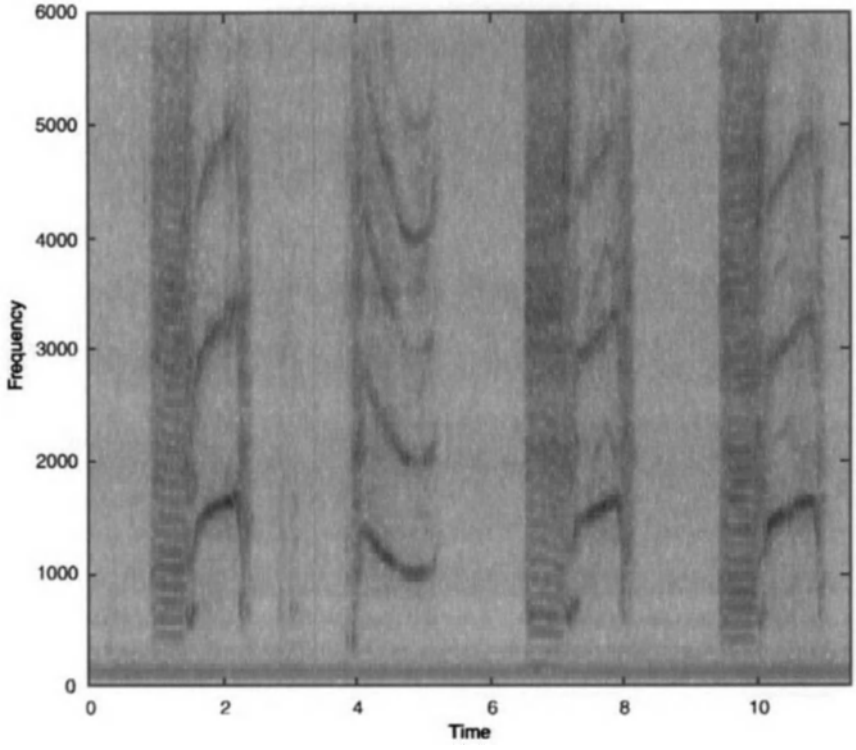

Figure 6 *A typical spectrogram of a killer whale call. This spectrogram also shows amplitude-modulated calls (banded) followed by frequency-modulated upsweeps.*

sounds composing the dialects tend to be within the range of human hearing and predominate around 500 Hz to 10 kHz. Two pods that feed on fish in generally the same area, and who come into acoustic range of one another now and then, can rapidly and at distance distinguish which pod is approaching. Presumably, they can then decide, based on past experience, whether it is prudent to interact at closer range with the other pod or to change course. Researchers who study the pods can distinguish them as well and have placed hydrophones in inlets and bays that announce the arrival or passing by of certain well-known pods.

Dialects may have simply evolved because of behavioral drift as animals that travel together hear each other more than those that do not. However, it is likely that the different dialects now serve important social functions for group cohesion and intergroup recognition. Killer whales in other areas of the world "all" have slightly different sounds as well, but it is presently unknown whether adjacent and at-times interacting pods have a dialect system similar to the system in the Pacific northeast.

C. BELUGAS (*DELPHINAPTERUS LEUCAS*) Sometimes known as the "canaries of the sea," belugas produce a wide variety of whistles, amplitude-modulated pulses, and echolocation clicks. While previous attempts have been made to categorize beluga calls, their nonclick sounds defy categorization. A thorough analysis of the calls of belugas shows that each and every sound can be a point on a continuum between other sounds. Belugas also have the ability to alter the frequency of their echolocation clicks. Individual belugas that were moved from one area to another shifted the frequency of their echolocation clicks from ~60 kHz to ~100 kHz, apparently to avoid the increased background noise in their new habitat in the lower frequency range. Unlike other odontocetes, belugas are able to alter the physical shape of their melon, perhaps to adapt to sound transmission differences due to their movements between the open ocean and less saline estuarine waters.

D. NARWHALS (*MONODON MONOCEROS*) Narwhal clicks are some of the most intense sounds ever measured, up to 218 dB re 1 μPa. These clicks range up to 100 kHz, with peaks at 20 and 40 kHz. Clicks tend to be produced in two types of series: click trains have between 3 and 10 clicks per second, whereas click bursts contain between 110 and 150 clicks/sec. It has been hypothesized that click trains are used for searching for prey and that the much faster click bursts are used as the animal closes in on its prey, analogous to the click repertoires of some bat species.

E. BEAKED WHALES (ZIPHIIDAE) Very little is known about beaked whale sounds. This group is difficult to locate and frequently difficult to approach. There are a few recordings from the wild and from captivity. Whistles are known to range from 500 Hz to at least 10.7 kHz, while clicks range up to 125 kHz. It is believed that these ultrasonic clicks are used for echolocation, and indeed this is a plausible assumption. However, echolocation has not been investigated in detail in the beaked whale group. Whistles, as in dolphins, are most likely used for social interactions.

F. DOLPHINS (DELPHINIDAE) Dolphins also have echolocation clicks, burst-pulse sounds that consist of rapid sequences

of clicks, and (for many dolphins but not all) pure tone whistles. While echolocation and other clicks can have frequencies above 100 kHz, most whistles of dolphins center around 7 to 15 kHz (and are therefore within the human hearing range). Each single whistle tends to last about 1 to 2 sec., rarely up to 3 sec. While the repertoires of many species and populations of delphinid cetaceans [including the killer whales mentioned previously, as well as pilot whales (*Globicephala* spp.) and other open ocean animals] have been described, we know by far most about the common bottlenose dolphin (*Tursiops truncatus*), mainly due to studies in captivity. Researcher Randy Wells and colleagues, working in the Sarasota–Bradenton area of west Florida, have also carried out excellent sound analyses of vocalizing bottlenose dolphins in nature.

There are no universally accepted classifications of the specifics of communication sounds, although begin-frequency, end-frequency, and kind of frequency modulation within the structures of whistles are usually used for descriptions. In bottlenose dolphins, researchers tend to come up with about 20 to 30 distinct whistle sounds, with many intergrading variations among them.

Bottlenose dolphins (and probably quite a few other species as well) have individualized whistle contours that are called signature whistles. With practice, humans can distinguish up to about seven vocalizing dolphins in an aquarium tank, and the dolphins can probably do even better. Signature whistles are certainly used by dolphins to recognize each other, but they also appear to be used in other social contexts. For example, one dolphin will often mimic the signature whistle of another animal in order to begin social contact. Perhaps the mimicry itself is a form of saying "hello."

Interestingly, signature whistles in Florida bottlenose dolphins appear to be more alike in mothers and their male offspring than in mothers and their daughters. The Sarasota population of dolphins is generally matriarchal, with daughters being closely affiliated for many years or for life, but sons leaving the natal group as subadults. It has been hypothesized that sons and mothers thereby recognize each other easily after prolonged times (perhaps extending to years) apart. This recognition could be important in avoiding inbreeding and in facilitating other kin-related social behaviors, such as lowered aggression. While signature whistles have been studied intensively in recent years, the true functions are not yet known.

There is some debate on which dolphin species and populations exhibit individualized sounds such as signature whistles. In common dolphins (*Delphinus* spp.), there appears to be a lack of sound "signature" per individual, and it has been guessed, but with little data support, that there may well be regional dialects per population or subpopulation, as in killer whales.

The complexity of sounds may well have to do with the complexity of behavior or some aspect of level of individual and therefore group "excitement." In long-finned pilot whales (*Globicephala melas*), for example, whales that are resting make very simple nonwavering whistles. Whistle complexity increases during feeding and bouts of socializing, and variability of whistles and other sounds increases greatly when two groups approach each other. Similar situations appear to exist for other delphinids, although detailed analyses of sounds per patterns of behavior have not been carried out, mainly because behavior below the waves is usually poorly known.

In at least Hawaiian spinner dolphins (*Stenella longirostris*) (and possibly in all other social dolphin and other toothed whale groups), there is a general relationship in amount of whistling, burst pulsing, and echolocation clicking with apparent alertness of the group. A resting group produces few sounds, whereas a feeding or socially active one produces many. This means that it is likely that each individual vocalizes more, but it is unknown whether this is merely an average for the group with much individual variation (perhaps different by age, social status, and gender) or whether each animal indeed indicates its state of alertness by the number (and complexity) of sounds produced.

Whistles are generally regarded as social communication signals, and clicks are typically thought to be used for echolocation. However, certain species, including some phocoenid porpoises, are specialized for very high-frequency hearing. These do not produce whistles, and they may use their high-frequency clicks for communication as well as echolocation.

Much has been written about the supposed "intelligence" of dolphins, and they are indeed large-brained highly behaviorally flexible social mammals. However, the supposition by many lay people that dolphins "have language," which implies sentence structure of some sort, with nouns, verbs, and modifiers, is unlikely to be the case. Dolphin sounds are complex, but appear to serve mainly signaling, emotive, and recognition functions. It is likely that as sounds of toothed cetaceans are studied in more detail in the near future, we will discover further complexities and marvelous adaptations besides that anthropomorphic wish for language.

G. PORPOISES (PHOCOENIDAE) Porpoises show a great range in vocalizations. The most commonly studied species is the harbor porpoise (*Phocoena phocoena*). Harbor porpoise vocalizations cover an extreme frequency range from 40 Hz to at least 150 kHz. Their vocalizations are composed of five major components. The first is of low-frequency calls ranging from 1.4 to 2.5 kHz, produced at high amplitudes. There are probably used for long-range detection. Midfrequency calls, between 30 and 60 kHz, are produced at low amplitude. Broadband midfrequency calls are made between 10 and 100 kHz. High-frequency components range between 110 and 150 kHz and are used for detection and classification of objects. All of these calls are variations of click trains. The repetition rate of clicks appears to be fairly constant within a click train when animals are "at ease" and varies between 15 and 36 clicks per second. When alerted by a prey item or other object at short ranges, harbor porpoises can produce between 500 and 600 clicks per second. The last type of vocalization are whistles, which range between 40 and 600 Hz.

D. Sirenians

1. Manatees The Caribbean manatee (*Trichechus manatus*) tends to produce sounds between 0.15 and 0.5 sec in duration. They show a relatively complex structure and range between 600 Hz and 12 kHz, but are typically 2.5 to 5 kHz. The fundamental frequency is at times less intense than the first harmonic. Calls consist mainly of chirp-squeaks, squeals, and

screams. Amazonian manatee (*T. inunguis*) calls are similar in structure, although they may be higher in frequency (6–8 kHz) than those of the Caribbean manatee. The frequency content of vocalizations differs by sex, with female calls lower in frequency than those of males. Neither species is thought to echolocate. Manatees do not vocalize often, but do so under conditions of fear, aggravation, and male sexual arousal. Mothers and calves appear to use acoustic signals to facilitate rejoining each other.

2. Dugongs (Dugong dugon) Dugongs appear to vocalize more often than the normally quiet manatees, with one study recording vocalizations in over half of recording attempts. Dugongs appear to produce three major types of sounds: chirp-squeaks, barks, and trills. They also produce intermediate sounds with multiple components of the three main types. Chirp-squeaks are short frequency-modulated signals that extend upward to 18 kHz. They are about 60 sec in duration, typically have a slight downward trend in frequency, and have between two and five harmonics. Barks are loud broadband signals that range between 500 Hz and 2.2 kHz. No frequency modulation is seen, and the barks last between 0.03 and 0.12 sec. Trills are a series of individual notes, lasting between 100 and 2200 msec. The notes typically begin at about 3.1 kHz and rise to 3.9 kHz. The frequency sweep is not linear, but rather an oscillating up and down. The functions of these sounds are not yet totally clear, but there are good indications that they are used for social communication.

IV. Conclusions

Marine mammals have a very rich behavioral tapestry of sounds. The carnivores that come to land or ice to breed produce some in-air sounds but generally are not nearly as vociferous as their totally terrestrial taxonomic relatives. Almost all marine mammals become loquacious underwater, however. The basic description here merely hints at this richness in an environment where sight and smell are not transmitted as efficiently as sound. Sound is used for communication and for wresting information from the environment. While only toothed whales are thought to have sophisticated echolocation, it is likely that many sounds give information on depth of water, obstruction ahead, or even silent conspecifics simply by the alteration of sound reflections in different environments.

Our acceptance that sound is critically important to marine mammals also gives us cause for worry. Since the advent of motorized shipping and now ever more with industrial seismic, intense military sonar and other human sources of sound, major parts of the oceans are becoming extremely noisy from nonbiological sources. We do not yet know the details of how noises can affect communication, masking, passive listening, and behavior and nervousness of mammals exposed to them.

South American Aquatic Mammals

ENRIQUE A. CRESPO
Centro Nacional Patagónico, Puerto Madryn, Argentina

I. South American Marine and Freshwater Ecosystems

The marine and freshwater ecosystems of South America are very rich in aquatic mammals. Seventy species have been reported to occur within these ecosystems (Table I); most breed locally, and only five species that appear occasionally belong to Antarctic or sub-Antarctic ecosystems. A number of species are found in South America that occur in other parts of the world or the Southern Hemisphere, such as rorquals, ziphiids, and some delphinids. However, 19 species can be considered endemic to the coastal waters or the river systems of South America.

The distribution of marine mammals at sea is related to the distribution pattern of ocean currents that is defined by the characteristics of the major water masses, mainly temperature and salinity. The marine mammal assemblages of South America can be explained in part by the water masses that move around the continent (Fig. 1). However, depth and ocean productivity may also play an important role in the presence, absence, or high concentration of individuals of a given species. Four different water masses each have their own marine mammal assemblage. These are (a) the Humboldt Current, (b) Equatorial Front of the eastern tropical Pacific, (c) Malvinas Current, and (d) Brazil and South Equatorial Atlantic Currents. In addition, a fifth assemblage is found in continental waters; it is heterogeneous due to the isolation between some of the river basins. Finally, a sixth assemblage that could be defined as "erratic circumpolar" can also be found. However, it is composed of isolated individuals from Antarctic or sub-Antarctic populations that breed or live southward of the Polar Front but move erratically into northern water masses.

II. Marine Mammals of Cold Water Marine Ecosystems

In the extreme south of the continent, the Antarctic circumpolar current moves from west to east and splits into two branches: the Malvinas Current in the Atlantic and the Humboldt Current in the Pacific. The cold marine ecosystem in the Pacific almost reaches the equator with waters between 8 and 15°C, but in the Atlantic the cold-temperate system reaches 40°S. Off Peru an upwelling system gives rise to high levels of primary and secondary productivity.

Several cold-water marine mammals are found in both the Humboldt and the Malvinas Currents. Among those species the most common in coastal waters are two otariids (the South American sea lion *Otaria flavescens* and the South American fur seal *Arctocephalus australis*) and two small cetaceans (the dusky dolphin *Lagenorhynchus obscurus* and Burmeister's porpoise *Phocoena spinipinnis*). Other small cetaceans, such as the dolphins of the genus *Lagenorhynchus* (*L. australis* and *L. cruciger;* the latter more pelagic and less known) and the southern right whale dolphin (*Lissodelphis peronii*), can be included. Two related species, the Chilean dolphin (*Cephalorhynchus eutropia*) in the Pacific and Commerson's dolphin (*C. commersonii*) in the Atlantic, are endemic to the southern parts of the ecosystems.

One of the most conspicuous species in the southwestern Atlantic is the southern right whale (*Eubalaena australis*). With a geographic distribution between 20° and 55°S, one of the highest breeding concentrations is at Península Valdés (42°S). It has been recovering in the present century after a long depletion of its population size, at rates over 7%, like other stocks in South Africa, Australia, and New Zealand. The whales can be observed in several places in the Atlantic: Uruguay, southern Brazil, and Buenos Aires Province in Argentina. At Santa Catarina, Brazil, it seems that a new breeding area is starting to be established. On the Pacific side there are signs of recovery and a possible northward extension of the distribution range.

The spectacled porpoise (*Phocoena dioptrica*) is known from the eastern coast of South America and several sub-Antarctic islands, and the South American marine otter (*Lontra felina*) is known from Perú to Staten Island in the southern South Atlantic. Two fur seals are endemic to the Galápagos and the Juan Fernández Archipelagos (respectively, *Arctocephalus galapagoensis* and *A. phillippii*). The latter is also found in a few other places in Peru and Chile. The Galápagos are also home to an endemic sea lion, *Zalophus wollebaeki.*

The pilot whale (*Globicephala melas*), Risso's dolphin (*Grampus griseus*), and killer whale (*Orcinus orca*) can be in-

[a]Endemic species.

cluded in the cosmopolitan species with locally abundant populations. Eight species of Balaenopteridae and eight ziphiids are common to cold waters of both sides of South America. However, the pygmy beaked whale *Mesoplodon peruvianus* has been recorded only from Peruvian waters (also recorded from México and California) and a recently described species, Bahamonde's beaked whale *M. bahamondi,* from the Juan Fernández Archipelago, Chile.

The dynamics of oceanographic and biologic processes that sustain the high productivity of the Peruvian ecosystem can be disturbed by what has been called the El Niño southern oscillation (ENSO event), whose main characteristic is the inflow of tropical waters into the upwelling region close to Christmas. The nature of ENSO is irregular and unpredictable, and the impact on the intermediate levels of the food chain (e.g., abundance of anchovies) affects finally the seabirds and marine mammals. Demonstrated effects of ENSO events on fur seals, sea lions, dusky dolphins, and seabirds have included those on survival, recruitment, and the general condition of the individuals as a consequence of reduced food availability. An ENSO event is part of a more general pattern of oceanographic change affecting not only the Peruvian ecosystem, but also the entire Southern Ocean.

III. Marine Mammals in Tropical Water Ecosystems

On the Atlantic side, the South Equatorial Current moves from east to west and turns southward becoming the tropical Brazil Current with exclusive influence up to 28°S. The northern Equatorial Current moves northward and turns clockwise in the Caribbean zone. Between 33° and 40°S the Atlantic marine ecosystem shows mixed characteristics of the opposing flows of the Malvinas and Brazil Currents. On the Pacific side of South America the Humboldt Current turns to the west after forming the Tropical Front at around 5°S.

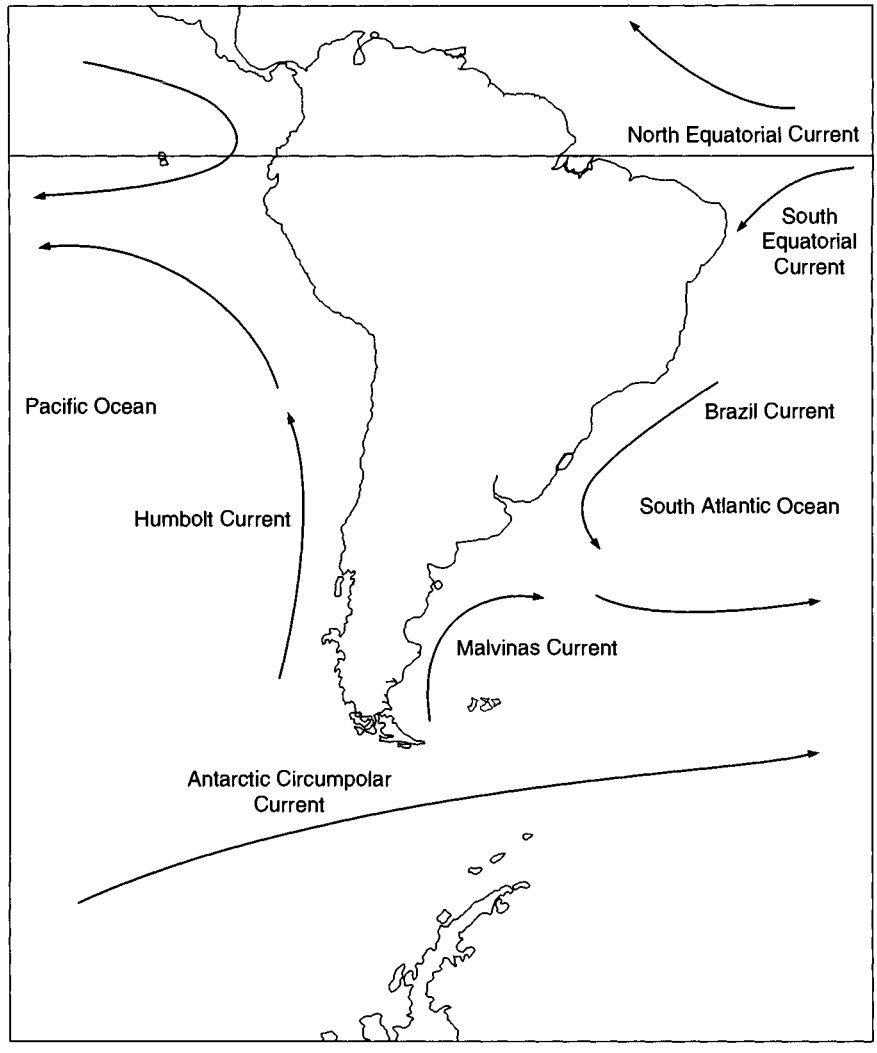

Figure 1 *Oceanic currents around the South American continent.*

Both the Atlantic and Pacific tropical systems show species assemblages typical of warmer waters globally. They include dolphins of the genus *Stenella*, (*S. attenuata*, *S. longirostris*, and *S. coeruleoalba*), common dolphins (*Delphinus delphis* and *D. capensis*), the melon-headed whale (*Peponocephala electra*), the rough-toothed dolphin (*Steno bredanensis*), Fraser's dolphin (*Lagenodelphis hosei*), Bryde's whale (*Balaenoptera edeni*), both species of Kogiidae, the short-finned pilot whale (*G. macrorhynchus*), the pygmy killer whale (*Feresa attenuata*), and the false killer whale (*Pseudorca crassidens*) among others. The Clymene dolphin (*Stenella clymene*), the Atlantic spotted dolphin (*S. frontalis*), the marine coastal population of the tucuxi (*Sotalia fluviatilis*), and the Caribbean manatee (*Trichechus manatus*) are found only in the Atlantic. Some species, such as the common dolphins, the false killer whale, and the bottle-nose dolphin (*Tursiops truncatus*) range from the tropics far south in the Atlantic, in the area of mixed waters of the Brazil and Malvinas Currents. Gervais' beaked whale *Mesoplodon europaeus* is known from the east coasts of North America and Caribbean islands and the eastern Atlantic Ocean.

IV. Aquatic Mammals in River Basins

South America is very rich in river basins, and all the aquatic mammals in continental waters are endemic. The most important hydrographic systems are the Amazon, the Orinoco, and the Paraná-Uruguay rivers. However, other small river systems are located in cold and high-latitude parts of the continent. Most of those systems are isolated from each other. The Amazon and Orinoco basins hold important populations of aquatic mammals. The most conspicuous include the boto (*Inia geoffrensis*), a freshwater population of the tucuxi (*Sotalia fluviatilis*), and the Amazon manatee (*Trichechus inunguis*). Two otters are also found in those basins and also in the Paraná–Uruguay River systems: the giant otter (*Pteronura brasiliensis*) and the long-tailed otter (*Lontra longicauda*). The cold river systems in southern Argentina and Chile sustain populations of the river otter (*Lontra*

provocax), which is also found on Staten Island at the extreme southern end of the continent.

V. Occasional Visitors from the Antarctic

Five species of pinnipeds that breed on sub-Antarctic islands or the Antarctic ice (the Artarctic fur seal *Arctocephalus gazella*, the subantarctic fur seal *A. tropicalis*, the leopard seal *Hydrurga leptonyx*, the crabeater seal *Lobodon carcinophaga*, and the Weddell seal *Leptonychotes weddellii*) move erratically to more northerly waters of both sides of South America. Probably as a consequence of population increases over the last few decades, it has become more frequent to sight individuals moving as far north as the Equator. The southern elephant seal (*Mirounga leonina*) can be included in this list; while most breeding groups are circumpolar, there is an important and increasing breeding stock at Península Valdés, Patagonia, around 42°S in the Atlantic Ocean.

VI. Problems Faced by Aquatic Mammals in South America

Problems faced by marine mammals in South America are much like those they face in other parts of the world. They include incidental catch in fisheries, direct exploitation, competition for fishing resources, and habitat loss and degradation. Most of the species in South America are insufficiently known. For most of them there is no information about abundance and population trends. Exceptions include the pinnipeds, the southern right whale, and few species of small cetaceans such as the dusky and Commerson's dolphins in Patagonia and river dolphins in the Amazon. However, abundance has been estimated for these for only small parts of their ranges.

While large whales are fully protected, giving them the opportunity to recover, a long list of species of small cetaceans are taken incidentally in coastal and high-seas fisheries both in the tropics and in cold-water ecosystems. The most critical situation is probably that of the franciscana, *Pontoporia blainvillei*. However, there are other species or local stocks which interact heavily with different types of fisheries in direct and incidental takes. Examples include the coastal population of the tucuxi in some parts of Brazil, local populations of dusky dolphins in Peru and Patagonia, both species of common dolphins and Burmeister's porpoise in Peru, Commerson's dolphins in Patagonia, and Chilean dolphins in southern Chile. The problem of incidental catch of aquatic mammals in fishing gear has not been addressed by the authorities as part of fishery management to date in the countries of the region.

Direct takes mostly for food, oil, or bait also include the use of genital organs for aboriginal beliefs in the case of small cetaceans and illegal small-scale commerce between South America and Asian countries in a black market in the case of otariids. Cases are known for the Pacific and the Atlantic Oceans and the river basins and include several species. Economic reasons were involved in turning an incidental into a direct catch in Peru during the 1980s. These conditions can be amplified with poverty and hyperinflation. Direct takes are also a matter of concern with other aquatic groups, such as the hunting of river otters for furs in the river systems.

Regarding competition for fishing resources, there is a general perception by fishermen all around the world that some marine mammals, mostly pinnipeds, are currently depleting the target species of fisheries. The perception is sustained by the relative increase of marine mammal populations in the last few decades and the decrease of fishing stocks in the same period. In South America this is thought to be the case with the South American sea lion, *Otaria flavescens*. Even though there has been no formal proposal for culling in the countries of the region, with the exception of Peru where the problem has been discussed by the government, private sector and nongovernmental organizations (NGOs), sea lions are shot illegally by fishermen in many places throughout the distribution range. There is also a general belief that reducing the populations of competitors will increase the stocks of the target species of the fishery, a supposition that to date has not been supported by data; culling carried out around the world has not increased levels of target species or catches.

Loss of habitat is the most important problem that faces freshwater and coastal species. Indiscriminate clearing of rainforest for the use of land in agriculture and cattle growing is currently going on, and many species are declining sharply. Dams and other barriers in large rivers have been or are being planned for hydroelectric power, irrigation, or flood control. These projects have significant impact on regional development and positive benefits for society. Nevertheless, negative consequences in the river ecosystem for river dolphins, manatees, river otters, and other wildlife include, at least, the isolation of populations of aquatic mammals and their prey and unnatural water flows and interruption of migratory paths. In addition to dam construction, other threats include pollution, mining, the use of dynamite for fishing, and incidental and direct catches in fisheries. In coastal areas the most important problems include intensive fishing and POLLUTION by hydrocarbons, agrochemical and heavy metal products, and intensive boat traffic. The importance of each of these varies with the area considered.

VII. Need for International Agreements in Conservation Policies

With the exception of endemic species, most South American aquatic mammals have a wide distribution and occur or breed passing through political boundaries, e.g., those of Brazil, Peru, Uruguay, Argentina, and Chile. Legal protection or status is not the same in each country and sometimes there is little or no enforcement. As an example, the South American sea lion is shot by fishermen in southern Brazil, is one of the tourist targets in Argentine Patagonia, is allowed to be killed if necessary in Chile, and is a potential culling target in Peru. The dusky dolphin is incidentally and directly taken in Peru and northern Chile and incidentally taken in Patagonia. South American fur seals and Commerson's and Peale's dolphins were used for crab bait for many years at the southern tip of South America. The franciscana crosses the boundaries of Brazil, Uruguay, and Argentina and while it is protected by law in the three countries, incidental mortality is still a cause for concern.

At the national level, incidental mortality or bycatch should be considered in fishery management models and decision making. At the international level, agreements should be pro-

moted among the countries of the region in order to give general or particular status of protection for a given species. As an example, in 1991, Colombia, Chile, Ecuador, Panama, and Peru approved the Action Plan for the Conservation of Marine Mammals in the Southeast Pacific in order to help the governments of the region to agree convenient policies for marine mammal conservation and management. The Atlantic region still lacks such an agreement.

South American Sea Lion

Otaria flavescens

HUMBERTO LUIS CAPPOZZO
Museo Argentino de Ciencias Naturales, Buenos Aires, Argentina

The scientific name of the South American sea lion has been under discussion for many years. Two names were in use until a few years ago: *Otaria flavescens* (Shaw, 1800) and *Otaria byronia* (de Blainville, 1820). More recently, use of *O. flavescens* has been recommended; this is the name used throughout the distribution area in South America. The common name changes with location: *lobo marino de un pelo, león marino del sur, lobo marino del sur, lobo común, lobo chusco, leão marinho,* or *lobo marinho de um pelo.* "South American sea lion" is preferable to "Southern sea lion," as it prevents confusion with Australian and New Zealand sea lions, species also distributed in the Southern Hemisphere.

This species is one of seven that make up the subfamily Otariinae, part of the family Otariidae, usually called otariids, or pinnipeds with ears. It is one of the largest and most dimorphic otariids. Adult males are much heavier than females. Differences in size between males and females have also been documented among juveniles, and even newborns. The sex ratio at birth is 1:1. Adult males reach a maximum length of around 3 m and weigh 300 to 350 kg; adult females are about 2 m long and weigh up to 150 kg. The newborn sea lion usually weighs between 12 and 15 kg and is 0.75 to 0.86 cm long. Adult males have a characteristic hairy, thick neck. The color is generally brownish, from the very dark brown of adult males to almost yellow in females. Pups are black at birth. After the molt of the embryonic coat (*lanugo*) at 2 months, the first juvenile HAIR is reddish brown, changing in color with age and sex (Fig. 1). The South American sea lion eats mainly fish and squids, but its diet is very variable and it adapts easily to locally abundant prey, including crustaceans and even penguins.

I. Distribution and Population Status

South American sea lions are widely distributed along the Atlantic and Pacific coasts of South America: from Torres in southern Brazil to Cape Horn in the extreme south of the Atlantic coastline, and from Cape Horn to Zorritos in northern Peru, on the Pacific. Total population has been estimated at 110,000 for the southwestern Atlantic coast, concentrated mainly on the Patagonian coast and southern islands. There is no reliable information concerning the Pacific population, but it is considered smaller.

Variation of the substrate and weather phenomena affect DISTRIBUTION. For example, the occurrence of El Niño on the Peruvian Pacific coast influences the whole marine ecosystem by a drastic superficial thermal inversion that affects the entire trophic web from the plankton up to the top predators. Every time El Niño occurs, there is a drastic population decrease due to higher death rates and migration. Also, on the coasts of southern Brazil and Buenos Aires, Argentina, there has been a great reduction of habitat because of human use of the zone.

South American sea lions do not spend long periods away from the coast, as many pinnipeds do, and they gather in groups or colonies. There are both permanent and nonpermanent colonies; the latter are mainly reproductive settlements. At the permanent colonies, during the breeding season, the individuals that do not participate in the reproductive activity stay in the colony segregated in nonreproductive groups.

A. Population Flow

There is little information regarding migrations and seasonal movements. To the north of the Uruguayan breeding

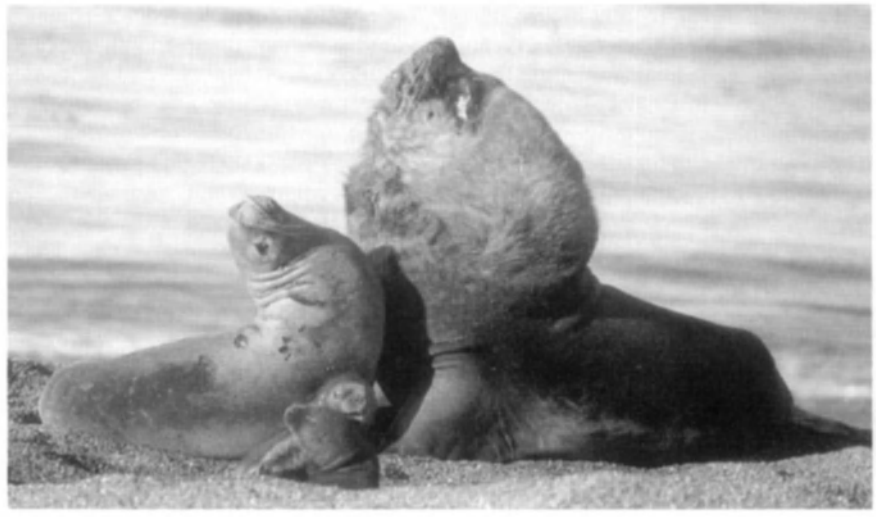

Figure 1 *Adult female, adult male, and offspring of South American sea lion.*

grounds, in southern Brazil, there are only two nonbreeding haul-out rookeries where subadult males predominate, with seasonal movements. Aberrant records for the species have been reported for Rio de Janeiro, Brazil 23°S, and even to 13°S but these are always solitary individuals.

In Argentina, the species was widely distributed from the La Plata river to Cape Horn, but at present only two subadult male rookeries remain in the Buenos Aires Province: at Mar del Plata and Quequén harbors, as well as a breeding rookery at Isla Trinidad, 39°S. To the south, they breed along the Patagonian coast, from Punta Bermeja to Tierra del Fuego. There are 18 breeding and nonbreeding colonies between Punta Bermeja and Punta Leon, in Northern Patagonia, for which a flow of individuals showing a seasonal pattern has been reported. There is a gap of about 200–300 km between the northern and the central Patagonian stocks. The main concentration of this species occurs in central and southern Patagonia, where there are more than 53 breeding and nonbreeding rookeries.

A recent study analyzed the genetic variability between two rookeries: Isla de Lobos, Uruguay, and Punta Norte, Península Valdés, Argentina. The results suggest that both rookeries belong to the same population. The population of the southwestern Atlantic is therefore apparently homogeneous, with movements between rookeries.

II. Reproductive Behavior

Males become sexually mature in their sixth year of age, whereas females produce their first offspring about the fifth year or before. The reproductive behavior of marked individuals was studied for 10 years at Punta Norte rookeries in Peninsula Valdés, Argentina.

A. Mating Strategies

Adult males and females arrive at the breeding rookeries during the first half of December. The males defend a position on the central breeding area, and during the peak of the breeding season they also defend females in ESTRUS. In other rookeries such as Puerto Pirámide (also located at Península Valdés), males defend the territories where females go to mate. In a female-defense polygynous mating system, with males capable of forcing copulation, the female's first priority would be to survive the breeding season and then to mate with high-quality males. Males attempt to mate with as many females as possible. Adult males may maximize their reproductive success through the selective defense of those females that are close to estrus. Adult females develop choice of the male with which they copulate by changing the associated male before giving birth or by mating with more than one male during their maximum sexual receptivity. Thermoregulatory requirements interact with rookery topography to shape mating strategies, variation in mating success, and the mating system type. At Punta Norte, the pebble substrate is homogeneous regarding thermoregulatory advantages. Thus, sites advantageous for THERMOREGULATION are not a limited resource that can be used to attract females. Consequently, males acquire mates by selective female defense or abduction. However, at the Puerto Piramide rookery, a variation in the quality of the substrate with respect to reducing thermal stress favors the development of a territorial system where the best territories contain water or are close to the water. Here, the abduction of females or direct defense of females by males is not required, as females preferentially gather in wet territories. Thus, the topography and substrate of the breeding area, along with thermoregulatory requirements, are driving forces that generate adaptative changes in male mating behavior. Individuals that are sexually mature but cannot compete gather in "bachelor clubs" close to the main breeding area. These subadult or nonterritorial males may develop alternative mating strategies: group raids, solitary breeding (single male with a single female or with a small isolated harem), or female interception (keeping females that leave the main breeding area on the way to and from the water).

B. Breeding

The breeding and pupping season begins in mid-December and extends to early February. Most of the pups are born dur-

ing January, usually 2–3 days after the mother's arrival at the rookery. Copulations occur on land 6 days after parturition, and females spend 2–3 days more with their pups fasting. Mothers begin leaving their pups temporarily and foraging offshore at between 1 and 4 days; each foraging trip is followed by 2 days of nursing bouts on land. Lactation continues for 8–10 months, although it is not unusual to find females with unweaned yearlings. Lactating females spend around 53% of the time at sea diving, with median and maximum depths ranging from 19 to 62 and from 97 to 175 m, respectively. The pups wander about and tend to gather in groups; they spend most of the time sleeping or playing (Fig. 2). The number of pups in these groups increases as the season goes on. When the mother returns to the colony, she calls her pup and they recognize each other by sound and smell. Each female nurses only its own pup. In 10 years of study at Punta Norte, Península Valdés, only three cases of true adoption were documented, although it is not infrequent to see pups suckling from females other than their mothers, "stealing" milk.

The death rate of pups is usually high, with main reasons being the separation from their mothers, starvation, being crushed by large males where the ground is hard, abuse from juveniles, or predation by other species.

C. Dimorphism

The degree of dimorphism of South American sea lion pups is similar to that of other otariids. Newborn males are 9–18% heavier than females at Península Valdés. Assuming that there is no sex difference in energy expenditure by fetuses, sexual dimorphism in the size of newborn pups suggests that South American sea lion mothers invest more energy in sons than in daughters during gestation. Contrary to other otariids, in which males increase in mass faster than females, no sex difference was found in growth rates among South American sea lions. The size dimorphism present at birth in this species persists during the nursing period, suggesting that sons continue to be more costly to their mothers than daughters. It is not known if differences in size found at birth in the South American sea lions of Península Valdés persist until weaning, but there is some evidence suggesting that this may be true.

Six-month-old male pups at the Malvinas (Falkland) Islands are longer than females; the difference in length remains in 18 month-old individuals and is even more marked in older juveniles. Data for other otariids show that sexual dimorphism at birth continues through weaning.

III. Interactions with Other Species

In some areas of their distribution along the South American coasts, South American sea lions live sympatrically with South American fur seals, but they do not compete with them for breeding space because their respective breeding seasons are out of synchrony. Killer whales prey on sea lions that are at sea and have been seen at Península Valdés preying on groups at the shore by surging out of the water onto the beach and returning with a sea lion in their jaws. Sharks have also been seen eating sea lions in Uruguay.

Human exploitation has been hard on pinnipeds. Some species were hunted down to extinction (Caribbean monk seal) or barely survive (Mediterranean monk seal), whereas others were spared thanks to the remoteness of their location, as the Antarctic phocids and the fur seals at Patagonian islands. Pinnipeds in general were killed to obtain oil, fur, and meat either for subsistence or for commercial purposes. The South American sea lion was hunted mainly for oil, as its fur is not as valuable as that of the South American fur seal (*Arctocephalus australis*). In Southern Chile it is still captured by fishermen as bait for the southern king crab. It is also hunted by fishermen who regard it suspiciously as sea lions are supposed to compete for the same fishes they seek and damage fishing gear. The South American sea lion endured long periods of exploitation with a severe reduction in ABUNDANCE. Although it is estimated that only 20% of their historical number remains, recent signs of recovery have been reported.

Southern Fur Seals

Arctocephalus spp.

JOHN P. Y. ARNOULD

Macquarie University, Sydney, Australia

Southern fur seals (genus *Arctocephalus*) are generally recognized as comprising eight species and four subspecies. As the name implies, southern fur seals occur almost exclusively in the Southern Hemisphere with only one species being found north of the equator. They are circumpolar in distribution, occurring in all the Southern Hemisphere oceans. The generic name, *Arctocephalus*, comes from the Greek words *arktos* and *kephale*, meaning "bear headed," and many of their facial characteristics reflect their terrestrial carnivore ancestry.

The majority of Southern fur seals were overexploited during large-scale commercial hunting in the 18th and 19th centuries, and many species were so depleted in numbers that they were considered extinct. Fortunately, because of the isolated nature of the islands on which many southern fur seal species occur, remnant populations persisted and all known species survived. Populations are recovering at various rates, and several species (in particular the Antarctic fur seal, *A. gazella*) have been the focus of extensive research since the 1980s which has improved our understanding of pinniped biology greatly.

I. Diagnostic Characters

The most obvious diagnostic feature separating fur seals from sea lions is the presence of an underfur layer in their pelage. The density of hair follicles in the underfur of fur seals is approximately 50 times greater than that in terrestrial mammals and this layer plays an important role in their THERMOREGULATION. Fur seals are generally smaller than their sea lion conterparts. Another difference between the two groups can also be found in the baculum (penis bone), the tip of this bone being narrow in fur seals whereas in sea lions it is broad. In addition, fur seals have six pairs of upper postcanine teeth, compared to five in sea lions, and the third upper incisor is less circular in horizontal cross section.

The southern fur seals can be distinguished from the northern fur seal, *Callorhinus ursinus*, by the extent to which the fur line extends on the fore flippers. In the northern fur seal the fur stops at the base of the flippers in a sharp line, whereas in southern fur seals it extends across part of the flipper, ending in a line over the metacarpals. A more prominent difference between these species is the shape of the SKULL, with the angle of the slope from the top of the nasal bone to the tip of the premaxilla being much greater in the northern fur seal. This gives the head of the northern fur seal a distinctive shortened-snout appearance in comparison to southern fur seals.

Within the southern fur seals there is a relative uniformity in appearance. This led to some confusion among early researchers about the classification and nomenclature of the various species in the genus. The history surrounding this has been discussed by Bonner (1981, 1994), Gardner and Robbins (1998), and Rice (1998). The classification used here is taken from Rice (1998), and the scientific and common names for each species are given in Table I. The discreteness of their distributions aids in the identification of the different species and in the areas where sympatry occurs morphometric, behavioral, vocalization, and habitat choice differences can be used to separate the species.

Pelage color among southern fur seals is generally uniform dark brown to dark gray on the dorsal surface with a grizzled appearance caused by the tips of the guard hairs (outer fur layer) being white or pale in color. The fur is a lighter color on the ventral surface, especially around the abdomen. There can be considerable variation between individuals of a species in the shading of the pelage and the degree to which it appears grizzled depending on age and sex. For example, older Antarctic fur seal and Australian fur seal (*A. pusillus doriferus*) females often have a lighter, more grizzled appearance than younger individuals. The time elapsed since the last molt, which

occurs annually in late summer–early autumn, also affects the appearance of the pelage due to wear and soiling.

There are two notable exceptions to the general pelage color within southern fur seals. Sub-Antarctic fur seals (*A. tropicalis*) have a distinctive COLORATION: the chest and face (muzzle and around the eyes to just below the ears) are pale yellow or creamy in color while the top of the head and dorsal surface are dark brown-gray (Fig. 1). The demarcation in coloration is more pronounced in males, which also have a conspicuous tuft of dark hair on the forehead that becomes more erect when the animal is excited. In the Antarctic fur seal population on South Georgia, 0.1–0.2% of individuals have a white pelage. These animals are not albinos and have normal skin and eye pigmentation. This white-phase pelage has not been reported in any of the other Antarctic fur seal populations.

Figure 1 *Male sub-Antarctic fur seal* (A. tropicalis). *Photo © J. Arnould.*

Pups of all the southern fur seal species are born with a black natal coat (lanugo). In the Antarctic fur seal and the New Zealand fur seal (*A. forsteri*), pups develop a grizzled appearance soon after birth, whereas in Cape and Australian fur seals (*A. pusillus* subspp.), the ventral surface can vary from gray to pale yellow. In all species, the natal pelage molts 3–4 months after birth to reveal a silky-smooth gray or brown fur.

The Galapagos fur seal (*A. galapagoensis*) is the smallest of the southern fur seals (and the Otariidae) with mean female and male adult mass at 27 and 64 kg, respectively (see Table 1). Most of the other species are slightly larger, with mean masses ranging from 34 to 58 kg for females and 75 to 188 kg for males. The exceptions to this pattern are the Cape fur seal (*A. pursillus pusillus*) and the Australian fur seal (*A. p. doriferus*), which have mean masses of 58 and 76 kg for females and 247 and 279 kg for males, respectively (Fig. 2). These two subspecies also differ from the remainder of the genus in having some behavioral traits reminiscent of the sea lions. In particular, *A. pusillus* subspp. display very thigmotactic tendencies (tolerance of physical contact between individuals), behavior not seen in other fur seals but common in sea lions. In addition, the mode of terrestrial locomotion and aspects of their vocal repertoire resemble those of sea lions more than those of other fur seals do.

Differences in the shape of the flippers can be used as diagnostic characters between several Southern fur seal species, especially when their distributions overlap. For example, the fore flippers of New Zealand seals have a more triangular shape than those of Australian fur seals, which are more paddle shaped and curved (Fig. 3). Similarly, Antarctic fur seals have proportionally

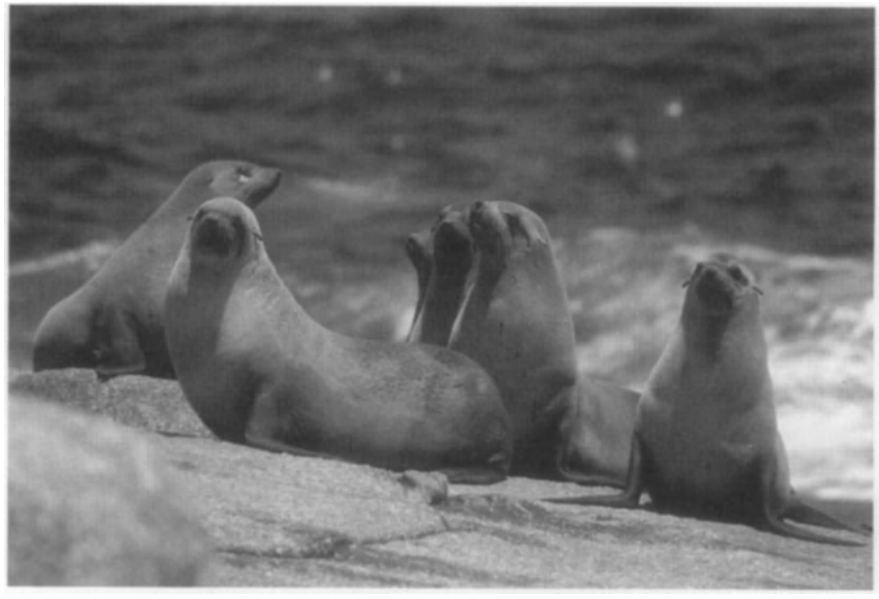

Figure 2 *Female Australian fur seals* (A. pusillus doriferus). *Photo © J. Arnould.*

longer hind flippers than sub-Antarctic fur seals. Snout lengths in southern fur seals also vary, being longest in the Juan Fernandez fur seal (*A. philippii*) and shortest in the Galapagos fur seal. In addition, the rhinarium (soft tissue of the nostrils) is smooth and inconspicuous in Antarctic and Galapagos fur seals, whereas it is inflated and bulbous in Juan Fernandez and New Zealand fur seals.

II. Distribution and Population Sizes

The large-scale HUNTING during the commercial sealing era severely depleted the populations of southern fur seals and it is known to have reduced the breeding distribution of many species. For several species, the presealing distribution and population size are not accurately known, as sealing ships did not always keep detailed records of the number or species taken. This is particularly so for species that have overlapping ranges such as the New Zealand and Australian fur seals in southern Australia and the Antarctic and sub-Antarctic fur seals on several sub-Antarctic island groups.

Figure 3 *Female New Zealand fur seal* (A. forsteri). *Photo © J. Arnould.*

The current breeding distributions of southern fur seals are shown in Fig. 4 and their population sizes are given in Table I. The Guadalupe fur seal (*A. townsendi*) is the only southern fur seal species found in the Northern Hemisphere. Its breeding colonies are currently restricted to Isla Guadalupe, situated off the Pacific coast of Mexico, but it once had a wider distribution, including the Channel Islands (of California) and the San Benito Islands (off Baja California). The most recent (1992) estimate of the Guadalupe fur seal population size is >7000 individuals, making this by far the rarest of the southern fur seals.

The distribution of the Galapagos fur seal is limited to the equatorial Galapagos Islands. The population increased following cessation of the extensive sealing in the 19th century and, currently estimated at 40,000 individuals, may have recovered to presealing levels. However, pup production and reproductive success in this species have been shown to be heavily reduced by the periodic El Niño events, which undoubtedly affects the population size (Trillmich and Ono, 1991).

Further to the south, off the coast of Chile, the Juan Fernandez fur seal is confined to the islands of the same name. This species was once very abundant and is estimated to have numbered over four million prior to exploitation. It was thought to have been hunted to extinction until it was rediscovered in 1966. Currently, the Juan Fernandez fur seal occupies four main breeding colonies and has a population size of approximately 18,000, making it the second rarest of the Southern fur seals.

The South American fur seal (*A. australis gracilis*) is found at many sites along the Pacific coast of South America, from Peru down to the islands west of Tierra del Fuego and in the

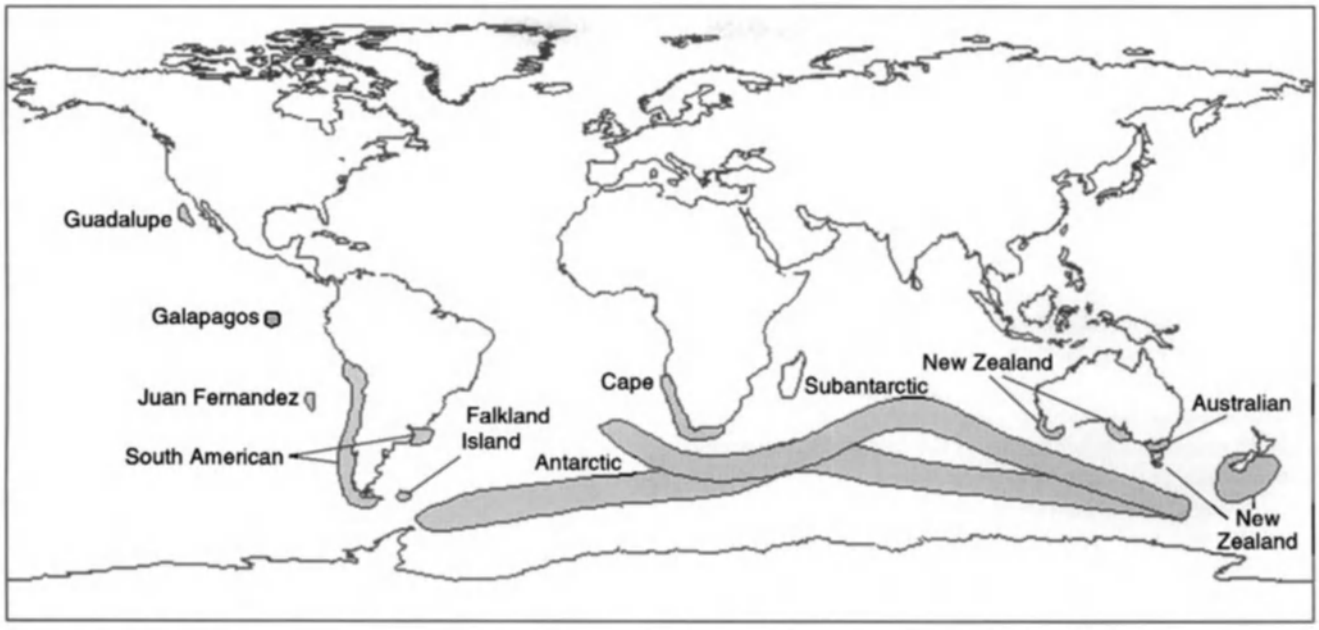

Figure 4 *Distribution of southern fur seals.*

Straits of Magellan, and on the Atlantic coast in southern Brazil and Uruguay. The colonies in Uruguay were exploited regularly in a small, controlled harvest until as recently as the early 1990s. The majority of colonies occur on offshore islands except in Peru where the dramatic increase in population since the 1960s (from 40 in the 1950s to over 20,000) has occurred mostly on three mainland colonies at Punta San Juan, Paracas Peninsula, and San Fernando. The Falkland Islands subspecies (*A. a. australis*) is found on the Falkland Islands where its numbers are still greatly reduced as a result of commercial sealing, which continued into the early part of this century. The total population size for both subspecies is presently estimated at 235,000–285,000 individuals.

In addition to colonies along the coast of the South Island of New Zealand, the breeding distribution of the New Zealand fur seal extends eastward as far as the Bounty, Antipodes, and Chatham Islands and southward to the Snares, Auckland, and Campbell Islands. There are also substantial colonies of New Zealand fur seals along the southern coast of Australia (see Fig. 4). Colonies in the Recherché Archipelago (Western Australia) and Kangaroo Island (South Australia) have been increasing rapidly in size and there is the potential for competition to develop between them and the sympatrically breeding Australian sea lion (*Neophoca cinerea*). The most easterly located colony of New Zealand fur seals in Australia is situated on Maatsuyker Island (<200 individuals; southern coast of Tasmania), which is also an important haul-out site for Australian fur seals. These two species do not presently have sympatric breeding colonies, but historical evidence suggests that the New Zealand fur seal was once found in large numbers alongside the Australian fur seal throughout Bass Strait (southeastern Australia). The total new Zealand fur seal population is estimated at 135,000, with approximately 35,000 being found in Australia. Interestingly, molecular studies have shown significant genetic variation, not only between Australian and New Zealand subpopulations of this species, but also within the latter, suggesting deeply divergent lineages "bordering on species-level distinction" (Lento *et al.*, 1997).

Although separated widely in their distributions, the Cape fur seal and the Australian fur seal show morphological and genetic similarities consistent with their status as subspecies. The Cape fur seal breeds at 25 colonies around the coasts of South Africa and Namibia. It is unique among fur seals in that the four largest colonies are located on mainland sites. The fact that the Namib Desert, which is devoid of large predators, borders these colonies may explain their location. The Cape fur seal has been subject to controlled harvests for over a century, yet the most recent (1993) estimate of population size is 1.7 million individuals, increasing at 3% per annum. In contrast, the Australian fur seal has not been subject to commercial harvesting since 1923, but the population is currently estimated at only 35,000–60,000 individuals and breeding colonies are restricted to nine islands in Bass Strait. While the largest colony (Seal Rocks) has recently experienced increases of 6.2% per annum (Shaughnessy *et al.*, 2000), the population size is still well below the estimated 175,000–225,000 individuals present prior to the commercial sealing era. The slower recovery, and smaller preexploitation size, of the Australian fur seal population in comparison to the Cape fur seal is thought to be attributed to differences in food availability. Australian fur seal colonies are situated in the nutrient-poor waters of Bass Strait, whereas Cape fur seals forage in the highly productive waters of the Benguela Current.

The sub-Antarctic fur seal has a total population of >300,000 and a widely dispersed breeding distribution with colonies on several sub-Antarctic and subtemperate island groups located north of the Antarctic polar front. The main focus for the species is on Gough Island in the South Atlantic Ocean where

colonies total over 200,000 seals. A small population (250) is located to the west at nearby Tristan da Cunha. To the east, in the southern Indian Ocean, substantial colonies exist on the Prince Edward Islands (75,000), the Iles Crozet (1000), and Amsterdam Islands (50,000). A small population also exists to the southwest of Australia on Macquarie Island (<200) where the species breeds sympatrically with the Antarctic fur seal and some hybridization has occurred (Goldsworthy *et al.*, 1999). Hybridization between sub-Antarctic fur seals and Antarctic fur seals has also been recorded at Marion Island (Price Edward Islands) where the latter is greatly outnumbered (only 1200). These two species also breed sympatrically on Iles Crozet.

The Antarctic fur seal also has a very large breeding range and is the most southerly breeding of the *Arctocephalus* species. With the total population in 1990 estimated at over 1.6 million and growing at an annual rate of 9.8%, the Antarctic fur seal is now likely to be the most numerous of the Southern fur seals. Over 95% of the population breeds on South Georgia in the South Atlantic Ocean, but colonies are found on numerous island groups spreading eastward as far as Macquarie Island. All colonies are located south of, or on, the Antarctic polar front with the exception of those at Marion Island, Iles Crozet, and Macquarie Island. The species was considered extinct until a small remnant population of 1000–3000 individuals was discovered in 1950 on Bird Island (northwest tip of South Georgia). From this colony emanated the phenomenal recovery of the species with the recolonization of many sites being attributed to emigration from the expanding South Georgia population. The rapid recovery of the South Georgia population is thought to have been facilitated by its predominant prey, Antarctic krill (*Euphausia superba*), being found in superabundance in the surrounding waters.

The nonbreeding range of most southern fur seal species is often much greater than the breeding distribution and is determined by the movements of males and juveniles. These segments of the population are not restricted in the same way as adult females, which must return regularly to the natal colony in order to suckle their pup. Only in Antarctic fur seals, which nurse their pup for just 4 months, do females depart after weaning from the natal colony (to unknown destinations) until the next breeding period. Except for the Guadalupe, Juan Fernandez, and Galapagos fur seals, males of all species undertake some form of seasonal movement. This usually occurs after the breeding season or during the winter months when local food availability is reduced. The evidence for such movements comes from resighting tagged individuals and/or the predictable seasonal appearance of large numbers of individuals far from their breeding colonies. For example, there is a large influx of subadult and juvenile New Zealand fur seal males at Macquarie Island between February and April. Tagged individuals from colonies in New Zealand and Australia, the only potential source for these animals, have been resighted at Macquarie Island (Goldsworthy *et al.*, 1998). Whether such movements constitute structured migrations or reflect individual dispersal patterns may vary between species and different age classes. Satellite telemetry has been used to show that adult male Antarctic fur seals from South Georgia migrate toward the Antarctic Peninsula following the breeding season (Boyd *et al.*, 1998).

III. Foraging Ecology

Southern fur seals feed on a variety of prey species, including fish, cephalopods (octopus, squid, and cuttlefish), crustaceans (krill, shrimp, rock lobster), and even penguins and other seabirds. Studies of several species have shown great temporal variation in diet composition, with seals exploiting seasonally abundant prey items such as spawning squid or schools of migrating fish. In addition, substantial differences in diet can be found between populations of the same species. For example, the Antarctic fur seal population at South Georgia feeds almost exclusively on Antarctic krill, whereas at Heard and Kerguelen Islands (southern Indian Ocean), seals of this species feed primarily on myctophid fishes. The majority of detailed studies, however, have concentrated on the diet of adult females because natal colonies have been the easiest to sample for feces (the most commonly used technique for determining diet). Consequently, for most species, there is little information on the diet of adult males or how it varies seasonally.

The advent of electronic time-depth recorders in the mid-1970s enabled the foraging behavior of seals to be investigated in great detail for the first time, and numerous studies have subsequently been conducted on most species. As with diet studies, the majority of research on southern fur seal species has involved lactating females due to their relative ease of handling and recapture in comparison to adult males. Although they are known to be able to dive to much greater depths, it has been shown in all species that foraging activity occurs mainly in the surface mixed layer (<50–60 m) at night. The pattern of diving depths throughout the night generally reflects the diel vertical migration of their main prey. The larger body size of males would be expected to enable them to dive deeper than females, and studies of Antarctic fur seals have indeed shown that the mean forage depths of males (100–200 m) are greater than in females (<50 m). Interestingly, these studies have shown that in some areas males forage mostly during daylight hours. Studies on males of additional species are required to determine whether sex differences in foraging behavior are common in southern fur seals.

In recent years, information on the foraging zones of several southern fur seal species has also been obtained through the use of satellite telemetry and geolocation. Studies of lactating female Antarctic, sub-Antarctic, and New Zealand fur seals have found that most foraging activity occurs in up-welling zones, oceanic frontal systems, or continental shelf-edge regions, areas generally high in primary productivity. There is little information about the foraging locations for other age and sex classes in southern fur seals.

IV. Reproduction

The breeding biology of the southern fur seals is similar to that of other otariid seals (sea lions). Females give birth to a single pup each year, and the reproductive cycle consists of a

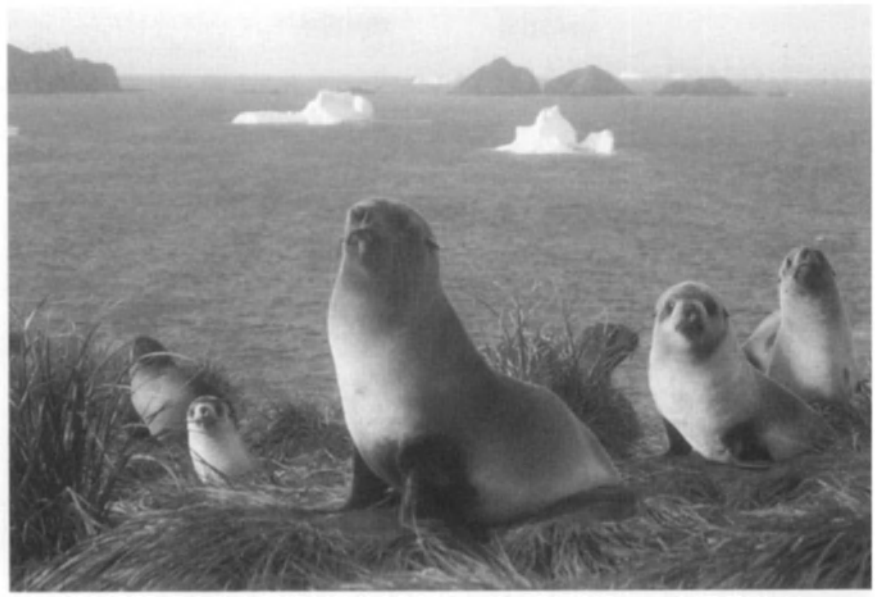

Figure 5 *Antarctic fur seal* (A. gazella) *females and pups. Photo © J. Arnould.*

perinatal attendance period of 6–10 days, culminating in estrus and copulation; an embryonic diapause lasting 3–4 months; and an active gestation of 8–12 months. Females have two pairs of mammary glands and lactate for 8–12 months, but several species may suckle their pup into part of the second year. The exceptions to this are the Antarctic fur seal (Fig. 5), which has a lactation period lasting only 4 months, and the Galapagos fur seal in which weaning may occur at >3 years of age and females can suckle successive offspring at the same time. Differences in food availability and seasonal predictability may explain these divergent strategies.

Timing of the pupping season is fairly consistent, occurring between October and December in the Southern Hemisphere species and in the corresponding late spring–early summer period of June–July in the Northern Hemisphere for the Guadalupe fur seal (Boyd, 1991). Estrus synchrony, measured as the period over which 90% of births occur, varies from 21 days in the Antarctic fur seal to 70 days in the Galapagos fur seal and is negatively related to latitude (Boness, 1991). High estrus synchrony is considered a prerequisite for polygyny, and resource defense polygyny has been demonstrated clearly in New Zealand, Antarctic, and Australian fur seals. As is common in polygynous species, southern fur seals are sexually dimorphic and have some of the most extreme male:female mass ratios of any mammal. In addition, the operational sex ratio, defined as the average ratio of fertilizable females to sexually active males at any given time, has been shown to be correlated positively to the degree of SEXUAL DIMORPHISM in Southern fur seals.

Speciation

RICK LEDUC
Southwest Fisheries Science Center, La Jolla, California

Speciation, in its most basic sense, is the formation of new species. As such, it is an integral part of the evolution and radiation of life on earth. Typically, one SPECIES (the parent or ancestral species) splits into two or more sister species, although there are also descriptions of one species evolving into another over evolutionary time along a single lineage (allochronic speciation). Speciation is also usually considered nonreversible once it is completed; a single species may split into two, but two species do not combine into one. However, in some taxa, particularly plants, hybrid origins of species are relatively common, although in these cases the parent species continue to persist. A more explicit definition of speciation by divergence (and other rarer processes) is partly dependent on the species concept applied. One may think of it as the splitting of an evolutionary lineage (phylogenetic species) or as the formation of reproductive isolating mechanisms between two populations (biological species). Other species concepts (and their related definitions of speciation) appear in the literature; however, the biological and phylogenetic species concepts are the two most often employed. The perspectives on the speciation process can also affect how the taxa are described. For example, in a cladistic interpretation, the ancestor is considered extinct after a speciation event; the sister species that remain are considered distinct from it as well as from each other. However, one may also see descriptions of one species splitting from another, whereby one of the resulting sister species is equated with the parent species.

I. Elements of the Speciation Process

The origins of taxa at all systematic levels, even kingdoms and phyla, lie in speciation events. Despite its importance, and the abundance of evidence for its occurrence, the process is not easily described or understood. One reason for this difficulty is that speciation takes many generations to complete, which for organisms larger than microbes is usually much longer than the life span of any single research project. For large mammals, it may take thousands of years. Data collected on any given taxon therefore represent a "snapshot" of the process, and it may be difficult to tell from this snapshot whether speciation has already occurred, is occurring, or is merely a future possibility. It is not surprising then that it is even more difficult to understand the forces driving the process.

Despite these difficulties, evolutionary biologists have been able to identify some of the elements that play a role in speciation, either as causes or as effects. One common thread of speciation models for sexually reproducing organisms is the evolution of barriers to gene flow between species, i.e., reproductive isolation. This aspect of speciation is explicit in the biological species concept and implicit in other species concepts. These barriers to gene flow, or reproductive isolating mechanisms, are genetically determined biological mechanisms, in contrast to extrinsic barriers such as geographic isolation. Prezygotic isolating mechanisms prevent the formation of HYBRIDS and include social or behavioral segregation, genital or gametic mismatch, and chromosomal or genetic incompatibility. Postzygotic mechanisms include hybrid inviability or sterility, and selection against hybrids. Although they need to be efficient to maintain the integrity of the species, these isolating mechanisms need not be absolute. Wild and captive hybrids of different marine mammal species have been recorded many times, including a fertile hybrid between the blue whale (*Balaenoptera musculus*) and the fin whale (*B. physalus*). The fact that the parent species in these cases are still quite distinct indicates that breakdowns of isolating mechanisms are relatively rare and possibly inconsequential (in an evolutionary sense) events.

Speciation also typically involves the development of some degree of differentiation between two species, be it morphological, behavioral, physiological, or ecological. One may see discussions of so-called cryptic or sibling species, those that are virtually indistinguishable morphologically, yet are reproductively isolated. However, cryptic species is more of an operational designation than a biological one, as our ability to detect differences is limited by the types of data collected or by our limited perceptions. What looks the same to an investigator may be very different indeed to the potential mates. No two valid species per force can be identical in all respects, and characterizing the differences between groups is integral to understanding if speciation has occurred as well as the mechanisms that underlie it.

Some of the differences between species may have arisen during or subsequent to speciation, i.e., during or after their establishment as reproductively isolated taxa. However, many other differences between species have their origins in the geographic variation that was inherent within the parental species prior to the speciation event. Generally, whether originating before, during, or after speciation, most differences are caused and maintained by differential selection and adaptation to the environment, but they may be subsequently enhanced or even new differences added by the mechanisms of species recognition and mate choice (sexual selection) among individuals. In fact, differences involving species recognition and mate choice may be important factors in prezygotic reproductive isolation. Furthermore, in addition to the differences brought about by natural and sexual selection, many other genetic differences arise that are selectively neutral and often invisible above the molecular level. These are by-products of reproductive isolation, mutation, and genetic drift and are not integral to the speciation process, although they may provide good evidence of its occurrence. In the absence of extensive breeding data, distinct molecular or morphological differences usually provide indirect evidence for reproductive isolation, in much the same way that some differences also provide indirect evidence for differential selection.

In the classic speciation scenario, the geographic range of an ancestral species is split by a vicariance event, creating two

allopatric populations. In time, the two populations become differentiated in both genotype and phenotype by adapting to selective differences in their respective environments, by the accumulation of selectively neutral mutations, or both. At this stage, their biological reproductive isolation is largely theoretical, as their geographic isolation precludes any opportunities for interbreeding. If range expansion later leads to the populations becoming partially sympatric, and the gene pools still remain distinct, either by pre- or postzygotic isolating mechanisms, then speciation can be considered complete. If only postzygotic mechanisms have developed, then reinforcement would occur quickly via selection for prezygotic isolating mechanisms, such as social segregation or refinements of mate choice. In other words, if hybrids were inviable or sterile, the selective pressure for positive assortative mating would be strong.

II. Variations of the Process

There have been a number of challenges to and complications of the basic sketch of the speciation process depicted above. For example, is geographic isolation, or allopatry, necessary for the genetic differentiation and formation of the reproductive isolating mechanisms that are needed for speciation, or can such mechanisms arise in sympatry or parapatry? Closely related sympatric species are very common in nature and their geographic origins are not always evident. Due to the swamping effect of even limited interbreeding between incipient species (populations on the verge of speciation), it has been difficult to formulate broadly applicable and plausible evolutionary models to explain speciation in sympatry. Therefore, the observations of sympatric sister species have usually been interpreted as the result of secondary contact between species that originally formed in allopatry. However, not all cases of sympatric sister species can be explained so easily. One well-known example is the monophyletic swarm of closely related African cichlid species that inhabit geologically young Lake Victoria. To use allopatric speciation as a causal mechanism of this swarm, which certainly arose within the confines of the lake, one must invoke allopatry on a small scale, such as between separate reefs along the shoreline, followed by secondary contact. It is debatable that this mechanism could account for the large number of species present. However, recent speciation models that combine ecological variation, mate selection, competition, and differences in morphological and/or behavioral characteristics hold promise as realistic mechanisms for sympatric speciation. In marine mammals, sister species that are at least partially sympatric are common (e.g., the common dolphins, *Delphinus* spp.; the harbor and larga seals, *Phoca vitulina/P. largha*), as well as others who are parapatric (e.g., the two South American species of *Trichechus*, the Caribbean and Amazonian manatees). Generally, the mobility of marine mammals makes microallopatric speciation models implausible, but in some cases, the biogeographic patterns of the species do not lend themselves easily to an explanation involving separation and secondary contact on a larger scale. In addition, the complex behaviors of many marine mammal species could facilitate rapid evolution of the prezygotic isolating mechanisms that are important components of sympatric speciation models. Although it has not been investigated, such models may be applicable to some marine mammal species pairs.

Even the most ardent advocates of sympatric speciation concede that allopatric speciation has played the major role in evolution. However, even within the basic framework of allopatric speciation, questions still need to be addressed. One is the role played by ecological and selective differences in the speciation process. When two populations diverge so that speciation results, are the differences generally due to differing selective pressures or just to simple geographic isolation persisting over sufficiently long periods of time? The incorporation of selection into the speciation process, first argued by Darwin, is integral to the idea of ecological speciation and adaptation. Furthermore, if relatively few mutations can lead to key morphological adaptations, divergence and speciation can be very rapid, whether in sympatry or in allopatry. Such a scenario is plausible in the case of closely related species that demonstrate simple yet dramatic differences, such as long- and short-beaked species of *Delphinus* (*D. capensis* and *D. delphis*, respectively). With behaviorally complex animals such as marine mammals, one must also consider whether morphological adaptations allowed exploitation of a new niche or whether there were behavioral shifts that led to changes in the selective pressures on the morphological characters. In the case of the resident and transient killer whales (*Orcinus orca*) in the northeastern Pacific, the behavioral divergence in foraging strategies appears to be greater than the morphological differentiation between the two groups.

In contrast to the ecological speciation discussed previously, studies on terrestrial animals have found evidence that long periods of geographic isolation, even in nearly identical habitats, can be sufficient to bring about speciation. In these cases, it is thought that ecological adaptation has played a lesser role in speciation than geographic separation. This model may also have relevance to marine mammals. For the 13 or so species of the beaked whale genus *Mesoplodon*, which are clearly distinct species but morphologically and behaviorally very similar, their critical feeding habitats have been hypothesized to be sufficiently uniform over large geographic scales to imply that speciation was more likely driven by differences in sexually selected characters that arose in allopatry rather than by adaptations to differing environments. In other words, ecological adaptation has played a relatively minor role in the radiation of this genus. Under this type of scenario, the differentiation of male secondary sex characteristics, for example (which are presumably selectively neutral relative to the environment), requires concerted evolution of both the genes coding for the male sex traits and for those coding for female mate choice.

Besides the underlying mechanisms for speciation in allopatry, one must also consider the extrinsic mechanisms that lead to populations becoming allopatric. In the vicariance model of biogeography, the range of a parent species becomes split when geographic barriers to gene flow arise within areas previously occupied. The resulting allopatric populations then differentiate via selection or drift into separate species. For

example, many terrestrial organisms of the north temperate regions had their ranges bisected during the Pleistocene by glaciers advancing down the middle of the continents. In many cases, the daughter populations on either side of the ice diverged into different species, not interbreeding even when secondary contact occurred with the retreat of the glaciers. For marine organisms, a widely recognized vicariance event is the rise of the Isthmus of Panama approximately 3 million years ago, blocking dispersal between the eastern tropical Pacific and the Caribbean. Many sister species of fish and invertebrates occur on opposite sides of the isthmus and show levels of molecular divergence compatible with 3 million years of separation. However, there are no recognized sister species of marine mammals that are separated by this barrier and thought to have arisen as a result of its formation. This may be due to the extreme mobility of cetaceans (the only marine mammal group with significant diversity in tropical latitudes), which facilitates gene flow on a global scale, at least on the time scales necessary for speciation. After all, most tropical cetaceans, especially the pelagic species, have pantropical distributions. Some other plausible vicariance events in the marine environment that involve physical barriers are a drop in sea level causing the isolation of peripheral seas (e.g., Mediterranean Sea) or the spread of arctic ice sheets isolating the North Atlantic from the North Pacific. The influence of events such as these on marine mammal speciation has yet to be examined.

In many cases, the barriers that arise may be more ecological than physical, such as wide expanses of unsuitable habitat. Examples include warm equatorial waters acting as barriers for cold temperate and polar species or deep pelagic waters for coastal and neritic species. In some cases, these barriers are intermittent, in that certain climatic conditions periodically weaken them as obstacles to dispersal. Dispersing animals may be able to cross such barriers and found new populations, with no regular occupation of the intervening geographic region. This mechanism is comparable to an island model of biogeography for terrestrial organisms, where small groups of founders disperse to islands from a source region and speciate allopatrically. STRANDING records of many marine mammal species contain extralimital records, or stragglers, of individuals or groups that wander far outside their normal range. If such wanderers are able to survive and reproduce in their new haunts but subsequent dispersal is infrequent enough and/or selective pressures are different enough, the new population may differentiate into a new species. This is a plausible mechanism for the rise of species groups characterized by (mostly) widely allopatric species, each with fairly restricted ranges, such as species in the dolphin genus *Cephalorhynchus* and fur seal genus *Arctocephalus*. In one scenario, during glacial maxima, cold boundary currents may have extended far enough into low latitudes for cold temperate species of the Northern Hemisphere to invade the Southern Hemisphere (or *vice versa*), giving rise to the so-called antitropical species pairs, examples of which are found in the genera *Lissodelphis* (right whale dolphins), *Hyperoodon* (bottlenose whales), and *Mirounga* (elephant seals), or to antitropical distributions of conspecific populations, as in the long-finned pilot whale (*Globicephala melas*) or in some mysticetes. Conversely, in a warm period, the poleward extension of warmer waters may have allowed tropical species to disperse around the Cape of Good Hope, invading the Atlantic Ocean from the Indian Ocean and speciating in the respective ocean basins (e.g., perhaps giving rise to the Atlantic endemic dolphin species of *Stenella*, *S. frontalis* and *S. clymene*). In some cases, however, it may be difficult to differentiate between a vicariance event and a dispersal event. For example, during the glacial maxima mentioned earlier, it is difficult to tell if a small founding population dispersed across the equator or if the ancestral species was able to extend its normal range to and across the low latitudes, only to be divided anew by a warm water habitat during the interglacial period. Some clues may be found by examining unrelated taxa. During vicariance events, whole biotas may be divided at the same time, giving rise to numerous species pairs of different taxa, but all with similar distribution patterns. Because the different species in a community can be assumed to have widely varying dispersal abilities, dispersal events would be less likely to lead to such a congruence of distribution patterns across unrelated taxa.

When secondary contact occurs between two previously allopatric populations, the reproductive isolation of two new sympatric species is only one possible outcome. Alternatively, one species may outcompete and eliminate the other, or the two might interbreed and a zone of intergradation may arise. Only in the first two cases would speciation have been completed, and the outcome may depend on the degree of differentiation between the two populations or the stringency of mate choice by individuals. However, only the first result, that of two species occurring in sympatry, will be evident to an investigator after the fact. From the other results, it would be difficult or impossible to determine that separation and secondary contact had ever occurred, let alone speciation. This is important to remember when making inferences about the degree of differentiation or duration of separation that is required for speciation; sympatric species represent only those cases where differentiation was sufficient to cause reproductive isolation *and* to allow the coexistence of the two species.

III. Other Factors

In addition to the aforementioned problems in describing the speciation process in general, other problems can arise when interpreting it with real animals. At the onset, inferences about speciation patterns and mechanisms require a good understanding of the systematic relationships among species. This understanding cannot be taken for granted; the systematic relationships within many marine mammal taxa are but poorly understood. For instance, the delphinid genus *Lagenorhynchus* has long been thought to contain three species in the temperate Northern Hemisphere and three in the Southern Hemisphere, their origins representing perhaps three dispersal events across the tropical latitudes. However, it has been suggested that the two species in the North Atlantic are unrelated to the other four, which leaves only one antitropical species pair in the group and limits hypothesized transequatorial speciation to the Pacific Ocean basin. In another example, one

hypothesized origin for the species of seals in the genus *Pusa* is that the landlocked species that occur in Lake Baikal and the Caspian Sea (*P. sibirica* and *P. caspica*, respectively) are offshoots of the mostly marine Arctic Ocean species *P. hispida*, resulting from southward dispersal during a glacial period. Alternatively, they could be descendants of the extinct *P. pontica*, which occupied the vast inland Paratethys Sea during the Miocene and Pliocene. Under the latter scenario, the disappearance of the Paratethys Sea would represent a vicariance event that isolated the ancestors of *P. sibirica* and *P. caspica*. This hypothesis also illustrates the importance of incorporating fossil taxa into inferences about speciation patterns and mechanisms.

The rate of speciation is dependent on many factors, including the population sizes of the incipient species, the differences in selective pressures that they are under, and the level of genetic variation contained in the populations. If a few individuals colonize a new area, or if a vicariance event isolates a small population at the periphery of a species range, the smaller population is likely to be under different selective pressures than the rest and is also likely to represent a biased sample of the source gene pool. These factors together can make their divergence and speciation proceed fairly rapidly. Some genetic macromutations that involve large sections of chromosomes can accelerate the process even more, providing essentially instant reproductive isolation, provided that enough individuals with the new arrangement arise for reproduction to occur and a new gene pool to be established.

Ever since Darwin considered how species arose and proposed a mechanism for evolution, our understanding of the speciation process has been refined. There are many elements that come into play, such as adaptation, selection, genetic drift, competition, dispersal, mate choice, social organization, and mutation. By developing speciation models and collecting appropriate data on various taxa, evolutionary biologists continue to investigate how important these different factors are and how they interact, both in general and for specific speciation events.

Species

WILLIAM F. PERRIN
Southwest Fisheries Science Center, La Jolla, California

I. What Is a Species?

Although the term "species" is widely used, there is no agreement on exactly what it means beyond the general conception of a basic taxonomic or evolutionary unit. It is very important to make progress in our understanding of species and how to define them, not least because much of the legal machinery of international conventions, national legislations, and regulations dealing with wildlife and the conservation of biodiversity uses the term in specifying what they seek to protect. If we cannot agree on what constitutes a wild species, we may not be able to agree on how to conserve and protect it.

There are a number of species concepts in use for vertebrates (Claridge *et al.*, 1997). In the *biological species concept* (BSC; Mayr, 1963), a species is a group of interbreeding or potentially interbreeding individuals separated from other such groups by intrinsic (genetically fixed) barriers to gene flow. In cases of sympatry or parapatry, direct evidence of noninterbreeding may be available, but more commonly morphological separation has been used as a proxy to indicate lack of gene flow; in this case the definition works fairly well. In the case of allopatry, however, there is difficulty. While the same operational criterion has been used, in nearly all such cases we do not know whether the groups would interbreed if the chance arose. The barrier to interbreeding may be a purely physical geographic one.

In the more recently developed *phylogenetic species concept* (PSC), a species is "the smallest population or group of populations within which there is a parental pattern of ancestry and descent and which is diagnosable by unique combinations of character states" (Cracraft, 1997), with no inference about potential interbreeding. Indeed, interbreeding is considered a shared primitive character and, as such, is not able to diagnose a lineage, which the PSC requires. In the case of sympatry, this concept does not differ materially from the BSC. Both have difficulties with allopatric populations (biological subspecies may equate to phylogenetic species) and with paraphyly. Phylogenetic taxonomists insist on reciprocal monophyly (having diagnostic unique characteristics, a single common ancestor, and no reticulation) between most closely related (sister) species, but this may be violated by the real phenomenon of lineage sorting in the case of some newly evolved but widely recognized species; e.g., because polar bears evolved from brown bears relatively recently, some brown bears are still related more closely genetically to polar bears than they are to other brown bears. In practice, adherents to the biological species concept use morphological characters in exactly the same way as phylogenetic taxonomists, albeit as proxy indicators of reproductive isolation. One difficulty faced by

strict phylogenetic species-level taxonomy is that different genes or sequences may have different phylogenies due to differential modes of inheritance or introgression; a gene tree may not equal a species tree.

The two species concepts are actually complementary perspectives on evolution and can reinforce each other. To quote Avise and Wollenberg (1997), "Historical descent and reproductive ties are related aspects of phylogeny and jointly illuminate discontinuity." Furthermore, more important is not the process of specifying units to fit into the simplifying Linnaean binomial system, but rather describing and understanding in detail the coalescent genealogy and demography of discontinuous populations. Where did they come from, how are they different, and where are they likely to go? Whether they are called species (always, under the phylogenetic species concept) or subspecies (sometimes, under the biological species concept) is little more than semantics rooted in perspective. This is generally true also in the conservation of diversity. For example, named subspecies are accorded the same legal protection as species in the U.S. Endangered Species Act and Marine Mammal Protection Act. However, in the IUCN (International Union for the Conservation of Nature, or World Conservation Union) scheme of categorization of threatened taxa, species are given higher priority for protection than subspecific taxa or populations (IUCN, 1996).

There are additional species concepts, e.g., the *cohesion species concept* (Templeton, 1989), under which a species is "the most inclusive group of organisms having the potential for genetic and/or demographic exchangeability." Some pairs or groups of sympatric or parapatric species, such as wolves (*Canis lupus*) and coyotes (*Canis latrans*), may make up *syngameons* (Templeton's term) of species that are fully interfertile and may at times interbreed extensively but nonetheless have persisted separately for GEOLOGICAL PERIODS of time. Some of the species of southern fur seals (*Arctocephalus* spp.) may fall into this category (discussed later). Despite sporadic or scattered interbreeding, they would qualify as full species under the cohesion species concept.

While the various species concepts are necessary (because of the legal need to define units for conservation) and laudable attempts to model the results of actual evolutionary processes, they are human constructs, and as for all such constructs, in certain circumstances even the most commonly accepted species concepts fray at the edges. One problem of the biological species concept in its application (mentioned earlier) is that of closely related allopatric species, whether they be defined by morphological or genetic characters. If at some point they became sympatric or parapatric because of some geological or climatic change, would they then freely and effectively interbreed (be one species)? Are they a little different from each other only because of inconsequential genetic drift due to physical separation or are their differences the result of important differential ecological selection that has led to a permanent parting of their evolutionary paths? Even if their morphological differences are great, the question remains of whether this is due to large genetic differences, or of pleiotrophic effects of a small difference unassociated with genetic differences that would prevent interbreeding? For the most part, of course, answers to these questions will remain unobtainable. However, we can deduce what might happen from looking at the results of some "natural experiments." In one possible example, a zone of hybridization/intergradation between two subspecies of spinner dolphins, *Stenella longirostris*, in the eastern tropical Pacific is thought to perhaps be the result of recontact after separation during an earlier cooler climatic period (Perrin *et al.*, 1991). HYBRIDIZATION in the putative zone of recontact is evidenced by greater variance in body size and color pattern. The two subspecies, the eastern spinner *S. l. orientalis* and Gray's spinner *S. l. longirostris*, are morphologically so dissimilar that they were formerly thought to belong to different species (eastern spinners were identified as *S. microps* and Gray's spinners in Hawaii as *S. roseiventris*).

Thus, some of our present allopatric species may be transient taxa that will be absorbed or blended back into a pooled line of descent; i.e., they were never really "good" species at all.

Antitropical species seem especially good candidates for potential recontact and subsequent reticulation; sporadic movement of cool-water forms across the equator during cooler geological periods is thought to have played an important role in speciation, e.g., in the porpoises, including the formation of antitropical pairs of putative species. Species pairs that potentially represent such transient situations include the northern and southern right whale dolphins *Lissodelphis borealis* and *L. peronii*, the Pacific white-sided dolphin *Lagenorhynchus obliquidens* and the dusky dolphin *L. obscurus*, the northern and southern right whales *Eubalaena glacialis* and *E. australis*, Baird's and Arnoux's beaked whales *Berardius bairdii* and *B. arnuxii.*, North Atlantic and southern bottlenose whales *Hyperoodon ampullatus* and *H. planifrons*, and the northern and southern elephant seals *Mirounga angustirostris* and *M. leonina*.

Examples of nonantitropical allopatric species complexes include the four *Cephalorhynchus* species *C. hectori*, *C. commersonii*, *C. eutropia*, and *C. heavisidii;* they are sharply distinct morphologically but undoubtedly closely related. The Ganges and Indus susus (formerly *Platanista gangetica* and *P. minor*) are presently separated geographically but are thought to have been in contact in Recent, perhaps historical, time, and Rice (1998) has recognized the likely inconsequential nature of any differences by downgrading them to subspecies in *P. gangetica*. Among pinnipeds, the eight currently recognized species of southern fur seals, *Arctocephalus* spp., are almost entirely allopatric, but there are at least four breeding sites where two species (*A. gazella* and *A. tropicalis*) have begun to co-occur as populations have recovered from severe depletion by sealing in the last century (Rice, 1998). At two of these (Marion Island and Heard Island), limited hybridization has occurred, but at the others (Îles Crozet and Bass Strait) it has not been observed. In the North Pacific, there are two allopatric species of sea lions in the genus *Zalophus* (formerly three; the Japanese sea lion *Z. japonicus* is almost certainly extinct). The three seals in the genus *Pusa* are allopatric, albeit strongly differentiated. The allopatric Mediterranean monk seal *Monachus monachus* and Carribean monk seal *M. tropicalis* are very similar morphologically (the latter is extinct). The three manatee species *Trichechus manatus*, *T. senegalensis*, and *T. inunguis* are allopatric.

All of these are potential cases of geographical forms within a species being perceived as evolutionary species because of allopatry. In some cases, of course, the question is entirely moot. For example, while the Orinoco and Amazon drainages could merge in the future (bringing *T. manatus* and *T. inunguis* into contact and possible full interbreeding), the same could not happen for Amazon and Congo drainages (inhabited by *T. inunguis* and *T. senegalensis*) under any conceivable geological scenario short of reversal of continental drift; thus the latter two forms are "good" species *perforce* under any species concept.

All of the marine mammal species recognized today were described on morphological grounds. For the cryptic pair *Delphinus delphis* and *D. capensis*, genetic data provided part of the basis for recognition of more than one species where previously there had been thought to be only one. [A third species, *D. tropicalis*, is of uncertain status pending both further morphologic and genetic investigation (LeDuc *et al.*, 1999).]

The operational criterion of at least one absolutely differentiating character that is commonly used to indicate species-level difference in morphologically based taxonomy has been extended by some to genetic characters. This is done by considering one fixed difference in DNA sequence between populations (in sympatry or allopatry) to connote species-level difference. However, the potential number of genetic characters (total number of nucleotides in the genome, several billion) is so much greater than the potential number of morphological characters, probably by several orders of magnitude, that this argument by analogy seems injudicious. In fact, genetic investigations have found such fixed differences between certain isolated human populations. Few would argue then that these populations must comprise separate species, as they are undoubtedly fully interfertile and satisfy the criteria of a single species under the biological species concept or any concept of evolutionary species. In another example, Hector's dolphins, *Cephalorhynchus hectori*, from east and west sides of the South Island of New Zealand were found to have no mtDNA control-region sequence haplotypes in common (Pichler *et al.*, 1998). They are thus fully diagnosable and reciprocally monophyletic terminal taxa, qualifying as species under the phylogenetic species concept (Crafcraft, 1997), if such a decision were to be based on this single genetic character. Very few would agree with such a decision, although most would probably accept designation of the two populations as *evolutionarily significant units* (something worth saving because of unique genetic or morphological diversity; Ryder, 1986) and agree that they should be managed separately. More recently, the trend has been toward use of a suite of fixed genetic differences (preferably unlinked) as a criterion for species-hood; this parallels the practice of most morphological taxonomists of not recognizing a species based on a single point of difference but rather on the basis of multiple concordant characters (Avise and Wollenberg, 1997).

II. The Future

While Rice's (1998) classification recognized 127 species of marine mammals, the status of many of these is open to question. For example, Rice "lumped" the northern right whale *Balaena glacialis* and the southern right whale *B. australis* into a single species *B. glacialis*, but some authors have preferred

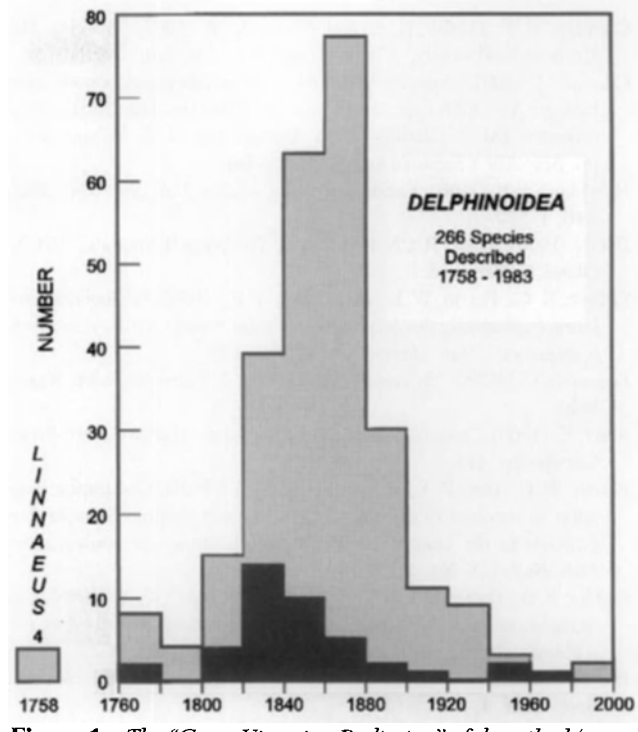

Figure 1 *The "Great Victorian Radiation" of described (nominal) species in the cetacean superfamily Delphinoidea (Monodontidae, Delphinidae, and Phocoenidae); all but 44 (shaded) are now placed in synonymy. Data from Hershkovitz (1966) and Rice (1998).*

to continue recognition of three species (under the genus *Eubalena*), one reason being the existence of fixed genetic differences between the two forms (but see discussion earlier of allopatric species). [Most recent usage is to recognize three species, including the North Pacific *E. japonica;* see Species List]. In another example, Rice (1998) provisionally listed three species of humpbacked dolphins, *Sousa teuszi, S. plumbea,* and *S. chinenis,* but he discussed the results of taxonomic work in progress that indicate that there likely is only one species, with pronounced geographical variation (*S. chinensis* has priority and would be the name borne by a single species). In still another example, the number of recognized species of southern fur seals (*Arctocephalus*) may decrease from eight. These and many other examples demonstrate that the *alpha* (species-level) *taxonomy* of marine mammals is still very much in flux: new species are almost certainly yet to be discovered, some species will be lumped, and others may be split (Fig. 1). There is still work for the taxonomists.

Spectacled Porpoise

Phocoena dioptrica

R. Natalie P. Goodall
Centro Austral de Investigaciones Científicas, Tierra del Fuego, Argentina

The spectacled porpoise is known from a large number of skeletons, mostly from Tierra del Fuego, but from few fresh specimens. As late as 1976, the species was known from only 10 occurrences (nine specimens), all off southeastern South America. Recent surveys have located isolated crania and made a few at-sea observations near widely scattered offshore islands in the Southern Ocean.

I. Taxonomy

Phocoena dioptrica was first described by Lahille in 1912 from a female collected near Buenos Aires. The only synonym is *P. storni*, based on a cranium from Tierra del Fuego. *Phocaena obtusata* Philippi, 1893, sometimes thought to be of this species, has been shown to be a synonym of *Cephalorhynchus eutropia*. In a revision of the taxonomy of the Phocoenidae, *P. dioptrica* was put in a new monotypic genus, *Australophocaena*, but recent studies of phocoenid mitochondrial DNA have returned it to the genus *Phocoena*. The specific name, *dioptrica*, refers to the double eye patch seen in most specimens. The common name in Spanish is *marsopa de anteojos*.

II. Diagnostic Characters

The spectacled porpoise is highly distinctive with its unusual pigmentation, small head and facial features, and the large male dorsal fin.

A. Pigmentation

Color patterns have been depicted for few animals. Young animals ($n = 4$) are dark gray dorsally and light gray ventrally with darker gray or brownish streaks, including a well-defined mouth-to-flipper stripe. This pigmentation changes in the adult to black on the dorsal surface, sharply separated on the sides from the pure white ventral region, although there is feathering on some specimens (Fig. 1). Animals seen in the water may appear lighter. The flipper stripe may lighten or disappear with growth. Both young and adults have dark lips surrounded by white; the eye patch is a dark circle, variably outlined by a lighter or white ring. Most animals had a dark upper tail stock and flukes, which are lighter below. The dorsal surface of the flipper varies from white or mottled gray to black, often ending in a sharp line at the base of the flipper.

B. Size and Shape

The spectacled porpoise is a robust animal with a rounded head and no beak. The gape is short, and the flippers are small and situated well forward on the body. The dorsal fin is broadly triangular and shows strong sexual dimorphism, being much larger and more rounded in males. The rather small flukes have rounded tips with a fairly straight posterior border. External measurements are available for 27 specimens. Seven females ranged from 124.6 (a calf) to 203.5 cm in length. Six animals of unknown sex were from 94 cm, the smallest animal found, to 198+ cm. Nine males measured from 109+ (a neonate) to 224 cm, the largest animal known. This probably does not represent the maximum size for the species. Weights are available for five animals, from a fetus at 1.6 kg, to an 85-kg female, and a 115-kg male.

III. Distribution

The spectacled porpoise is circumpolar in cool temperate, sub-Antarctic, and low Antarctic waters. Specimens are known from Brazil (32°S) to Tierra del Fuego, the Falklands (Malvinas), and South Georgia in the southwestern South Atlantic, Auckland and Macquarie Islands in the southwestern South Pacific; Heard and Kerguelen in the southern Indian Ocean, Burney Island, Tasmania and South Australia (Fig. 2). It is associated with the Falkland (Malvinas) current and the West Wind Drift on both sides of the Antarctic Convergence.

Sightings are rare but widely distributed: off Uruguay, South Georgia, Îles Kerguelen, the Auckland Islands, south and southeast of New Zealand, Tasmania, Patagonia, and, recently, Heard

Figure 1 *(A) A male spectacled porpoise found dead in Chubut, Argentina, in June 1985. This animal, with a length of 205 cm, weight of 115 kg, and 6 GLGs, was sexually but not physically mature. Photograph by A. Purgue. (B) A 180-cm lactating female spectacled porpoise found May 27, 2000 at Bahía San Sebastian, Tierra del Fuego. This is the first animal we have seen with white flippers; they have a dark trailing edge. Photograph by R. N. P. Goodall.*

Island. The southernmost sighting was at 58°02′S, 62°19′W in the Drake Passage. The degree of contact among populations in the different oceans is unknown.

IV. Ecology

Once thought to be an inshore animal, recent records from offshore islands show this species to be oceanic in temperate to subantarctic waters. Although sighted in deep waters far from land, spectacled porpoises sometimes enter river estuaries and channels. We do not know why so many specimens are found on the beaches of Tierra del Fuego (some 160 to 1999) and so few elsewhere. Surface water temperature records to date range from 5.5 to 9.3°C.

Nothing is known about the abundance of this species. It is the second-most frequent species found in beach SURVEYS in eastern Tierra del Fuego but is uncommon elsewhere.

There are no observations of feeding behavior. Only four stomachs have been examined. One contained a small piece of algae and another meager amounts of anchovy (*Eugraulis* sp.) and stomatopods. Nothing else is known of the diet of this porpoise.

Killer whales (*Orcinus orca*), leopard seals (*Hydrurga leptonyx*), and sharks are possible predators of this species. The stomach of a killer whale stranded in Brazil (33°45′S) contained remains of two porpoises, possibly this species.

V. Behavior

Nothing is known of migrations or seasonal movements of this species. Most sightings have been pelagic, but some animals must move inshore off Tierra del Fuego, where they strand or die in nets.

Swimming behavior is described as "unobtrusive." Two animals circling in a small bay at South Georgia in March 1995 reacted to boat noise by STRANDING and were pushed back to deeper water. The swimming before stranding was reported as "slow and steady, with dorsal fins breaking the surface together." A refloated calf had a respiration rate of four to seven breaths a minute. It swam with a slow, rolling motion, arching its back strongly on each dive. A prominent dorsal fin in diving adults was reported for New Zealand.

All sightings to date have been of one to three animals, with one sighting of two large animals with a calf. Mother–calf pairs were stranded twice, but there have been no mass strandings. Five of the seven fresh specimens came ashore alive. Nothing is known of the social behavior, sounds, or associations of this species.

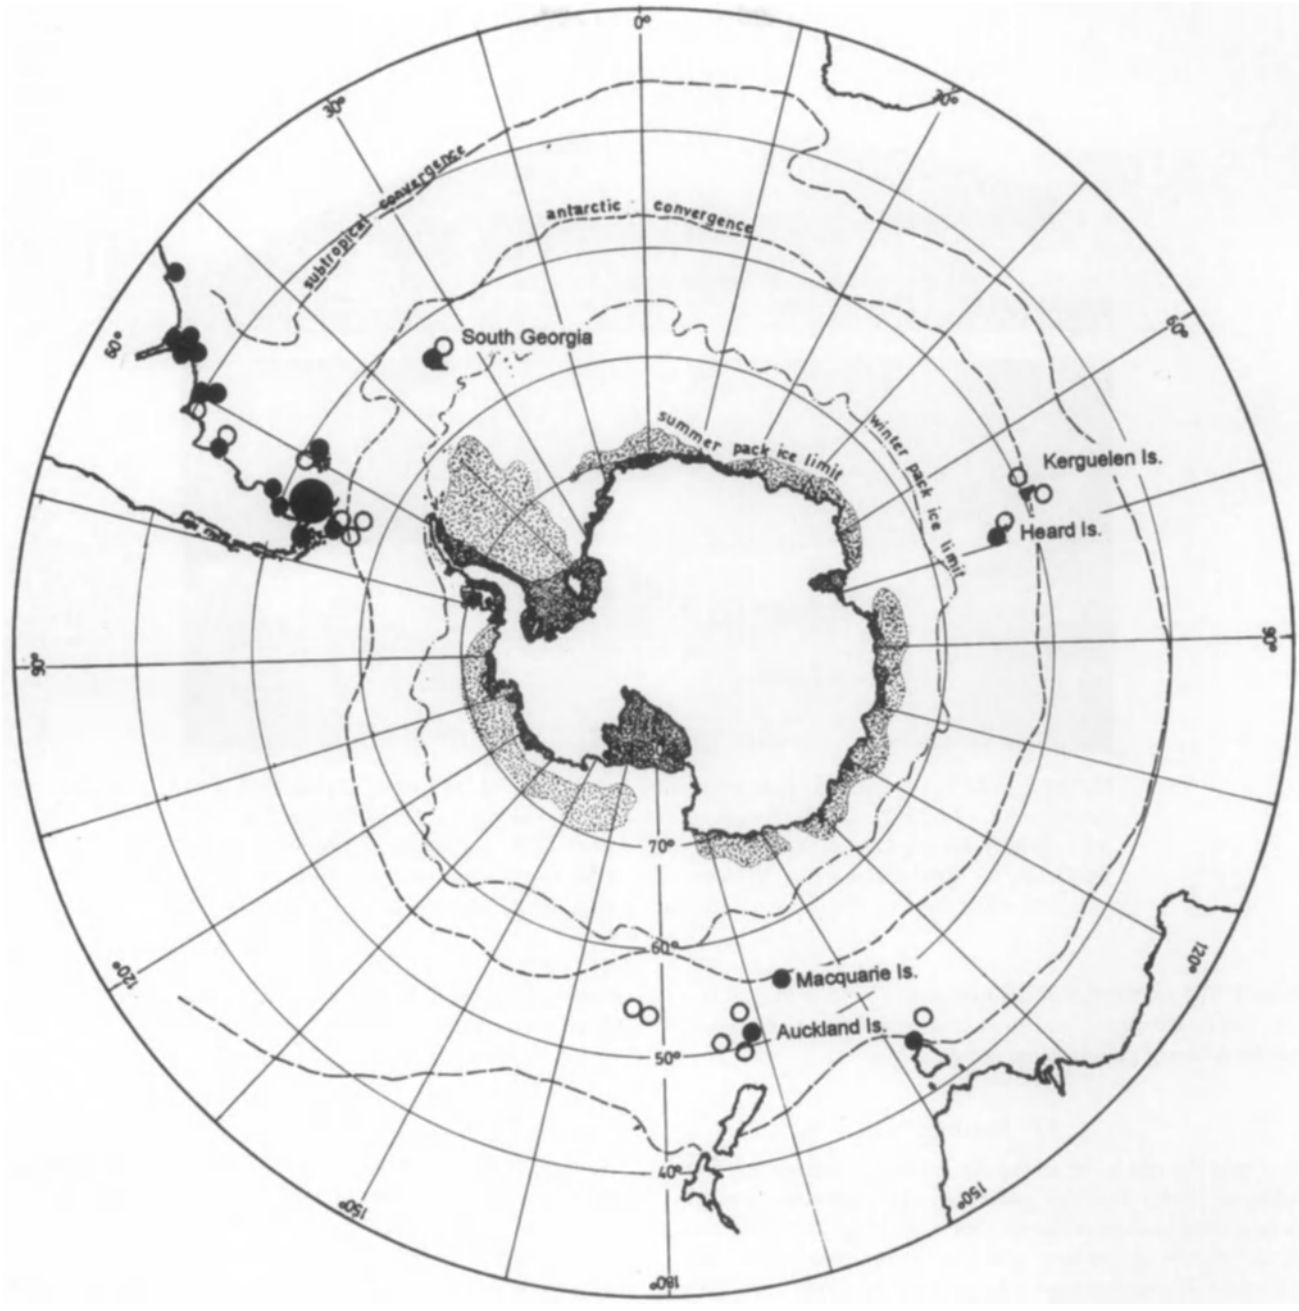

Figure 2 *Map showing the presently known distribution of the spectacled porpoise. Open circles represent sightings, closed circles are single strandings, and the large closed circle represents over 160 specimens.*

VI. Internal Anatomy

The skull has been illustrated and described in several works. Condylobasal lengths ranged from 279 to 324 mm (n = 46). The teeth vary from spade to peg shaped and are often hidden in the gums. Counts range from 19 to 26 upper and 19 to 22 lower teeth per side; posterior teeth are in a shallow groove without alveoli. The vertebral count is C7, T14, L14–16, and Ca 32–33 (65–69 total). From three to six cervical vertebrae are fused. There are usually 14 ribs: the first 9 bicipital and 8 sternal ribs. The phalangeal count of one specimen was I = 2, II = 7, III = 4, IV = 3, and V = 4. The facial complex system has been studied, but little else is known of the internal anatomy.

VII. Life History

Little reproductive information is available. Gonads were examined for one male, which at 205 cm and 6 GLGs was sexually mature. Males of 189–224 cm and 4-5 GLGs were phys-

ically mature. No ovaries have been examined. Three females of 183–186 cm had calves or fetuses. Female teeth show a change in layering after the second or third GLG, suggesting an early sexual maturation, as found in harbor porpoises. Only one female of 203.5 cm and 6 GLGs was physically mature. The youngest age at complete physical maturity was three animals of unknown sex with 3 GLGs. The maximum age to date (n = 27) was an animal of unknown sex with 8 GLGs. The smallest neonates examined measured 94 and 190 cm. Calves of 125–163 cm with unerupted teeth stranded in February to May; birth is probably in late spring or summer (November to February). A calf was seen in December off Heard Island. There is no information on pregnancy rates, gestation, or lactation periods.

No ectoparasites have been reported. Nematodes were found in the blowhole and nasal sacs of the Lahille specimen and in the stomachs of three animals from Tierra del Fuego. Nothing else is known of parasites or disease.

VIII. Interactions with Humans

No spectacled porpoises have been kept in captivity.

Remains of spectacled porpoises were found in 6000- and 1400-year-old kitchen middens of the canoe people in Tierra del Fuego, who harpooned cetaceans for food. In this century, whaling captains off South Georgia and fishermen off Uruguay also hunted spectacled porpoises for food. The first four specimens known came ashore alive and were collected by fishermen. There is no known deliberate exploitation of this species at present. At least some of the specimens found in Tierra del Fuego were taken incidentally in coastal gill nets; the location of the dead animals coincides with that of fishing areas. At least one animal died in offshore bottom or midwater trawls off Patagonia.

None of the biological information needed for conservation and management is available.

Speed

FRANK E. FISH
West Chester University, Pennsylvania

The simplest locomotor parameter that has the greatest survival value for marine mammals is swimming speed. High speeds allow for active pursuit of prey, escape from predators, and increased maneuverability. Low swimming speeds are used for foraging and migrating to minimize transport costs and maximize the distance traveled for the work performed. Swimming speed is a function of the power expended by the muscles and transmitted by propulsive movements of the appendages. High swimming speeds require large energy expenditures because the power to generate the propulsive thrust is directly related to the cube of speed. Fast swimming animals use oscillating hydrofoils (i.e., whale flukes, phocid hind flippers, otariid fore flippers) to generate large thrust forces. Paddling, used by the sea otter, is associated with slow swimming due to the high inefficiencies of thrust generation.

Research on swimming speed was motivated by accounts of extraordinary speeds, particularly for dolphins, associated with unresolved mechanisms to reduce hydrodynamic resistance (drag). Accurate swimming speed measurements of free-ranging marine mammals have been rare, and few data are available concerning the duration of swimming efforts. Reports on swimming speed of marine mammals have, in many instances, been anecdotal and often unreliable. The reason for questioning these reports is that estimates of swimming speeds based on observations from ships, airplanes, or shorelines have often been made without fixed reference points, information on currents, or accurate timing instruments. Originally, speeds of cetaceans were reported from whaling operations that were based on distressed and wounded animals. More recently, swimming speeds of animals performing routine behaviors were collected by means including boat measurements, timing of captive animals, theodolite tracking, observations correlated with map locations, sonar tracking, and radio-tagged animals. These methods still have limitations regarding accurate speed measurements. Even with the use of satellite-tracking systems, the resolution and sampling rate are too low to accurately measure short-duration swimming efforts, such as occurs for sprints. The diving pattern and high probability that animals do not swim in straight lines between consecutive locations measured by satellites tend to skew the data toward minimum transit speeds, which are well below routine and maximum speeds.

I. Cetaceans

Swimming speeds are categorized as (1) sustained and (2) sprint swimming. Sustained swimming is characterized by an activity level maintained for long-time durations. These speeds are steady low-level activities. Sustained speeds are the preferred swimming speeds and are probably minimum speeds for the most efficient generation of thrust. Sustained speeds are associated with routine swimming and cruising associated with migration, transit to foraging sites, and DIVING. Sprints are high-speed, maximum effort movements. These are short duration activities. Sprints are used during chases and rapid accelerations.

A. Sustained Swimming

Both mysticete and odontocete whales display low sustained speeds. For mysticetes, the low sustained speeds (1.8–13.0 km/hr) encountered during feeding would be associated with high drag. Mysticetes obtain food by FILTER FEEDING, which involves straining water directly through the whale's baleen plates or gulping a large quantity of water (at least 60 m^3 or 70 tons) by depressing the lower jaw and filling the throat pouch. Filter feeding would induce additional drag on the animal, depressing speed.

Odontocetes display a similar range of sustained swimming speeds with mysticete whales. One record for sustained swimming by a killer whale (*Orcinus orca*), although probably incorrect, is unfortunately widespread in the literature. The killer whale was reported to swim for 20 min at 45.0–55.8 km/hr. Data were obtained from questionnaires placed aboard a ship. Because the killer whale was "playing" around the ship, the animal was probably BOW RIDING and thereby swimming at a higher speed with less effort.

When direct observation of swimming speed has not been obtainable, physiological characteristics have been used as an indicator of sustained swimming ability. Species with greater adaptation for deep, long-duration dives are precluded from fast sustainable swimming. Deep divers possess increased oxygen stores via increased hematocrit (i.e., percentage of blood occupied by cellular components) and hemoglobin concentration, but at the expense of oxygen transport capacity for rapid swimming. Belugas (*Delphinapterus leucas*) are regarded as slow swimmers that can dive to great depths and remain submerged for extended periods. The hematocrit and hemoglobin concentration of these whales is greater than for the faster swimming *Cephalorhynchus commersonii, Lagenorhynchus obliquidens, Orcinus orca,* and *Tursiops truncatus.*

B. Maximum Speeds

Maximum speeds are associated with duration times in seconds and levels of performance indicative of maximum effort. For free-ranging cetaceans, this behavior may be associated with flight or pursuit, where presumably motivation is high. The range of reported maximum speeds varies considerably for mysticetes (7.6–48.2 km/hr) and odontocetes (5.4–55.1 km/hr). Balaenopteridae are the fastest of the mysticetes. The comparative higher speeds of Balaenopteridae may be due to the highly streamlined body contour characteristic of the family. Within Odontoceti, the highest speeds are attained by members of Delphinidae, whereas Platanistidae are the slowest.

Systematic studies of maximum swimming speeds are few. In one study a top speed of 27.9 km/hr for a *Lagenorhynchus obliquidens* swimming in a towing tank was measured. Maximum speeds for trained animals over a 0.7- to 2.8-sec swim were 27.9 km/hr for *Tursiops truncatus,* 28.8 km/hr for *Delphinus delphis,* and 28.8 km/hr for *Pseudorca crassidens.* In open ocean tests, maximum speeds of 39.8 km/hr for *Stenella attenuata* and 29.9 km/hr for *Tursiops* were recorded. The latter study indicated that swimming speed is related to duration of activity. *Tursiops* can swim at 11.1 km/hr indefinitely, 21.9 km/hr for 50 sec, 25.2 km/hr for 10 sec, and 29.9 km/hr for 7.5 sec. Speeds as high as 54.0 km/hr were reported for burst swims by *Tursiops.* The maximum swimming speed of a school of free-ranging *Delphinus* sp. responding to multiple passes by an airplane was 24.1 km/hr, although the average speed for the school was 17.3 km/hr. The lower average speed may have resulted from the presence of newborn dolphins within the school.

C. Size Dependence of Speed

Although there is a considerable range of overlap for maximum swimming speeds regardless of taxonomic status, there is a marked dependence of specific speed on size. Large whales have low-length-specific swimming speeds compared to smaller dolphins and porpoises (Table I). Experiments on trained delphinids showed that smaller dolphins, such as *Stenella attenuata,* can sprint at 6.0 body lengths/sec, whereas a 38-times more massive *Orcinus orca* can sprint at only 1.5 body lengths/sec. Indeed, a 27.4-m blue whale (*Balaenoptera musculus*) sprinting at 36.7 km/hr would have a length-specific speed of 0.37 body lengths/sec. This trend is explained as a matter of scaling whereby animals maintain the same proportion of muscle mass in the body independent of size, but smaller animals have relatively greater muscular power outputs than larger animals.

II. Sirenians

Dugongs (*Dugong dugon*) and manatees (*Trichechus* spp.) are considered to swim in a leisurely manner (2.2–2.9 km/hr). As herbivores, sirenians do not require speed and rapid acceleration to catch prey. Low-speed swimming allows for precise maneuverability, which is necessary to navigate in restricted waterways and feed on rooted plants. Sirenians will migrate and cruise at speeds of 2.9 to 6.8 km/hr. Sprints of over 21.6 km/hr have been reported for sirenians and would aid in escape from predators such as crocodilians and sharks.

III. Pinnipeds

Pinnipeds exhibit sustained swimming speeds for horizontal swimming and diving of 2.2 to 9.4 km/hr. Dive velocities for small pinnipeds are associated with the minimum cost of transport to prolong dive duration and distance covered. However, the additional energy cost of a slightly increased swimming speed for deeper and longer dives by southern elephant seals (*Mirounga leonina*) is offset by pronounced bradycardia to manage available oxygen stores. Maximum swimming speeds

TABLE I
Maximum Length-Specific Velocities for Trained Delphinids

Species	*Mass (kg)*	*Body length (m)*	*Maximum velocity (km/hr)*	*Length-specific velocity (body length/sec)*
Stenella attenuata	52.7	1.86	39.8	6.0
Tursiops truncatus gilli	89.0	1.91	29.9	4.3
Lagenorhynchus obliquidens	91.0	2.09	27.9	3.7
Delphinus delphis	104.8	1.83	28.8	4.4
Tursiops truncatus	149.2	2.06	27.9	3.8
Pseudorca crassidens	461.8	3.66	28.8	2.2
Orcinus orca	1995.8	5.16	28.5	1.5

are higher for otariids than phocids and the walrus. Otariids can maintain a speed of 18.5 km/hr for 3 to 5 min, although bursts of 24.1 to 28.8 km/hr have been reported. Maximum speed for phocids is 13.0 to 17.3 km/hr.

In addition to swimming, pinnipeds can move over land using terrestrial gaits. Walking by otariids requires alternate movement of the four limbs so that at least three of the limbs are in contact with the ground. As a result, walking speeds are low (2.6 km/hr) for fur seals and sea lions, which must coordinate movements of the enlarged flippers. For faster terrestrial speeds of 7.9 to 13.0 km/hr, a gallop or a bounding gait can be used.

IV. Sea Otter

Surface swimming by the sea otter (*Enhydra lutris*) is generally slower than submerged swimming. This difference in performance is related to the increased resistance to swimming at the surface. The interference pattern of waves generated by the animal at the surface produces a physical limitation to swimming at a higher speed. In addition, at the surface otters use inefficient paddle propulsion. Sea otters swim at speeds ranging from 1.6 to 2.5 km/hr at the surface. Speeds above 2.9 km/hr are performed during bouts of submerged swimming. The maximum escape speed for submerged swimming otters is 9.0 km/hr. During submerged swimming, the otter employs undulation of the body in concert with simultaneous paddling by the hind feet.

Spermaceti

DALE W. RICE
National Marine Mammal Laboratory
Seattle, Washington

permaceti is the term given to the liquid waxes present in the head of the sperm whale (*Physeter macrocephalus*).

The word comes from the late Latin *sperma*, "sperm" or "semen," and the classical Latin *ceti*, genitive singular of *cetus*, "sea monster" or "whale"—literally "semen of the whale." It was bestowed because of the superficial resemblance of these waxes to semen. The vernacular name "sperm whale" is a contraction of "spermaceti whale."

Spermaceti is present in greatest abundance in the spermaceti organ, or "case," and in the "junk." The case is an elongated

barrel-shaped organ, which makes up much of the bulk of the sperm whale's huge head. It consists of soft, white, spongy tissue that is saturated with spermaceti. The junk lies below the case and above the rostrum of the skull; it is also white, but it is more solid than the case and is faintly divided into segments by a series of transverse septa composed of denser tissue. It is also heavily saturated with spermaceti (Clarke, 1978; Rice, 1989). At body temperature, the spermaceti will flow freely as a clear, almost watery, fluid from the case and junk when the latter are slashed with a knife. As soon as it cools to about room temperature, however, it solidifies to a whitish wax similar to paraffin but not as hard. The different fractions may be separated by pressing at various temperatures between 10 and 35°C.

The oils of sperm whales and the other toothed whales (suborder Odontoceti) differ in composition from those of the baleen whales (suborder Mysticeti) (Gilmore, 1951). Those of the baleen whales consist exclusively of triglycerides. Triglycerides are esters compounded from one molecule of the tribasic alcohol glycerol ($CH_2OH{\cdot}CHOH{\cdot}CH_2OH$) and three molecules of various fatty acids. Lipids of the toothed whales, however, consist of a mixture of triglyceridic oils and wax esters, together with a small proportion ($\geq$2%) of diacyl glyceryl ethers in some species. These waxes are compounds formed from one molecule of a higher monobasic alcohol, mostly cetyl ($C_{16}H_{33}OH$) or oleyl ($C_{18}H_{35}OH$), and one molecule of a fatty acid.

Although wax esters are present in all odontocetes, only in the giant sperm whale and the Amazon river dolphin (family Iniidae) do they comprise a majority of the lipids present. In sperm whales the ratio of waxes to triglycerides varies with position in the body. An early study (Hilditch and Lovern, 1928) found that wax esters comprised 74% of the spermaceti in the head, but only 66% of the BLUBBER oil. More detailed studies revealed that even within the head, the proportion of wax esters varies with sex and age as well as position. In the spermaceti case this proportion ranged from 38 to 51% in a calf, 58 to 87% in an adult female, and 71 to 94% in an adult male. Proportions in the junk of the same three whales were 41–62, 65–94, and 91–98%, respectively (Morris, 1975).

Both the triglycerides and the waxes of the sperm whale are characterized by the virtual absence (<2%) of isovaleric acid, a branched, short chain (C_5), unsaturated fatty acid. This trait is shared with pygmy sperm whales (family Kogiidae), beaked whales (family Ziphiidae), and some river dolphins (families Platanistidae and Iniidae). This contrasts with the high proportion of isovalerate lipids in delphinoid cetaceans (families Monodontidae, Delphinidae, and Phocoenidae) (Litchfield *et al.*, 1975).

Wax esters of the sperm whale differ from those of all other toothed whales except the Amazon dolphin (*Inia geoffrensis;* family Iniidae) in that they consist predominantly of relatively long chain (C_{10}–C_{22}) fatty acids (Litchfield *et al.*, 1975). The fatty acid composition of wax esters in the case is mainly shorter chained, saturated acids at the center, with longer chained, more unsaturated acids at the periphery. In the junk, the anterior portion is mainly shorter chained saturated acids, whereas the posterior portion consists of longer chained, more unsaturated acids. The specific proportions of 25 fatty acid moieties in wax esters from the head of an adult female sperm whale were tabulated by Morris (1975).

Because of its heterogeneous lipid composition, and possible internal temperature gradients, the velocity of SOUND through the spermaceti organ varies in a way that could collimate or focus sound waves (Flewellen and Morris, 1978). This accords with the prevailing hypothesis that this organ functions as an acoustic lens to channel acoustic emissions.

In the 19th century when the old-style open-boat whale fishery was flourishing, the oil in the head of the sperm whale (the spermaceti proper) was simply ladled from the case and junk, and was kept separate from the oil that was rendered from the blubber (the remainder of each carcass was discarded). Spermaceti was favored for making candles, and the liquid blubber oil was used as a lamp fuel. In the years from 1804 to 1925, a total of 164,073,918 gallons of sperm oil (including spermaceti) was landed at United States ports. This quantity was the product of an estimated 262,134 sperm whales killed around the globe. Lesser quantities were taken by vessels out of British, French, and other foreign ports. In the peak year of 1837, American landings totaled 5,349,138 gallons, representing an estimated kill of 7472 sperm whales, and were worth $4,413,039 at the average going price of 82.5 cents per gallon. Discovery of the first commercially recoverable reserves of petroleum in 1859 triggered the phenomenal growth of the oil industry, so the demand for sperm oil plummeted. The last old-style American sperm-whaling voyage was made in 1925.

In the 20th century the modern harpoon-cannon whaling industry was carried out from factory ships and shore stations around the world. Oil was rendered from the entire carcass (minus the meat) of each whale, and that from sperm whales ("sperm oil") was kept separate from the oil of baleen whales ("whale oil"). In the early decades of this fishery, whalers took few sperm whales because the edible oil of baleen whales brought higher returns. By the end of World War II, however, baleen whale populations had been severely depleted, and new uses were being discovered for sperm oil. Because of its unique properties, it was in great demand as a high-pressure lubricant, but it also had a diverse array of other specialized industrial uses, such as an ingredient in hydraulic fluids, inks, detergents, and cosmetics, as a plasticiser, and as an agent in the tanning of leathers and the degreasing of wool (Anonymous, 1957). The rising demand led to rapid increases in sperm whale catches, which reached a peak in 1964, when 29,255 animals were killed, yielding 898,257 barrels (=152,703,690 kg) of sperm oil. The International Whaling Commission shut down the entire whale fishery after the 1984 season. Since the cessation of whaling, substitutes for sperm oil have been found—most notably the oil from the seeds of jojoba (*Simmondsia chinensis* of the family Buxaceae), a shrub indigenous to the Sonoran Desert. Jojoba oil has chemical and physical properties similar to those of sperm oil (Harris *et al.*, 1975).

Sperm Whale

Physeter macrocephalus

HAL WHITEHEAD
Dalhousie University
Halifax, Nova Scotia, Canada

Sperm whales are animals of extremes. They have unusually large body sizes, sexual dimorphism, brain sizes, home ranges, dive depths, and dive times; they have an ecological role that may be unrivaled in the ocean; their mitochondrial genetic diversity is unexpectedly low; and their vocalizations, social structure, and historical relationship with humans are all remarkable. The likelihood of evolutionary or ecological links between these extreme attributes form one of the scientific attractions of this animal.

I. Names

In 1758, Linnaeus described four sperm whales in the genus *Physeter*. It soon became clear that all refer to the same species, but there has been a long, and sometimes contentious, debate as to whether *P. catodon* or *P. macrocephalus* has precedence. Currently, most, but not all, authorities prefer *P. macrocephalus*.

The common name, "sperm whale," seems to have resulted from whalers misinterpreting the function of the spermaceti oil found in the massive forehead of the whale.

II. Taxonomy and Evolution

The closest living relatives of the sperm whale are the much smaller dwarf and pygmy sperm whales (*Kogia breviceps* and *K. sima*). There has been debate as to the next closest living relative of the three sperm whale species. In the early 1990s, Michel Milinkovitch and colleagues interpreted DNA data as indicating that the sperm whales are related more closely to baleen whales than other toothed whales. However, more recent genetic and morphological analyses support the traditional and intuitive (sperm whales have substantial teeth) inclusion of sperm whales among a monophyletic Odontoceti, or toothed whales. Sperm whales seem to have separated from other odontocetes early in modern cetacean evolution, about 20 million years ago.

III. Description

Sperm whales are the largest of the odontocetes and the most SEXUALLY DIMORPHIC cetaceans in body length and weight (Fig. 1). While adult females reach about 11 m in length and 15 tons, a physically mature male is approximately 16 m and 45 tons.

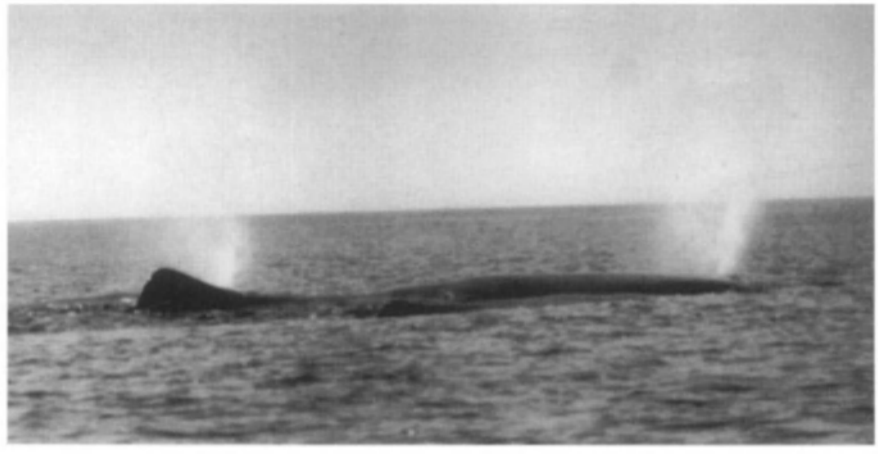

Figure 1 *Mature male with female sperm whale on the breeding grounds off the Galápagos Islands showing the considerable sexual dimorphism in adults (female in foreground). Photograph courtesy of H. Whitehead laboratory.*

Figure 2 *The head of the sperm whale. The volume above the narrow lower jaw and in front of the eye is largely filled with an oil-filled sac, the spermaceti organ. Photograph courtesy of H. Whitehead laboratory.*

The most distinctive feature of the sperm whale is a massive nasal complex (Fig. 2), one-quarter to one-third of the length of the animal, situated above the lower jaw and in front of the skull. It principally contains the spermaceti organ, which is enclosed in a "case" (Fig. 3). This is a roughly ellipsoidal shaped structure made of spongy tissue filled with spermaceti oil and bounded at both ends by air sacs. Between the spermaceti organ and the upper jaws is the "junk," a complex arrangement of spermaceti oil and connective tissue. Spermaceti oil, which has the properties of a wax, differs chemically from the oils found in the "melons" of most other odontocetes.

There is considerable asymmetry in the parts of the skull and air passages that surround the spermaceti organ. This is externally manifested most clearly by a BLOW, which is pointed forward and to the left from the tip of the snout. Compared with the blows of similarly sized baleen whales, the blow of a sperm whale is comparatively weak, low, and hard to see.

Behind the sperm whale's skull lies the largest BRAIN of any animal (mean of 7.8 kg in mature males). However, as a proportion of body size, the sperm whale's brain is not remarkable, and we have no direct information on the sperm whale's cognitive abilities, although its complex social system is consonant with those found in other cognitively advanced mammals.

The sperm whale has 20–26 large conical teeth in each rodlike lower jaw. These teeth do not seem to be necessary for feeding, as they do not erupt until near puberty, and well-nourished sperm whales have been caught that lack teeth, or even lower jaws. The teeth in the upper jaw seem to be vestigial and rarely erupt.

Large corrugations cover most of the body behind the eye, but the surface of the head and the flukes are smooth. The majority of the body is dark gray in most sperm whales, but there is often a bright white lining to the mouth and sometimes white patches on the belly. The occasional sperm whale has larger white patches, especially in mature males, around the head. The flippers are relatively small and paddle shaped, and the flukes are fairly flat and triangular shaped (Fig. 4). The dorsal fin is low, thick, and usually rounded. Especially in mature females, it may be topped by a white or yellowish rough callus. The dorsal ridge, behind the dorsal fin, consists of a series of large crenulations.

IV. Life History

The sperm whale is the epitome of the "*K*-selected" mammal, one presumed to have evolved in an environment of competition for resources with members of its own species. It has a very low birth rate, slow growth, slow maturation, and high survival.

Young are born, almost always singly and with an equal sex ratio, at about 4 months following an approximately 14- to 16-month gestation. Although sperm whales eat solid food before their first birthday, they continue suckling for several years. The females reach sexual maturity at about age 9 when roughly 9 m long, at which age growth starts to slow. They give birth roughly once every 5 years, although pregnancy rates have been found to vary between areas and in the same area at different stages of exploitation by humans. Female reproductive rates decline with age. Females reach physical maturity when growth ceases, at about 30 years old and 10.6 m long.

Males, which are slightly larger than females during the first 10 years of life, continue to grow at a substantial rate until well into their 30s, finally reaching physical maturity at about 16 m long when roughly 50 years old. In males, puberty is prolonged, lasting approximately between ages 10 to 20 years old. However, males seem not to generally take much of an active role in breeding before their late twenties.

V. Distribution and Migrations

With the exception of human and killer whales (*Orcinus orca*), few animals on Earth are as widely distributed as the sperm whale. They can be seen close to the edge of pack ice in both hemispheres and are also common along the equator, especially in the Pacific. As with so many aspects of sperm whale biology, the sexes have very different distributions.

Although sperm whales have been sighted in most regions of deep water, there are some areas which the whalers called "grounds," where they are more abundant. Many of the grounds coincide with areas of generally higher primary productivity, usually resulting from upwelling.

Concentrations of a few hundred to a few thousand sperm whales can be found in areas a few hundred kilometers across characterized by a relatively high deep water biomass and usually situated within grounds. Sometimes aggregations of 50 or more sperm whales can be found within a few kilometers, presumably the result of concentrations of food.

Female sperm whales almost always inhabit water deeper than 1000 m and at latitudes less than 40° (except 50°N in the North Pacific), corresponding roughly to sea surface temperatures greater than 15°C (Fig. 5). Although sometimes seen close to oceanic islands rising from deep ocean floors, female sperm whales are usually far from land.

Young male sperm whales accompany the females in tropical and subtropical waters. On leaving their female relatives, sometime between 4 and 21 years of age, the males gradually move to higher latitudes: the larger and older the male, the higher the average latitude (Fig. 5). Large males may be found near the edge of pack ice in both hemispheres, although from time to time they return to the warm water breeding grounds.

The large males of high latitudes can be found over almost any ice-free deep water, but, like the low-latitude females, they are more likely to be sighted in productive waters, such as those along the edges of continental shelves. However, in some areas, such as off New York and Nova Scotia, the large males are sighted regularly in waters less than 300 m deep.

Migrations of the sperm whale are not as regular or as well understood as those of most baleen whales. In some midlatitudes there appears to be a general seasonal north–south migration, with whales moving poleward in summer, but, in equatorial and some temperate areas, there is no clear seasonal migration.

Scientists have studied the movements of sperm whales using natural and artificial markings, as well as by following groups over periods of a few days. Sperm whales usually move through the water at about 4 km/hr. When feeding conditions are poor, their tracks are straight, resulting in daily displacements of about 90 km per day. However, when food is plentiful, the animals stay in much smaller areas 10–20 km across. Female home ranges seem to be generally of the order of 1000 km across. Some males roam more widely, but others are found quite consistently over several years in restricted coastal waters.

VI. Ecology

The sperm whale has a most catholic DIET consisting of many of the larger organisms that inhabit the deeper regions of the oceans. Females appear to principally eat squids weighing between 0.1 and 10 kg. Favored taxa include Ommastrephidae, Onychoteuthidae, Gonatidae, Pholidoteuthidae, Octopoteuthidae, Histioteuthidae, and Cranchiidae. Of these, the histioteuthids, mesopelagic gelatinous pelagic cephalopods weighing about 0.1–1 kg, have featured at or near the top of the list of preferred food items in several studies of sperm whales. Females will eat much larger prey, such as the giant squid (*Architeuthis*) and the jumbo squid (*Dosidicus*), as well as noncephalopod prey, especially demersal and mesopelagic fish.

Males use the same squid taxa as females, but tend to eat larger individuals. Additionally, they eat species that are largely

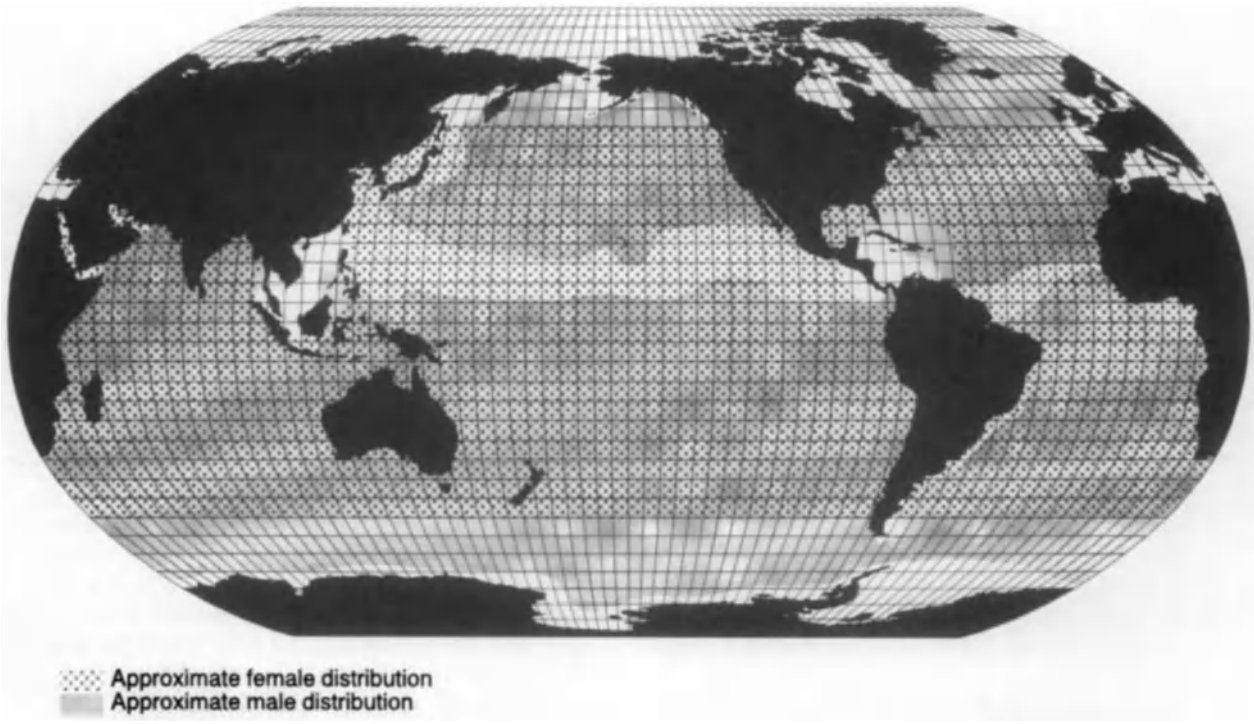

Figure 5 *Worldwide distribution of sperm whales: females, dark shading; males, light and dark shading.*

restricted to higher latitudes and are also more likely to eat demersal fish (including sharks, rays, and gadoids) than females. Off Iceland and in the northern Gulf of Alaska, their primary food is fish.

Sperm whales surely have competitors for many of these food items—beaked whale (Ziphiidae) and elephant seals (*Mirounga* spp.) also eat mesopelagic squid—and there may be important nonmammal predators of the species that the sperm whales use. For instance, the jumbo squid eats the smaller histioteuthid squids. Although we know virtually nothing of the quantitative ecology of the deep ocean, sperm whales, because of their size and numbers, seem to dominate this trophic level in terms of biomass removed. Rough estimates of the worldwide consumption of prey by the world's sperm whale population, about 100 million metric tons per year, are comparable with the current annual catch by all human marine fisheries.

VII. Populations and Stocks

There is no valid estimate for the number of sperm whales currently alive in any ocean or globally. Crude extrapolations from the few areas where there are useful estimates suggest that the total population may lie between 200,000 and 1,500,000 animals.

Information on stock structure in sperm whales is confused, but rather few differences have been found between animals in different ocean areas. Modern genetic studies have been unable to find any distinct stocks at geographical scales of less than an ocean basin. In the mitochondrial, maternally transmitted genome, sperm whales worldwide are remarkably homogeneous. Explanations for this unexpected result (also found in pilot, *Globicephala* spp., and killer whales) include a historical population bottleneck, a demographic consequence of the result of these whales' matrilineal social system, increased selection on the mitochondrial genome, or the indirect effects of selection of matrilineally transmitted cultural traits.

VIII. Sound Production

Unusually, the sounds of sperm whales consist almost entirely of clicks (although a few relatively quiet "squeals" and "trumpets" are made). However, these clicks are used in various ways. When sperm whales are at depth they generally produce regular trains of clicks, at rates of about one to two clicks per second, which most scientists believe are used to find food by echolocation. These "usual" trains are occasionally interrupted by periods of silence or accelerating series of clicks, called "creaks," which are thought to indicate that the sperm whale is homing in on potential prey.

While usual clicks are indicative of foraging at depth, "codas," stereotyped series of 3– ~20 clicks lasting 0.2–2 sec, are heard in social situations when whales are interacting. Groups of females have distinctive repertoires of codas, and coda repertoire also shows GEOGRAPHICAL VARIATION. Coda repertoire is probably acquired culturally from within family units.

Whereas codas are heard principally from social females, another form of click, the "slow click" or "clang," in which distinctively ringing clicks are repeated every 6–8 sec, is largely or

entirely produced by large males. The function of slow clicks is not clear, but they may attract females, repel other males, or be used to ECHOLOCATE off other whales.

The principal function of the spermaceti organ and its associated structures (the junk, air sacs and passages, and the *museau de singe* clapper system at the front of the organ, see Fig. 3) is thought to be to form, and perhaps focus, the sperm whale's click.

IX. Social Structure

The life of a female sperm whale is overwhelmingly social. She is always in the company of other females, some of whom are her relatives (Fig. 6). The basic element of sperm whale society is a family unit, consisting of about 12 females and their young. Most females probably spend their lives in the same unit, with their close female relatives. However, there are recorded instances of females switching units and nonrelatives showing long-term relationships. Two or more units may travel together for a few days as a cohesive group of about 20 animals.

Members of groups defend themselves and their offspring communally against predators and have been observed risking themselves to assist unit members in peril during a killer whale attack. Female groups occasionally mass strand on shorelines, usually with fatal results for all members.

Young males leave their natal unit when between 4 and 21 years old and then are found in loose aggregations, sometimes called "bachelor schools," with other males of approximately the same size and age. As the males age and grow they move to generally higher latitudes and the aggregation sizes become smaller, until the largest males are usually alone. Although repeat association between males on more than 1 day are rarely observed, mature and maturing males do strand on beaches together, suggesting significant social relationships on a scale not readily apparent to human boat-based observers.

X. Foraging Behavior

Sperm whales possess two quite distinct behavioral modes: foraging and social/resting. When foraging, the animals make repeated deep dives. Modal dives are to about 400 m and for about 35 min, but dives can be much deeper (to over 1000 m), shallower (e.g., when in shelf waters 200 m deep), or longer (to over 1 hr). Between dives the whales come to the surface to breathe for about 8 min. The dive is usually signaled by the raising of flukes out of the water (Fig. 4). The descent to depth, as well as the return to the surface, can be nearly vertical.

It is not known how sperm whales find and catch their food, but one plausible hypothesis is that they generally locate their prey using the usual click trains. Small gelatinous squid, such as histioteuthids, are usually both relatively unmaneuverable and BIOLUMINESCENT, so these can be captured using visual or acoustic cues. Larger, more muscular animals may need active chasing, including accelerating click trains ("creaks"). It has been suggested that sperm whales may use their clicks to stun squid, making them more easily catchable. However, there is currently only a little circumstantial evidence for stunning.

Groups of females and immatures spread out over 1 km or more of ocean when foraging, often forming a rank aligned perpendicular to the direction of travel. In contrast, males seem to forage independently.

XI. Social/Resting Behavior

Female and young sperm whales spend approximately 75% of their time foraging. However, during periods of several hours, often in the afternoon, they gather at or near the sur-

Figure 6 *A group of female sperm whales. Photograph by François Gohier.*

Figure 7 *Female sperm whales in resting/social mode off the Galápagos Islands. Photograph courtesy of H. Whitehead laboratory.*

face. At these times their behavior is highly variable. Sometimes the animals may lie still and quiet, closely clustered, for hours at a time, apparently resting (Fig. 7). Particularly at the start or end of nonforaging periods their behavior may be much more active, with breaches, lobtails, animals rolling, maneuvering and touching one another, and codas and creaks being emitted. Large males also lie quietly at the surface for long periods, but they are usually alone unless accompanying a group of females.

XII. Calf Care

Within the social units there is communal care for the young, with good, although not definitive, evidence for females suckling calves who are not their own offspring. Young sperm whale calves do not seem to be able to dive to foraging depths for as long as their mothers. Instead they remain at or near the surface, moving between those adult and immature members of their group while they are breathing. This babysitting begins soon after birth. Members of groups with young calves seem to stagger their dives, thus providing better babysitting for the young.

XIII. Defense against Predators

Killer whales have been observed attacking sperm whales, usually unsuccessfully, although they killed at least one sperm whale during a well-documented encounter off California, and sperm whale remains have, very occasionally, been found in the stomachs of killer whales. Pilot whales have been seen harassing sperm whales on a number of occasions, but whether they are any real threat to the much larger sperms is uncertain. Large sharks are also potential predators, especially of young animals.

When faced with predators, particularly killer whales, female sperm whales quickly cluster. Two defensive patterns have been described. In the "marguerite" or "wagon wheel" formation, the members of the group place their heads together at the hub, with the bodies radiating out like spokes. In contrast, when adopting the "heads-out" formation, the sperm whales face their attackers, tightly aligned in a rank, and seem to principally use their jaws for defense. Young calves stay toward the center of whichever defensive formation is adopted.

XIV. Breeding Behavior

The large mature males, in their late 20s and older, return to the tropical breeding grounds to mate, although the timing of such visits is largely unknown. When on the breeding grounds, the large males roam between groups of females, usually spending just a few minutes or hours with each. They are presumably searching for receptive females. There are no clear descriptions of mating itself. The breeding males seem to roam independently and generally avoid one another, although they are sometimes observed within the same group of females, and occasionally fight. These fights are rarely observed, but many large males have deep scars made by the teeth of other males.

XV. Sperm Whales and Humans

In the early 18th century, New Englanders began to hunt sperm whales for commercial purposes off their own shores. Over the next two centuries, sperm whaling grew to be a major worldwide industry. At its peak in the 1830s, about 5000 sperm whales were being killed each year by whalers from several countries, especially the United States, and the oil produced was a vital element of the burgeoning industrial revolution. The whalers sailed all oceans of the world in their stubby square-rigged ships. On sighting sperms, open whaleboats were lowered and rowed or sailed to the whales. The whalers threw harpoons into the animals, and then killed them using lances

(Fig. 8). Dead animals were towed to the whale ship, where the oil was baled from the spermaceti organ, the BLUBBER stripped from the body and boiled to render the oil, and virtually all the remainder of the carcass discarded. In the 19th century, sperm whaling had become such a significant enterprise that it had important effects on fields as diverse as literature (Herman Melville's great novel "Moby Dick") and ocean exploration. The open-boat hunt declined during the latter half of the 19th century because of the development of petroleum products as alternatives for sperm oil, the decline in the sperm whale population, and for other reasons.

After about 50 years of relative peace, the sperm whale populations were again hit hard following World War II. The whalers of the 20th century chased the sperm whales using mechanized catcher vessels equipped with sonar and killed them using explosive harpoons shot from harpoon guns. This whaling was also widely distributed and took a large number of sperms (up to 30,000 per year). However, unlike their earlier counterparts, the modern whalers used almost all of the whale, and preferentially targeted males. Much, but not all, of this whaling was carried out under the auspices of the INTERNATIONAL WHALING COMMISSION (IWC). The effects of 20th century whaling on sperm whale stocks are unclear, but it is likely that many stocks, particularly the male portions, were reduced substantially. Commercial sperm whaling declined in the 1970s and 1980s and virtually ceased with the IWC moratorium in 1988. Currently there is a small catch of sperm whales in Lamalera, Indonesia, using primitive methods, a "scientific" hunt for sperm whales off Japan, as well as some evidence for pirate sperm whaling.

Nowadays most interactions between sperm whales and humans are more benign. Sperm whales are the principal subjects of WHALE-WATCHING operations off Kaikoura (New Zealand), Andenes (Norway), and Dominica (West Indies). Scientists study their behavior from small vessels in these and a few other locations.

XVI. Conservation

It may seem that the sperm whale has survived the onslaught of the whalers better than most other large whales. There are probably still a few hundred thousand sperm whales left in the ocean, sperm whale food is of little interest to human fishers, and their deep water home is further from most sources of pollution than the preferred habitat of most other marine mammals. However, the effects of whaling seem to be lingering. In the southeast Pacific, where modern whaling on males was particularly severe, large breeding males are still scarce and calving seems depressed below the replacement rate. In other parts of the world, the picture appears brighter. For instance, the population of maturing males in the Antarctic seems to be increasing. However, sperm whales have very low reproductive rates even in the best of times—they do not recover quickly when depleted. They are also killed inadvertently in a range of ways, including ENTRAPMENT in fishing gear, choking on plastic bags, and collision with ships. The chemical POLLUTION levels in their blubber are generally higher than that of baleen whales, but lower than in inshore odontocetes.

XVII. The Colossal Convergence

A potential key to the sperm whale's simultaneous possession of a wide range of extreme biological attributes lies in a series of remarkable parallels with the African elephant (*Loxodonta africana*). These include large body sizes, brain sizes, substantial sexual dimorphism, similar life history variables, large ranges, remarkably congruent matrilineally based social

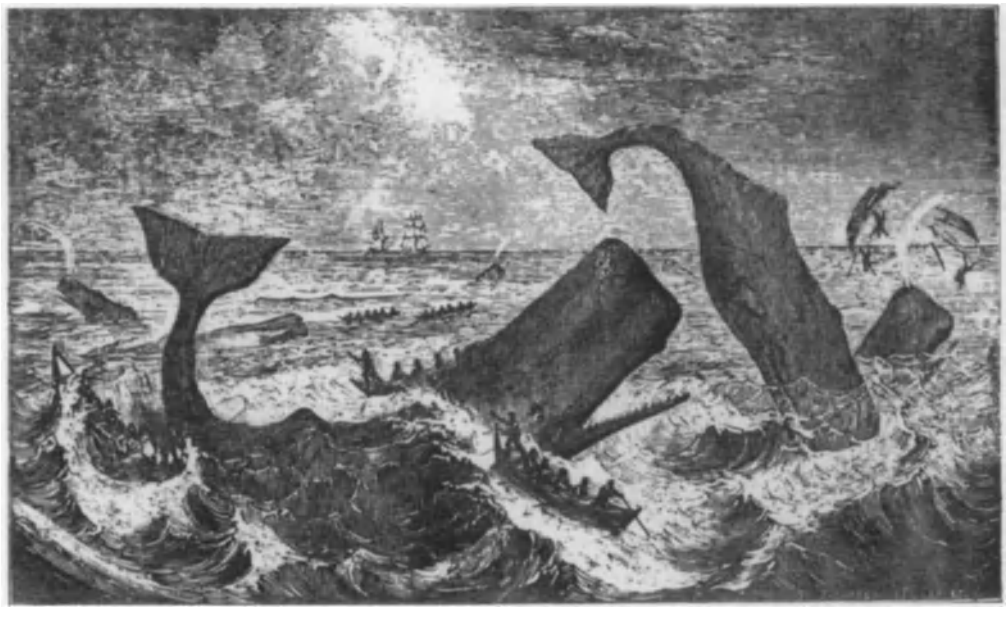

Figure 8 *Open-boat sperm whaling. From Beale (1839).*

systems, and breeding systems in which males roam between groups of females and generally only mate successfully when in their late twenties or older. The highly evolved spermaceti organ may have paralleled the trunk (another extreme nose) in allowing the animals efficient access to a wide range of resources. Meanwhile, in these animals, large sizes and cooperative societies gave efficient defense against predators, allowing long lives. Long, safe lives, in turn, promote the formation of significant long-term relationships among animals. Thus elephants and sperm whales evolved in highly social populations, near carrying capacity, and become dominant members of their ecological guilds. However, such animals are not well adapted to recovering from sudden depletion. Both the elephant and the sperm whale have been heavily hit, and, because their social structures are so important, exploitation has had consequences beyond animals killed directly.

Sperm Whales, Evolution

Guram A. Mchedlidze
Georgian Academy of Sciences, Tbilisi

Sperm whales include the cetacean families Physeteridae (the modern sperm whale) and Kogiidae (the modern pygmy and dwarf sperm whales). Modern sperm whales are represented by two genera only, but sperm whales were much more diverse in past times. Phylogenetically, sperm whales are usually thought to be close to the root of the odontocetes, and they retain many characters that are primitive for odontocetes. They do, however, also have some highly derived features and are not very similar to the primitive Eocene cetaceans (archaeocetes) that they are descended from. Physeterids and kogiids may be subsequent branches of the basal odontocete phylogenetic tree, or both may be derived from a common sperm whale ancestor, such as *Ferecetotherium* (Table I).

I. Physeteridae

Physeterids (including the modern sperm whale *Physeter macrocephalus*) are highly specialized for teutophagy at great depths, and many parts of sperm whale anatomy show adaptations for this behavior. Some specialized morphologies are already present in the oldest known physeterid, *Ferecetotherium kelloggi*, from the late Oligocene of Azerbajan, but many fossil sperm whales were probably fisheaters.

The earliest physeterid, *Ferecetotherium*, was small (approximately 5 m long) and had a small head. An increase in size and head size occurred in the Miocene, and modern *Physeter* has a body length of 16 m in females and 21 m in males. The

TABLE I
Better Known Genera of Physeteridae and Kogiidae

Physeteridae		
Ferecetotherium	Late Oligocene	Azerbajan
Diaphorocetus	Early Miocene	Argentina
Aulophyseter	Middle Miocene	United States, west coast
Idiorophus	Middle Miocene	United States, west coast
Orycterocetus	Middle Miocene	United States, east coast
Placoziphius	Upper Miocene	Europe
Scaldicetus	Middle Miocene	Europe, Japan
Physeter	Recent	All oceans, except polar
Kogiidae		
Kogiopsis	Late Miocene	United States
Scaphokogia	Miocene	Peru
Praekogia	Pliocene	Mexico
Kogia	Recent	All temporal to tropical oceans

head of *P. macrocephalus* is approximately one-third the size of the body. An increase in body size happened throughout physeterid evolution (Fig. 1).

Ferecetotherium had a relatively narrow rostrum. Miocene sperm whales are characterized by the widening of the rostrum. This widening took different paths in different species. In some clades, widening occurred in the maxillae and premaxillae, whereas in other clades only one of these elements enlarged. In the Miocene *Diaphorocetus* and *Orycterocetus*, the premaxilla and maxilla are nearly equal in width near the base of the rostrum, but the tip of the rostrum consists entirely of the premaxillae. In contrast, in *Physeter* the maxillae make up nearly all of the rostrum, and the premaxillae are only exposed near the tip of the rostrum. Widening of the rostrum was probably the result of the enlargement of the SPERMACETI organ, a large structure housed in a depression (the supracranial basin) on the forehead. The supracranial basin is characteristic of sperm whales, although it is relatively small in older forms. Posteriorly, this basin is bounded by the supraoccipital and the posterior plate of the right premaxilla, and laterally vertical plates of the frontals bound the basin. In modern *Physeter*, the lateral walls of the supraoccipital basin are formed by the maxillae. All physeterids, including *Ferecetotherium*, are also characterized by strong asymmetry of the rostrum, particularly the premaxillae and nasals.

Large evolutionary changes also occurred in the mandible. In modern sperm whales, the maxilla (upper jaw) is much wider than the mandible as a result of the widening of the rostrum and a narrowing of the mandible. These give the lower jaw a peculiar undersized image. This mismatch evolved gradually in physeterids. *Ferecetotherium* has a primitive mandible, not unlike that of archaeocetes. In late Eocene archaeocetes, the lower margin of the mandible is horizontal, but the mandibular depth increases posteriorly and TEETH are present on the ascending ramus. Physeterid specializations in the mandible of *Ferecetotherium* include the parallel edges of the ramus, the superior displacement of the mandibular condyle, and the reduced coronoid process.

As a rule, modern *Physeter* only has teeth in the lower jaw, although occasionally an individual is found with upper teeth. Upper teeth are still present in physeterids from Oligocene through middle Miocene. Teeth in *Physeter* are positioned in the upper edge of the mandible. In *Ferecetotherium*, posterior teeth are rooted in the upper edge of the mandible, but anterior teeth (except the first tooth) are implanted more laterally. The latter condition occurs in all teeth of *Kogia*. All physeterids have homodont and polydont teeth, as do most extant odontocetes. The tooth crowns of physeterids are small, and their roots are more shallow than those of archaeocetes.

In physeterid evolution, the length of mandibular symphysis increased from one-twelfth of the length of the mandible in the Oligocene to one-fourth in the Miocene, and one-half in *Physeter*. The mandible of *Ferecetotherium* has 27 teeth, whereas that of *Diaphorocetus* has 14. In the middle Miocene *Aulophyseter morricei*, upper teeth, if present at all, were only lodged in the gums, and all upper teeth were lost in the upper Miocene *Placoziphius duboisii*.

The great differences in the shape of the face and jaws between early physeterids and modern ones suggest that the teutophagic specializations of *Physeter* may not have been present in extinct relatives. It is possible that Oligocene and Miocene physeterids were ichthyophagous, as were most cetaceans. Modern sperm whales feed on deep-sea squid, and it is likely that early physeterids were not deep-sea animals.

The forelimb of physeterids is very different from that of Eocene cetaceans, but similar to that of other odontocetes. The humerus is shortened and the elbow is immobile. The hand forms a flat, smooth surface with no differentiation of individual fingers, causing the entire limb to be an effective rudder. In early physeterids, the head of the humerus changed considerably. The humeral head of *Ferecetotherium* is deviated externally and faces caudally, but the tubercles are situated anteriorly, as in archaic cetaceans. Whereas *Ferecetotherium* retains a greater and lesser tublercle of the humerus, the lesser tubercle of Miocene physe-

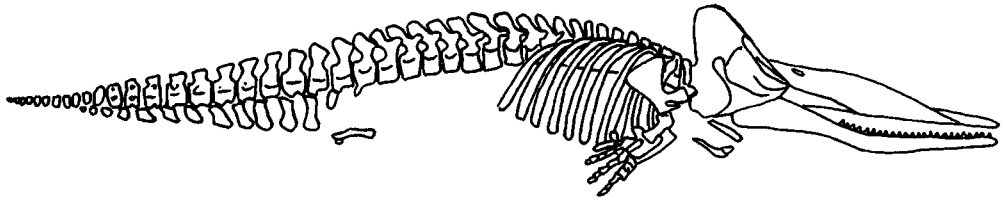

Figure 1 *Skeleton of* Physeter macrocephalus, *the modern sperm whale. Note the disproportionally large head and the supracranial basin.*

terids is enlarged greatly and the greater tublercle reduced. *Physeter* has a weak lesser tubercle, set medially on the humerus.

II. Kogiidae

One genus with two modern species constitutes the Kogiidae (*Kogia breviceps* and *K. sima*). *Kogia* is similar to *Physeter*, but the body of *Kogia* is much smaller (body length approximately 4 m) and the head is smaller (one-sixth to one-eighth of the body). The spermaceti organ is smaller than in *Physeter*, the blowhole more posterior, and the rostrum shorter. Proportions of the head in *Physeter* embryos are similar to those of adult *Kogia*. This suggests that these cetaceans are closely related and that *Physeter* has a more derived facial morphology.

Kogiids are poorly represented in the FOSSIL RECORD, and most specimens are incomplete. The genus *Kogiopsis* is known from a single mandible, and fragmentary SKULLS are known for Miocene *Scaphokogia* and Pliocene *Praekogia*. Another trend in the evolution of kogiids is the reduction of dental enamel. This trend started in the Miocene. In modern *Kogia* some enamel covers the tips of the teeth, whereas Miocene kogiids lack all enamel.

Phylogenetically, *Scaphokogia* is a basal branch of kogiids, retaining primitive morphologies of rostrum, premaxillae, and intermaxillary groove. It is, however, more derived than other kogiids in having a well-developed supracranial basin. *Scaphokogia* may represent an early, specialized branch of kogiids, the subfamily Scaphokogiidae. These went extinct near the end of the Miocene. *Praekogia* is closely related to *Kogia* in that both the nasal passages are anterior due to poorly developed telescoping.

Spinner Dolphin

Stenella longirostris

WILLIAM F. PERRIN
Southwest Fisheries Science Center, La Jolla, California

The spinner dolphin, *Stenella longirostris* (Gray, 1828), is the most common small cetacean in most tropical pelagic waters. It can be seen at a great distance as it spins high in the air and lands in the water with a great splash. It also commonly rides the bow wave of boats and thus can be observed closely.

I. Characters and Taxonomic Relationships

The spinner dolphin can be identified externally by its relatively long slender beak, color pattern, and dorsal fin (Fig. 1). The color pattern in most regions is three-part, consisting of a dark-gray cape, light-gray lateral field, and white ventral field. A dark band of even width runs from the eye to the flipper, bordered above by a thin light line. The rostrum is tipped with black or dark gray. In the eastern and Central American subspecies of the eastern tropical Pacific, *S. l. orientalis* and *S. l. centroamericana* (Fig. 2), contrast between the cape and the lateral field is very faint to absent, and the ventral field may be restricted to discontinuous axillary and genital-region patches. Various intermediate color patterns are exhibited by "whitebelly" spinners in a broad zone of HYBRIDIZATION between the eastern form and the more typically patterned Gray's spinner dolphin, *S. l. longirostris*, in the Central and South Pacific. The dorsal fin in adults in all regions is basically triangular, varying from a slightly falcate right triangle to an erect isoceles triangle. In the adult male of the eastern and Central American subspecies the dorsal fin may lean slightly forward, appearing to "be on backwards." This is correlated with the presence of a large postanal ventral hump. Both the dorsal fin and the hump appear to be sexual displays, probably important in male–male or male–female communication or both. In calves and juveniles in all regions, the dorsal fin is on average more falcate than in adults.

Sexually mature adults examined ranged from 129 to 235 cm (n = 1824) and weighed 23–78 kg (n = 33) (Perrin, 1998). Males are on average slightly larger than females in body size and most skull characters.

The spinner dolphin may be confused in the tropical Atlantic with the endemic Clymene dolphin, *S. clymene*, which is very similar in appearance and has been observed to spin, although not as acrobatically as the spinner dolphin. In the Clymene dolphin, the beak is relatively shorter, the flipper band narrows anteriorly, the lower margin of the cape dips lower toward the ventral field (in the spinner the cape and ventral-field margins are parallel), and there is usually a dark "moustache" mark on the upper side of the beak that has only rarely been observed in spinner dolphins.

The skull (Fig. 3) can be confused with those of *S. coeruleoalba*, *S. clymene*, and *Delphinus* spp.; all have a relatively long and narrow dorsoventrally flattened rostrum, a large number of small slender teeth (about 40–60 in each row), and medially convergent premaxillae and sigmoid ramus (Perrin, 1998). It differs from *Delphinus* in lacking strongly defined palatal grooves. The rostrum is narrower at the base than in *S. coeruleoalba* (57–84 mm vs 93–120 mm). It overlaps *S. clymene* in all skull measurements and tooth counts, but the skull (335–464 mm long in 112 adults) is proportionately longer and narrower. The vertebral count is 69–77 (n = 90).

The spinner dolphin is a member of the subfamily Delphininae *sensu stricto* (LeDuc *et al.*, 1999). Morphologically and behaviorally it is most similar to the Clymene dolphin, but in a cladistic phylogenetic analysis based on cytochrome *b* mtDNA sequences it was not closely linked to that species,

Figure 1 *A Gray's spinner dolphin* (Stenella longirostris longirostris) *in the Gulf of Mexico. Photograph by Robert L. Pitman.*

which was the sister species of the striped dolphin, *Stenella coeruleoalba* (LeDuc *et al.*, 1999). The morphological similarly between spinner and Clymene dolphins could be an instance of plesiomorphy (similarity through retention of primitive characters), but the correlated spinning behavior would seem to be highly derived, a probable synapomorphy. This puzzling discordance between molecular and morphological/behavioral characters shows the need for further molecular and morphological investigation; a hybrid origin of *S. clymene* has been suggested as one possible explanation (LeDuc *et al.*, 1999).

II. Distribution and Ecology

The spinner dolphin is pantropical, occurring in all tropical and most subtropical waters around the world between roughly 30–40°N and 20–30°S (Jefferson *et al.*, 1993). It is typically thought of as a high-seas species, but coastal populations and races/subspecies exist in the eastern Pacific, Indian Ocean, Southeast Asia, and likely elsewhere (Perrin, 1998; Perrin *et al.*, 1999; Perryman and Westlake, 1998; Van Waerebeek *et al.*, 1999). In the eastern and western Pacific, the pelagic form has been shown to prey mainly on small mesopelagic fishes and squids, diving to 600 m or deeper (Perrin and Gilpatrick, 1994; Dolar, 1999), but a dwarf subspecies in inner Southeast Asia, *S. l. roseiventris*, inhabits shallow waters in the Gulf of Thailand, Timor Sea, and Arafura Sea and consumes mainly benthic and reef fishes and invertebrates (Perrin *et al.*, 1999).

Predators include sharks, probably killer whales (*Orcinus orca*) and possibly false killer whales (*Pseudorca crassidens*), pygmy killer whales (*Feresa attenuata*), and short-finned pilot

Figure 2 *The Central American spinner* (Stenella longirostris centroamericana) *lacks a bold pattern and has an extremely long beak. Photograph by Robert L. Pitman.*

Figure 3 *Skull of* Stenella longirostris longirostris *adult male from Florida. From Perrin and Gilpatrick (1994).*

whales (*Globicephala macrorhynchus*). Parasites may cause direct or indirect mortality.

III. Behavior and Life History

Why the spinner spins is unknown. One animal may spin as many as 14 times in quick succession. It has been suggested that the large underwater bubble plume created by the violent spin and reentry may serve as an ECHOLOCATION target for communication across a widely dispersed school (Norris *et al.*, 1994). It is also probable that spinning is an outgrowth of an alert state and as such has a social facilitation function. It could also—at least at times—represent PLAY.

School size varies greatly, from just a few dolphins to a thousand or more. Spinner dolphins commonly school together with pantropical spotted dolphins, *S. attenuata,* and dolphins

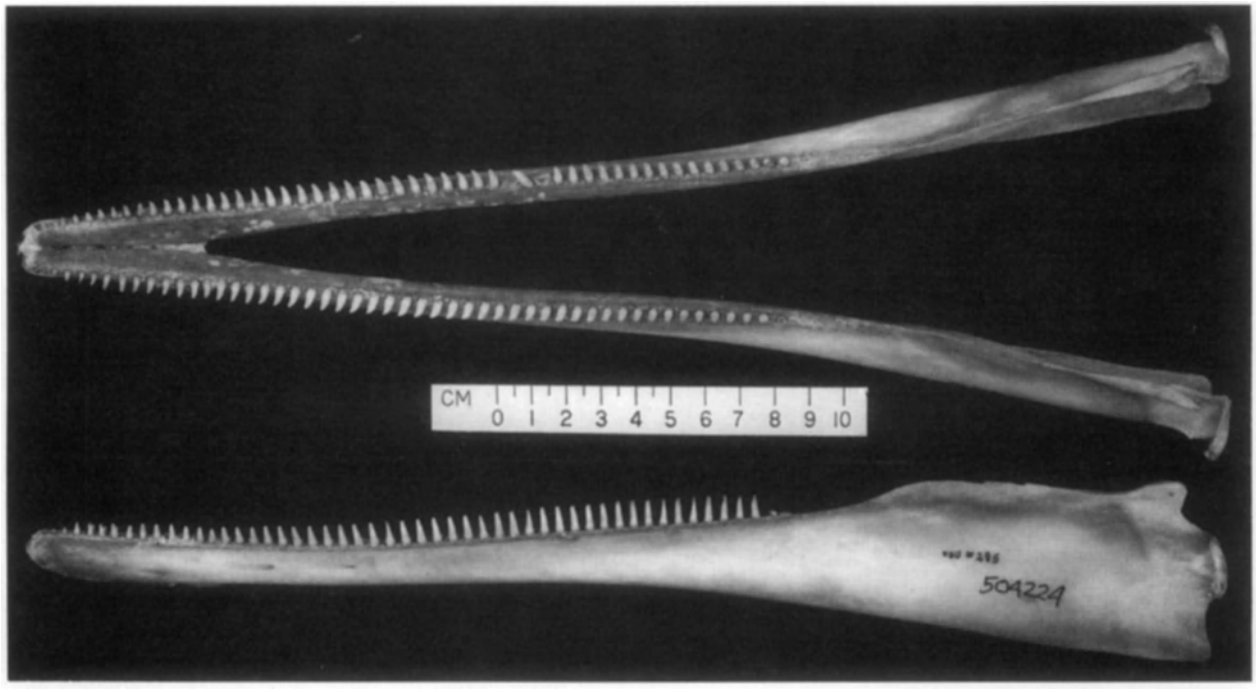

Figure 3 *(Continued)*

and small toothed whales of other species. Social organization in Hawaiian waters is fluid, with schools composed of more or less temporary associations of family units; the associations may vary over days or weeks (Norris *et al.*, 1994). Mating appears to be promiscuous. Adult males form coalitions of up to about a dozen individuals; the function of these is unknown. Maximum recorded movements of individuals are 113 km (over 1220 days) in Hawaii and 275 nmi (over 395 hr) in the eastern Pacific (Perrin, 1998).

Gestation is about 10 months. Average length at birth is about 75–80 cm. Length of nursing is 1 to 2 years. Calving interval is about 3 years. Females attain sexual maturity at 4–7 years and males at 7–10 years. Ovulation may be spontaneous. Breeding is seasonal, more sharply so in some regions than in others.

IV. Interactions with Humans

Spinner dolphins have been kept in CAPTIVITY only in Hawaii, where some have lived for several years. Large numbers have been killed incidentally since the early 1960s by tuna purse seiners in the eastern tropical Pacific; the population of *S. l. orientalis* is estimated to have been reduced to less than one-third of its original size (Perrin, 1998). Likely unsustainably high bycatches also occur in drift nets and purse seines in the Philippines (Dolar, 1994, 1999). As is the case for other small cetaceans caught in fishing nets, local human consumption of by-caught animals in several regions has led to the development of markets and large directed catches from unassessed populations (Perrin, 1999), boding ill for CONSERVATION of the species in these regions.

Steller's Sea Cow

Hydrodamalis gigas

PAUL K. ANDERSON
University of Calgary, Alberta, Canada

DARYL P. DOMNING
Howard University, Washington, D.C.

A very large sirenian once grazed on algae along the shores of the cold North Pacific Ocean. Shipwrecked with Vitus Bering's expedition on Bering Island, the larger of the Kommandorskiye (Commander) Islands, George Wilhelm Steller (b. 1709–d. 1746), the only biologist to observe the species alive before its extinction ca. 1768, observed and described the sea cow and recorded his observations on external and internal anatomy, natural history, and hunting as seen during his enforced stay on the island between November 1741 and August 1742.

I. Characteristics and Systematic Relationships

Two other common names for Steller's sea cow are the German "Borkentier," referring to its rough bark-like hide, and the Russian "kapustnik" (cabbage eater), which Steller attributed to inhabitants of Kamchatka, where dead sea cows reportedly washed ashore after storms. Because Steller's posthumously published observations (1751) predated Linnean taxonomy, the sea cow was given its formal scientific name by later authors on the basis of Steller's description (no type specimen has ever been designated). Among numerous synonyms, the generic and species names now recognized as correct are *Hydrodamalis* (Retzius, 1794) and *Hydrodamalis gigas* (Zimmerman, 1780). The latter combination was authored by Palmer (1895). The generic synonym used most commonly in the 19th century was *Rytina* (Illiger, 1811) (improperly emended to *Rhytina*). For full synonymy and comprehensive references, see Domning (1978, 1996).

Hydrodamalis gigas was a very large toothless sirenian. Sirenians are wholly aquatic, primarily vegetarian, mammals. *H. gigas* was the only sirenian adapted to cool-temperate or cold climates and an algal diet. It differed from all other mammals in feeding predominantly or exclusively on algae and in having a manus composed only of carpals and metacarpals, with the phalanges vestigial or absent. Its pectoral limb had a densely bristled blunt termination that Steller described as claw-like or hoof-like (Fig. 1). It differed from its predecessor (*Hydrodamalis cuestae*) in lacking teeth and from most fossil and living sirenians other than manatees in having a reduced deflection of the rostrum from the occlusal plane (Fig. 2). This characteristic correlated with feeding in the water column above the bottom. Its uniquely large size may have been a factor in its ability to tolerate cold. Surface water temperatures around the Kommandorskiyes range from 0°C in winter to 10°C in summer.

Like other sirenians, sea cows had paired nostrils, abdominal testes, a pair of axillary mammae, no hindlimbs, horny plates on the occlusal surfaces of the rostrum and mandibular symphysis for macerating vegetation, and ribs and other bones that were swollen (pachyostotic) and completely compact (osteosclerotic). It swam by dorsoventral undulation of the body and its horizontally expanded triangular caudal fluke, resembling those of cetaceans. See Domning (1978, 1994) for more detailed morphological diagnoses.

The order Sirenia is agreed to be monophyletic and has been placed in the superorder Tethytheria, which includes the Proboscidea (elephants) as well as an extinct group of marine herbivores, the Desmostylia. The cladistic analysis by Domning (1994), based on morphological characters of skull, mandible, and dentition, supports the conclusion that *H. gigas* was the last of two species in the genus *Hydrodamalis*, sharing the subfamily Hydrodamalinae with its ancestral genus *Dusisiren*. The Hydrodamalinae, Dugonginae, and Halitheriinae constitute the family Dugongidae. The Sirenia also include three other families: the extant Trichechidae (manatees) and the extinct Prorastomidae and Protosirenidae.

II. Distribution

Historically, the sea cow was known only from Bering and Medney (Copper) Islands at the western terminus of the Aleutians, 200 miles to the west of Attu Island and 150 miles east of the Kamchatka Peninsula. Pliocene and Pleistocene fossils demonstrate that the distribution originally extended around the North Pacific from Baja California, Mexico (30°N), along the coast of North America to the Aleutian chain and south in the western Pacific to Honshu, Japan (37°N). No evidence has been adduced for GEOGRAPHIC VARIATION. The northernmost Pacific was likely marginal habitat as members of the Kommandorskiye population may have been stunted. Adults at Bering Island had a body length ca. 750 cm (25 ft.) and a weight of 4500–5900 kg (10,000–13,000 lbs.). Fossil material

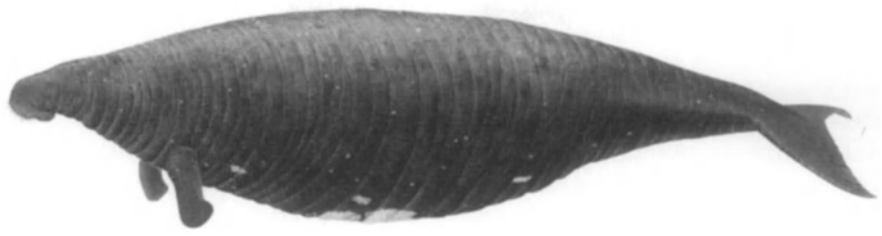

Figure 1 *A reconstruction of Steller's sea cow by Pieter Arend Folkens. Outstanding features are the relatively small head, bulky body, rough skin, whale-like flukes, and blunt unflipper-like pectoral appendages.*

from farther south suggests maximum body lengths may have reached 9–10 m.

III. Natural History and Behavior

Bering Island is approximately 50 miles in length and Medney Island 35 miles long. Both are narrow, high, and rocky. Sea cows foraged on softer parts of large marine algae ("kelp") on open coasts in rocky subtidal and intertidal waters. Steller referred to four types of macroalgae (all still undescribed in his day) as preferred foods; these have been variously identified but probably include such forms as *Agarum* spp., *Alaria praelonga, Halosaccion glandiforme, Laminaria saccharina, Nereocystis luetkeana*, and *Thalassiophyllum clathrus*. Tougher stems and holdfasts were not eaten, washing up in heaps on the shore where sea cows fed. Seagrasses have also been suggested as elements of the diet, but this is doubtful. Of the two available forms, *Phyllospadix* spp. are among the toughest seagrasses and *Zostera marina* grows on soft bottoms in protected waters. In any case, *H. gigas* was probably dependent on a small number of forage species. Feeding along the shoreline, with backs above water, the sea cows were not observed to submerge; they moved about using their flukes and maintaining position on the rocks with their bristle-tipped pectoral limbs. Algae growing on rock faces were bitten off or pawed free with the forelimbs, and the softer parts were separated by the bristly lips as if "cut off with a dull knife." If the animals were indeed unable to submerge, they could access food only to depths of about a meter below low tide level. Steller wrote that they fed "in herds," keeping the young in the center of the group. He did not specify herd size but referred to family groups as consisting of a pair with their offspring. In addition to rocky shorelines, Steller stated that sea cows were "fond of shallow sandy places along the seashore, but they like especially to live around the mouths of river and creeks, for they love fresh running water."

Sea cows had no fear of humans. Feeding with the head submerged and half of the back above water they were easily approached and could be touched or speared from the rocks. One method of capture was for a swimmer or a boat crew to approach the intended victim with a large hook attached to a line to the shore. When the hook had been driven into the animal's body, a shore crew would attempt to drag it toward the beach. Steller reported that sea cows made no sounds even when wounded by hunters. Of particular interest are the descriptions of both helping behavior and evident pair bonding in this context. Steller reported that while an animal was being dragged ashore other sea cows would attempt to dislodge the hook and/or break the rope. When one female had been dragged ashore, the accompanying male kept station offshore at the site for at least 2 days.

On the basis of his observation of "family groups" and the evidence of strong pair bonds, Steller suspected that the animals were monogamous. Mating apparently involved only a pair, with the male following or herding the female during prolonged

Figure 2 *Skulls of the two recent dugongids drawn to the same scale. The* Hydrodamalis gigas *skull (left) shows the lack of teeth and the relatively undeflected rostrum compared with the downwardly deflected rostrum of* Dugong dugon *(right). The dugong's tusks and molar teeth are indicated by arrows. The sea cow's head was relatively small compared with its body and that of the dugong relatively large so that the size of the two skulls does not reflect relative body size.*

"amorous preludes." Copulation involved mutual clasping with the pectorals, the female in an inverted position and the male above.

Steller's views as to the annual reproductive cycle present some enigmas. He observed mating behavior and copulation in the early spring, and deduced that gestation was more than 12 months, but stated that young were born "at any time of the year, but most frequently in autumn." Fall births would seem likely to put the young at a disadvantage, especially in view of his observations that "during the winter they are often suffocated by the ice that floats about the shore" and "in the winter the animals become so thin that, besides the bones of the spine, all the ribs show." As Steller did not arrive on the island until late November and left the following August, he could not have had direct knowledge of a concentration of births in the fall. He never saw more than one very small calf with a female, implying that births were single.

As an algivore, *Hydrodamalis* may have been dependent on an ecosystem in which the carnivorous sea otter (*Enhydra lutris*) suppressed invertebrate herbivory in shallow coastal waters. Like the sea cow, the sea otter is confined to the shallows within 1 km of shore where it forages for urchins and other invertebrate herbivores, usually to a maximum depth of about 130 ft. (40 m). Within this zone, otters keep sea urchins and other invertebrate algivores in check. *Hydrodamalis* was dependent on fast-growing kelps on rock faces and on the kelp canopy in deeper waters. Where sea otters are extirpated, grazing by urchins results in "kelp barrens." Thus sea cows depended on sea otter predation that maintained the shallow-water kelp community.

Steller reported both external and internal PARASITES. The crustaceans that he described as infesting the sea cows' skin have been interpreted as cyamids or caprellids, but identification will probably remain uncertain. The only specimens purported to exist are ones attached to alleged sea cow skin fragments, but these latter are likely to pertain instead to whales. "White worms half a foot long," observed by Steller in the stomach and intestine of the sea cow, were probably ascarid nematodes; both these and the ectoparasites probably went extinct with the sea cow itself. *Hydrodamalis*, at least the young, may occasionally have been prey for killer whales (*Orcinus orca*) and large sharks.

IV. Evolutionary Origins

Hydrodamalis evolved from tropical and subtropical, seagrass-eating dugongid ancestors that shifted from bottom feeding to surface feeding and from a seagrass in warm protected waters to an algal diet and a high-energy, low-temperature environment. Seagrasses, which have a large part of their biomass below ground in the form of roots and rhizomatous storage organs, are the preferred forage of the extant dugong (*Dugong dugon*) and apparently of the ancestral dugongid line. Kelps have no below-ground biomass. Their softer, more edible, growing portions (the bulk of nutritious biomass of the taller kelps) are at or near the surface, suspended by floats. Fossils record this transition from bottom rooting to surface foraging. *Hydrodamalis* descended from the widely distributed tropical genus *Metaxytherium*, a small-tusked, seagrass-eating Miocene halitherine dugongid. At the time a diversity of herbivorous marine mammals foraging along the east-central Pacific shorelines was presumably supported by a diverse flora of tropical and subtropical seagrasses, as well as algae (perhaps including kelps in cooler, more exposed microhabitats). The sister group and apparent immediate ancestor of hydrodamalines was the species *M. arctodites*, living in southern California and Baja California by about 14–15 Ma. Probably already present were the earliest members of its descendant genus *Dusisiren*, as well as a dugongine, *Dioplotherium allisoni*. These three sympatric sirenians, representing the three dugongid subfamilies, probably occupied distinct feeding niches. The large-tusked *Dioplotherium* with its strongly deflected rostrum was likely a bottom feeder, rooting for rhizomes of the larger seagrasses. The small-tusked *Metaxytherium* probably depended on the smaller rhizomes and leaves of seagrasses. *Dusisiren* and later hydrodamalines, in contrast, progressively gave up bottom and rhizome feeding, specializing on kelps growing higher in the water column, reducing their rostral deflections, and losing their tusks. Also present with these Miocene sirenians were three or more genera of desmostylians, hippopotamus-like bottom feeders, presumably also herbivorous and feeding on intertidal and subtidal seagrasses and kelps.

As the climate cooled after the Middle Miocene, and tectonic uplift rendered the western North American coastline more emergent (replacing protected embayments with more exposed, higher-energy habitats), the cold-water plants increased their dominance in the marine flora, and the tropical seagrasses finally disappeared altogether. With them went *Dioplotherium*, *Metaxytherium*, and all the desmostylians. By the Late Miocene, *Dusisiren*, having earlier thrown in its lot with the kelps, had increased its cold tolerance and its morphological specialization for kelp eating (passing through the successive evolutionary stages *D. jordani* and *D. dewana*) and had extended its range to the northwestern Pacific. By the end of the Miocene it had evolved into *Hydrodamalis cuestae*, which gave rise in the Pleistocene to *H. gigas*.

The prehistoric distribution of sea cows and sea otters (*E. lutris*) was coterminous. Anderson (1995) speculated on the evolution of a sea cow–sea otter relationship and sea cow morphology as follows: "As the hydrodamaline range shifted northwards, the adoption of a kelp diet may have contributed (along with the thermoregulatory demands of a cooling environment) to selection for large adult body size, high birth weight, prolonged parental care, and low reproductive rate. At the same time, the more effective chemical defenses of kelps growing below the sea otter foraging zone might have favored the sea cow's specialization for surface feeding and its loss of diving ability."

V. Extinction

The vulnerability of the sea cows in their last stronghold made it possible for the weak and scurvy-ridden castaways of Bering's expedition to secure an abundant supply of food and to escape to the mainland in the summer of 1742. Having found ways to capture the sea cows, the survivors were able to divert manpower to salvage materials from the wreck of their ship and build a smaller vessel in which to reach Kamchatka. That

voyage, made possible by sea cow vulnerability, carried with it the news of fortunes to be made in hunting sea otters and fur seals. A fur rush followed, fueled by sea cow meat. The first hunting expedition wintered on Bering Island in 1743–1744. By 1763 several parties had spent up to 9 months on the islands, living almost exclusively on sea cows and salting down barrels of meat to provision the 2- to 3-year expeditions to the Aleutian chain and the north Asian and North American coasts in search of furs. Sea cow hides were also used to make large skin boats (baidarkas or umiaks). In 1754–1755 a fur-hunting expedition was forced to winter on Bering Island because the sea cows had been extirpated on Medney Island. The last specimen on Bering Island was reported killed in 1766. Steller's biographer, Leonard Stejneger, summarized accounts of the unrestrained killing by the fur hunters and attributed the extinction of the sea cows to ruthless slaughter.

These magnificent animals would have been at least as vulnerable to healthy and skilled Pleistocene hunters along mainland shores as they were to the weakened Russians on the Kommandorskiyes. Domning (1978) has suggested that human hunting may have extirpated sea cows from areas within reach of aboriginal hunters, leaving only the population around the remote Kommandorskiyes. Over most of its range the sea cow may have been the only marine mammal to succumb to "Pleistocene overkill." The final drama played out on Bering and Medney Islands suggests a complementary and more complex and instructive story. Anderson (1995), following a suggestion by Delphine Haley, proposed that the final extinction of the sea cow resulted not solely from ruthless harvesting, but from a cascade of events beginning with extirpation of the local sea otter population around the islands in the first rush for furs. Decimation of the otters in all probability triggered a sea urchin population explosion and the disappearance of chemically undefended shallow water kelps that were the sea cows' main food supply. Invasion of the shallow waters by chemically defended deep-water kelps left the hunted remnant of the sea cow population with kelp that was likely toxic. Anderson proposed that this may have been a reenactment of events when North Pacific coastlines were first colonized by humans in the waning Pleistocene.

Steller's Sea Lion

Eumetopias jubatus

THOMAS R. LOUGHLIN
National Marine Mammal Laboratory, Seattle, Washington

The Steller's [or Steller] sea lion (or northern sea lion; *Eumetopias jubatus*) is the largest otariid pinniped and one of the more aesthetically appealing sea lions. In Greek, *Eumetopias* means having a well-developed, broad forehead; in Latin, *jubatus* means having a mane, as in the male. Called *qawax* (pronounced ka-wa; *qawan*, plural) by Aleut natives and *sivuch* (*sivuchi*, plural) in Russian, Steller's sea lions exhibit significant sexual dimorphism with males being larger (Fig. 1). The average standard length of males is 282 cm and of females is 228 cm (maximum of about 325 and 290 cm, respectively). Estimated average weights of males and females are 566 and 263 kg, respectively (maximum of about 1120 and 350 kg, respectively). Pup weight at birth is 16–23 kg and may be slightly larger in the western part of their range. Taxonomically they belong to the family Otariidae, of the order Carnivora, and can be distinguished by a conspicuous diastema between the upper fourth and fifth postcanine teeth. Their range overlaps with the California sea lion (*Zalophus californianus*), which is darker color and smaller in size.

It is an attractive animal. Pups are born with a wavy, chocolate brown fur that molts after about 3 months of age. Adult fur color varies between a light buff to reddish brown with most of the underparts and flippers a dark brown to black. Both sexes become blonder with age. Adult males have long, coarse HAIR on the chest, neck, and shoulders, which are massive.

I. Distribution

The Steller's sea lion was first described by the German physician/theologian George Wilhelm Steller based on a specimen that he obtained from the Russian Commander Islands while serving as naturalist on Vitus Bering's fateful voyage to Alaska in 1741–1742. It was also during this voyage that Steller described the northern fur seal (*Callorhinus ursinus*) and Steller's sea cow (*Hydrodamalis gigas*, now extinct).

Steller's sea lions occur through the north Pacific Ocean rim from Japan to southern California (Fig. 2). They abound on nu-

Figure 1 *An* Eumetopias jubatus *rookery showing pups (foreground) and adult females and males. Note the sexual dimorphism between the larger male and the smaller female. (NMFS photograph).*

merous breeding sites (rookeries) in the Russian Far East, Alaska, and British Columbia with lower numbers in Oregon and California. Washington is the only western coastal state that does not contain a Steller sea lion rookery, although pups were observed at one haul-out site in 1997 and 1998. Seal Rocks in Prince William Sound, Alaska, is the northernmost (60°09′N) rookery and Año Nuevo Island, California, the southernmost (37°06′N). Unlike their more gregarious cousin the California sea lion, Steller's sea lions tend to avoid people and prefer isolated offshore rocks and islands to breed and rest. Although rookeries and rest sites occur in many areas, the locations used are specific and change little from year to year. Steller's sea lions tend to return to their birth island as adults to breed, but they range widely during their first few years and during the nonbreeding season.

Steller's sea lion population numbers have declined since the 1980s by over 90% in most of Alaska and southern California, whereas populations in Oregon, British Columbia, and southeastern Alaska have remained stable or increased slightly (Fig. 3). The worse declines occurred in the Aleutian Islands and Gulf of Alaska, areas that historically were centers of abundance. Causes for these declines have not been identified but may be related to disease, reduced food availability through natural changes in the ocean or by fishing pressure, and the synergistic effects of commercial fishing and climate change. Studies of blood chemistry and body condition of females and pups during the breeding season are within normal ranges for pinnipeds, but similar studies of juveniles, the age class most likely suffering higher mortality rates, have not been accomplished. The large population declines resulted in the species being listed as "threatened" by the United States in 1992. A survey in 1989 provided a total estimate of about 116,000 Steller's sea lions range wide, and another in 1994 resulted in about 100,000 of which about 9% of the total were in Russia, 70% in Alaska, 12% in British Columbia, 8% in Oregon and California, and 1% in Washington. The decline continued throughout the 1990s.

II. Geographical Variation

Studies of mitochondrial DNA from Steller's sea lions throughout the range suggest that at least two stocks exist: an eastern stock (California through southeastern Alaska) and a western stock (Prince William Sound, Alaska, and westward). Continuing population declines resulted in the western population being listed as "endangered" in 1997; the eastern population remains listed as threatened. The Steller's sea lion has 30 metacentric or submetacentric chromosomes and 4 acrocentric chromosomes; the X chromosome is submetacentric and the Y is acrocentric ($2n = 36$).

III. Ecology

Steller's sea lions eat a variety of fishes and invertebrates. In Alaska, principal prey are walleye pollock (*Theragra chalcogramma*), Pacific cod (*Gadus macrocephalus*), Atka mackerel (*Pleurogrammus monopterygius*), octopus, squid, herring (*Clupea harengus*), flatfishes, sculpins, and a wide variety of other fishes and invertebrates. At specific times of the year other prey may be eaten when plentiful (e.g., Pacific salmon, *Onchorynchus* spp.). During the breeding season, females with pups generally feed at night; territorial males eat very little or not at all while on territory. Feeding occurs during all hours of the day once the breeding season ends.

The variety of the sea lion diet has been correlated with POPULATION DYNAMICS. In some Alaskan areas where the diet is diverse, sea lion numbers have been stable or increasing slightly. In areas where sea lions depend primarily on one prey item, the sea lion population is declining. Whether population trends

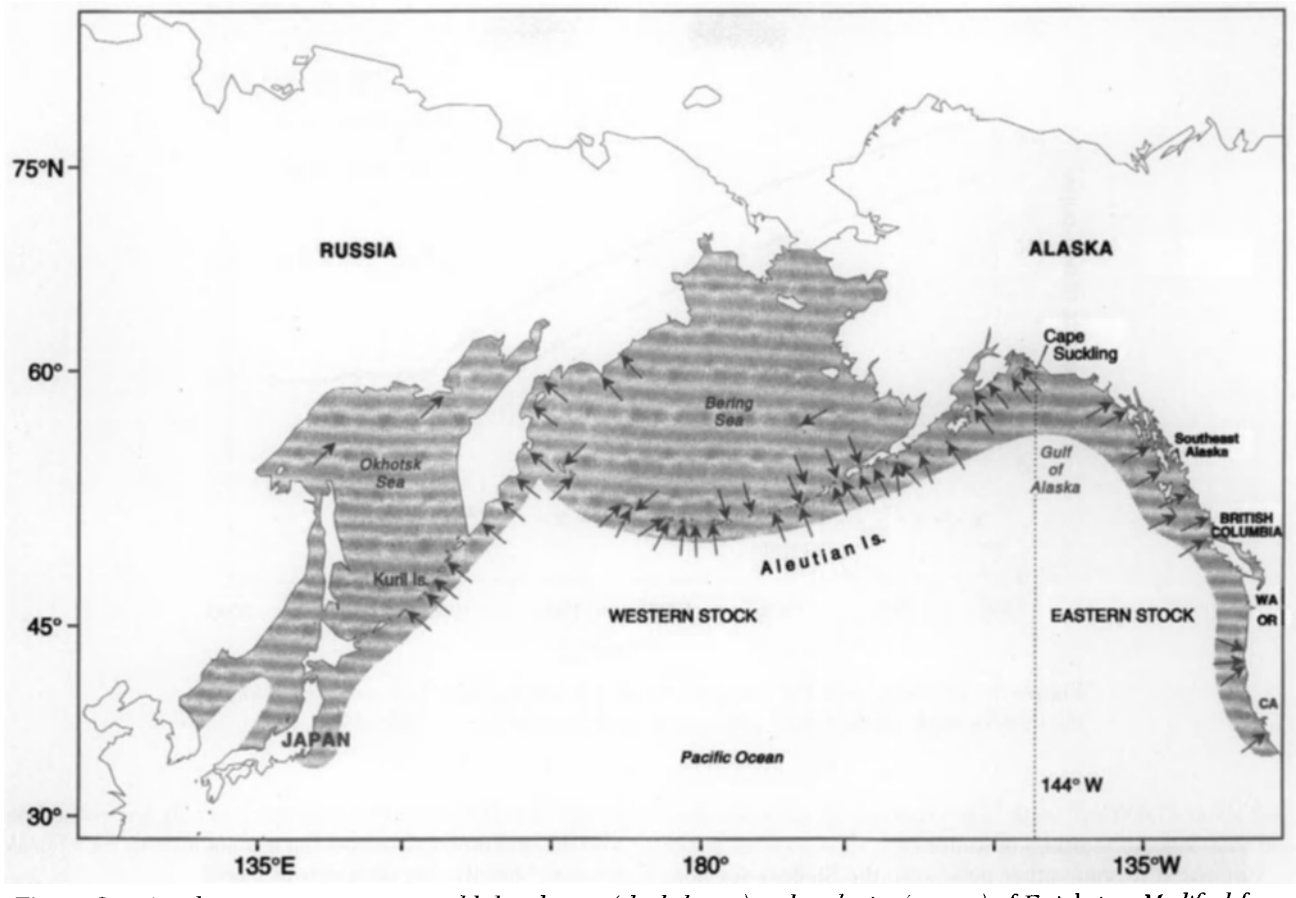

Figure 2 *Map depicting approximate world distribution (shaded area) and rookeries (arrows) of* E. jubatus. *Modified from Loughlin* et al. *(1987).*

are more closely associated with diet diversity is still equivocal, but the availability of a variety of prey is optimal for pinnipeds. Steller's sea lions are eaten by killer whales and sharks, but the possible impact of these predators is unknown.

A cacophony of NOISE engulfs rookeries and haul-out sites with animals of both sexes and all ages vocalizing throughout the day and night. Territorial males use low-frequency roars to signal threats to other males and to court females. Females vocalize frequently, calling to their pups and squabbling with other sea lions of all ages. Pups have a bleating, sheep-like cry and their voices deepen with age.

Grooming is performed by bending the head and neck backward and scratching with the claws of the hind flipper. Sea lions also rub themselves on rocks or other animals. While swimming, the fore flippers are used primarily for movement and the rear flippers for braking and turning.

IV. Notable Behavior

Observations of Steller's sea lions at sea suggest that large groups usually consists of females of all ages and subadult males; adult males sometimes occur in those groups but are usually found individually. On land, all ages and both sexes occur in large aggregations during the nonbreeding season. Breeding season aggregations are segregated by sexual/territorial status. Steller's sea lions are not known to migrate, but they do disperse widely at times of the year other than the breeding season. For example, sea lions marked as pups in the Kuril Islands (Russia) have been sighted near Yokohama, Japan (more than 350 km away), and in China's Yellow Sea (over 750 km away), and pups marked near Kodiak, Alaska, have been sighted in British Columbia, Canada (about 1700 km distant). Generally, animals up to about 4 years of age tend to disperse farther than adults. As they approach breeding age, they have a propensity to stay in the general vicinity of the breeding islands and, as a general rule, return to their island of birth to breed as adults.

The foraging pattern of adult females varies seasonally. Trip duration for females with young pups in summer is approximately 18 to 25 hr, trip length averages 17 km, and they dive approximately 4.7 hr per day. In winter, females may still have a dependent pup, but a mean trip duration is about 200 hr, with a mean trip length of about 130 km, and they dive about 5.3 hr per day. Yearling sea lions in winter exhibit foraging patterns intermediate between summer and winter females in trip distance (mean of 30 km), but shorter in duration (mean of 15 hr) and with less effort devoted to diving (mean of 1.9 hr per day). Estimated home ranges are 320 km^2 for adult females in sum-

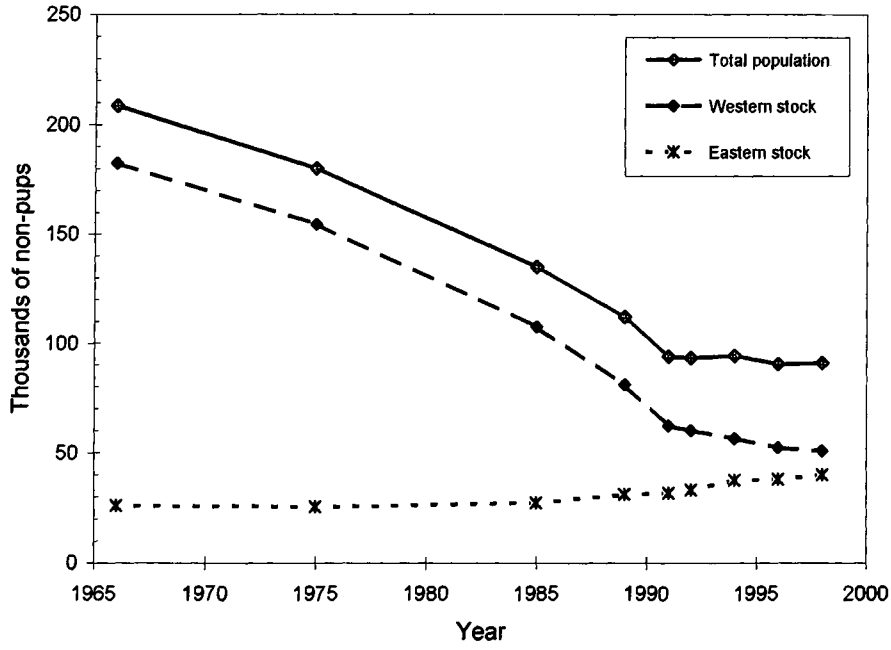

Figure 3 *The population status of Steller's sea lions throughout their range (solid line), the western stock (dashed line), and eastern stock (dotted line) in 1966–1998.*

mer, about 47,600 km^2 (with large variation) for adult females, and 9200 km^2 for yearlings in winter.

Compared to some other pinnipeds, the Steller's sea lion tends to make relatively shallow dives, with few dives recorded to depths greater than 250 m. Maximum depths recorded for individual adult females in summer are in the range of 100 to 250 m; maximum depth in winter is greater than 250 m. The maximum depth measured for yearlings in winter was 328 m.

V. Notable Anatomy, Physiology, and Life History

The upper postcanine number 5 is double rooted with the crown directed backward and does not occlude with lower postcanine 5; all other postcanines are singled rooted, slant somewhat forward, and have irregular conical pointed crowns. The diagnostic diastema between upper postcanines 4 and 5 may be caused by rapid growth and extension of the skull rather than by suppression of the fifth and sixth postcanines. Annual growth layers exist in the dentin and cementum with dark layers corresponding to winter and light layers to summer. Dental formula for permanent teeth is i 3/2, c 1/1, pc 5/5, total 34. *E. jubatus* has a double alveolar capillary supply, as in the Cetacea, unique among the pinnipeds.

Like most pinnipeds, Steller's sea lions give birth to a single pup each year; twinning is rare. Males establish territories in May in anticipation of the arrival of females. Viable births begin in late May and continue through early July. The sex ratio at birth is slightly in favor of males. Females breed about 2 weeks after giving birth. Copulations may occur in the water but most are on land. The mother nurses the pup during the day, and after staying with her pup for the first week, she goes to sea on nightly feeding trips. Pups generally are weaned before the next breeding season, but it is not unusual for a female to nurse her offspring for a year or more.

Females reach sexual maturity between 3 and 8 years of age and may breed into their early 20s. Females can have a pup every year but may skip years as they get older or when stressed nutritionally. Males also reach sexual maturity at about the same age but do not have the physical size or skill to obtain and keep a breeding territory until they are 9 years of age or older. Males may return to the same territory from 1 to 7 years, but rarely more than 3 years. While on their territory during the breeding season, males may not eat for 1–2 months. The rigors of fighting to obtain and hold a territory and the physiological stress over time during the mating season reduce the life expectancy of these animals. They rarely live beyond their mid-teens, while females may live as long as 30 years.

VI. Fossil Record

Otariids probably arose in North Pacific temperate waters from the Enaliarctidae; the earliest known otariid, *Pithanotaria starri*, is between 10 and 12 million years old. The earliest large otariid with most cheek teeth single rooted is from 2 mya Pliocene deposits in Japan and is assigned to the extant genus *Eumetopias*, although it is probably a different species from *E. jubatus*. A skull, teeth, vertebrae, and other parts of a postcranial skeleton of *E. jubatus* were recovered in California from Pleistocene deposits.

VII. Interactions with Humans

Steller's sea lions are rarely seen in aquaria because of their large size and pugnacious nature. Those in captivity in 1999 in-

cluded about 8 in the United States, 5 in Canada, about 4 in Denmark, and about 15 in Japan. Five in British Columbia at the Vancouver Aquarium and 3 at the Alaska Sealife Center in Alaska were held for both research and exhibit.

Steller's sea lions are an important subsistence resource for Alaskan natives who hunt them for food and other uses. Three hundred or more may be taken a year in Alaska.

Steller's sea lions may be affected by commercial fishing directly through INCIDENTAL CATCH in nets, by entanglement in derelict debris, by shooting, or indirectly through competition for prey, disturbance, or disruption of prey schools. The number of sea lions caught in trawl nets was high during the 1960s and 1970s but has declined since and is presently at very low levels. Incidental entanglement probably contributed to population declines in the Aleutian Islands and western Gulf of Alaska in the 1970s and 1980s, but is not presently considered an important component in the decline. ENTANGLEMENT in derelict gear is rare and unlikely to have contributed to the decline. In some areas, Steller's sea lions were killed deliberately by fishermen, but it is unclear how such killing affected the world population, especially since declines have occurred in areas used uncommonly by commercial fleets (central and western Aleutian Islands) or where fishermen rarely have guns (Russia). Commercial fisheries target on several of the most important prey eaten by Steller's sea lions. In combination, these fisheries remove millions of metric tons of fish. However, the complexity of ecosystem interactions, and limitations of data and models, make it difficult to determine whether fishery removals, directly or indirectly, have negatively impacted Steller's sea lion populations.

Stock Assessment

JEFFREY M. BREIWICK AND ANNE E. YORK
National Marine Mammal Laboratory, Seattle, Washington

stock assessment is an attempt to estimate the productivity or potential of a stock and to predict the future growth of the stock in the face of removals such as incidental catches, directed harvests, or natural causes. It also seeks to measure the capacity of the stock to recover from these removals. The status of the stock with respect to some reference level, such as the unexploited population size, is an element of a stock assessment, as well as the evaluation of the consequences of various management actions. For stocks that are subject to harvest or experience mortality incidental to fishing operations, a goal is to determine allowable removal levels (e.g., harvests that will allow the population to recover to some desired level during some time frame).

The components of a stock assessment will vary with the species considered, its stock identification, the quantity and quality of data available, and the methods and mathematical models employed. It is a process whose steps typically include (1) the definition of the geographic and biological extent of the stock, (2) collection of appropriate data, (3) choice of an assessment model and parameters, (4) specification of performance criteria and evaluation of alternative actions, and (5) presentation of results. While these steps were originally formulated for fishery stock assessments, they are equally applicable to marine mammal stock assessments.

Marine mammal stock assessments are often carried out to determine what level of mortality a stock can sustain. A stock assessment usually requires several pieces of information: current as well as historical abundance, trends in abundance and estimates of biological parameters (such as age at sexual maturity, natural mortality rate, sex ratio, and pregnancy rate), historical

harvests, age distribution, maximum sustainable yield level (MSYL), age-specific harvesting mortality, sustainable or replacement yield, spatial distribution of the stock in question, and other relevant factors that may vary by species and population.

I. Productivity

The productivity of a stock is determined by a number of factors, including abundance, rate of increase, population age structure, sex ratio, and the manner in which density dependence operates. Productivity is the amount by which the stock increases over a time interval (usually a year) and is the difference between the number of animals added (by reproduction and immigration) and the number that are lost (due to emigration and from natural causes—all causes not due to harvest). Ideally, immigration and emigration are zero or equal so their effects cancel each other. The amount by which the population increases each year (in the absence of a harvest) is the net production or the replacement yield, and this amount, if harvested, results in the population size at the end of the time period (usually a year) remaining the same size as at the beginning of the year. A related quantity, the sustainable yield, is the productivity when the stock is stable. This occurs when the various population rates (such as natural mortality and reproduction) have remained constant for sufficient time and the environment does not change. Fishery stock assessments generally determine productivity in terms of biomass whereas marine mammal stock assessments most often determine productivity in terms of number of animals. This is not only because marine mammals are difficult to weigh but also because they stop growing after reaching physical maturity, whereas most fish grow throughout their life. It thus becomes increasingly difficult to associate age and size for older animals, especially for cetaceans.

II. Models

Most stock assessments employ a mathematical model of the population to predict the historical trends in abundance as well as future trends under various removal scenarios and choice of model parameters. This approach assumes a constant environment and model parameters. These model parameters are estimated from available data or are fixed at various plausible values. The more reliable the basic data, the more reliable will be the assessment. A simple population model often used for modeling the dynamics of a population is the discrete, generalized logistic model:

$$N_{t+1} = N_t + R_{\max} N_t[1 - (N_t/K)^z] - h_t, \qquad (1)$$

where N_t is the population size (in numbers) at the start of year t, $R_{\max}$ is the maximum per capita growth rate, K is the carrying capacity or preexploitation abundance of the population, h_t is the harvest in year t, and z is a density-dependent exponent that determines at what population level (between 0 and K) the productivity is maximum. Equation [1] is a difference equation with the population size at time $t + 1$ being a function of the population size at time t.

The population level at which the productivity curve is maximum, the maximum net productivity level (MNPL), is considered to be greater than 50% of K for marine mammals. When the harvest is random with respect to age and sex, MSYL and MNPL are often used interchangeably. The International Whaling Commission (IWC) has usually adopted a value of 60% for the MSYL, which corresponds to a z of 2.39. A value of $z = 1$ results in a symmetric productivity curve with MSYL at 50% of K. This also corresponds to a linear density-dependent relationship between per capita rate of growth and density.

This model is simple in that it combines males and females, it ignores age structure, and it assumes constant environmental conditions and model parameters. It does, however, capture the basic dynamics of the population, including harvesting or other known removals. It has the desirable feature that the recruitment rate is density dependent: it is greatest at small population sizes and decreases as the population increases toward K. The sustainable yield as a function of N for the model shown earlier is given by

$$SY(N) = R_{\max} N[1 - (N/K)^z]. \qquad (2)$$

Productivity, therefore, increases as the population size increases, reaches a maximum at some level intermediate between 0 and K (the MSYL), and then declines to 0 at K. This can be seen in Fig. 1, which shows the sustainable yield curves for $z = 1$ (linear density dependence with MSYL = 50% of K) and $z = 2.39$ (nonlinear density dependence with MSYL = 60% of K). By solving for the population size when the productivity is maximum, the MSYL can be shown to be equal to $K(1/1 + z)^{1/z}$. Thus, if $z = 1$, MSYL = $K/2$ or 50% of K.

Equation [1] and similar models, often modified to include sex and age structure, have been used frequently to model cetacean, pinniped, and other marine mammal populations. If an estimate of $R_{\max}$ is available along with a time series of removals, then the model can be used to project an initial abundance, N_0, forward to any particular year. This procedure can be programmed to find

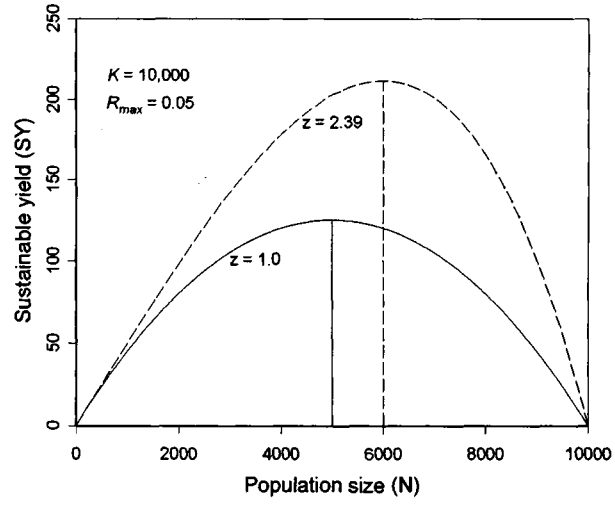

Figure 1 *Plot showing sustainable yield as a function of population size (see Eq. [2]) for a hypothetical population with R_{max} = 0.05, K = 10,000, and two values for the density dependent exponent, z.*

a N_0 that makes the population trajectory "hit" a current abundance estimate. This is a simplification of a technique employed to assess many marine mammal populations. Parameters of the model can be estimated by minimizing a measure of discrepancy between observed and model-predicted abundance.

III. Population Status

The IWC and the U.S. government (U.S. Marine Mammal Protection Act of 1972; MMPA) have based assessments on classifying stocks by their depletion level with respect to pre-exploitation population size and maximum net productivity level. The IWC new management procedure (NMP) was based on classifying stocks as initial management (IM), sustained management (SM), and protected (P), based on the MSYL and the current depletion level with respect to K. However, for stocks classified as IM or SM, the quota required knowledge of the MSY. The MSY, in turn, depends on, among other things, the level of density dependence (see Fig. 1). The revised management procedure (RMP) addresses shortcomings in the NMP such as the difficulty in determining MSY for a stock and relies primarily on estimates of abundance and their uncertainty and a simple population model such as Eq. [1] requiring few biological parameters.

The U.S. MMPA called for marine mammal populations to be maintained at an "optimum sustainable population" (OSP) level. The U.S. National Marine Fisheries Service defined OSP as a population level between the MNPL and the carrying capacity. The application of this requires the determination of what the current population status is with respect to the MNPL. In some cases, a range of MNPL was used, whereas in other cases an estimate was made whether the abundance was either less than or greater than the MNPL. The 1994 amendments to the MMPA required that a potential biological removal (PBR) be determined for marine mammal stocks. The PBR is equal to the maximum number of animals that can be removed safely from the population annually. It is calculated as the product of the minimum population estimate of the stock, one-half the maximum theoretical or estimated net productivity rate, and a recovery factor between 0.1 and 1. The assessment of allowable removals therefore hinges on an estimation of abundance and the productivity rate. The PBR is a conservative approach whose goal is to allow stocks to reach or maintain their OSP without having to estimate complicated quantities such as MNPL or K.

IV. Uncertainty and Other Considerations

Uncertainty and how to deal with it is a feature of all stock assessments. The environment can change as can the genetic structure of stocks. There is also uncertainty in the underlying population dynamics (termed process error), in the measurement of abundance or indices of abundance (termed measurement error), in the model structure, and in the model parameters. Common methods for dealing with some forms of uncertainty include bootstrapping (a method of resampling the data to estimate variability), maximum likelihood (a method for obtaining parameter estimates and their associated variability), and Bayesian statistical methods.

Bayesian statistical methods are being used increasingly to deal with uncertainty in stock assessments. Bayesian estimation involves integrating the product of the likelihood of the observed data and the prior probability distribution for parameters of interest to obtain what is termed the posterior distribution for the quantity of interest. Due to the complexity involved in integrating this product, it must often be estimated numerically by Monte Carlo methods (based on computer simulations using random numbers). An advantage of Bayesian methodology is that various sources of information on parameters, including observations from other stocks or species, can be incorporated into the assessment. The end result is not just a simple estimate of the growth rate, for example, but a probability distribution, showing the probability of different values of the parameter. A disadvantage of the Bayesian method is that it is often difficult to construct and obtain agreement on a prior distribution to use in an assessment.

Most stock assessments deal with uncertainty in model parameter estimates and management-related quantities but for the most part are still based on single-species population models. Some progress has been made in considering marine mammal stocks as part of a larger ecosystem that includes food webs and interacting (e.g., competing) species. While it would be preferable to consider a host of interacting factors that influence marine mammal stocks, the paucity of available data often precludes the estimation of the parameters necessary to model the various population interactions. It is likely, however, that future stock assessments will increasingly take into account ecosystem considerations.

Another issue that is becoming more important in fisheries and marine mammal stock assessment is the consideration of environmental factors. In the North Pacific, for example, decadal oscillations in climate features have been identified that can affect the distribution and abundance of fish and marine mammals (by affecting the distribution and abundance of prey species). Large amounts of data are required to be able to assess the effects of climate on marine mammals, but these data are beginning to be collected. Without these data it is very difficult to determine whether changes in stock abundance are due to climate, harvesting, or a combination of the two.

V. Examples

A. Cetaceans

Recent stock assessments carried out for both the eastern North Pacific gray whale (*Eschrichtius robustus*) stock and the Western Arctic bowhead whale (*Balaena mysticetus*) have used Bayesian assessment methods. Stock definition is not considered an issue for these two stocks, as there is little evidence for substock structure.

Both of these stocks migrate along the coast where they are counted by shore-based observers. Data collected include counts, which are analyzed to give abundance estimates along with standard errors (measure of uncertainty) and numbers of young and immature animals. Two different assessment models have been used, but both are age- and sex-structured models that incorporate density dependence in the reproductive rate. A method often used to estimate the posterior probability distribution of management-related parameters (such as

MSYL and RY) involves projecting the population model forward using as inputs parameter values that are chosen randomly from their prior probability distributions. A measure of the discrepancy between the observed abundance estimates and the abundances predicted by the population model, the likelihood, is then computed. This is repeated many times and management-related parameters are calculated for each case. These include historic abundance, current abundance, growth rate, MSYL, and RY. From this sample, a smaller sample is taken with probability proportional to the total likelihood computed for each trajectory. This second sample is an estimate of the posterior probability distribution of the management-related parameters. From these distributions the median or mean value can be obtained as well as other statistics of interest, including the answer to such statements such as "What is the probability that the RY is less than 100?" or "What is the probability that the current abundance is greater than the MSYL?" In practice, a conservative approach has often been adopted by computing such quantities as the lower 5th or 10th percentile of the RY and other distribution in determining allowable quotas.

Both the U.S. National Marine Fisheries Service and the IWC have assessed these two stocks. A Bayesian analysis using an age- and sex-structured model for gray whales resulted in a lower 10th percentile for a R_{max} of 4.7%. This, coupled with a minimum population estimate of 24,477 animals and a recovery factor of 1.0, resulted in a PBR of 575 animals, well above the average current annual take, which is less than 180. The IWC assessment was based on a Bayesian analysis using an age structure model. The results included estimates of K (30,000–34,000), N_{1997}/K (0.72–0.80), and RY (550–580). The harvest is much lower than the estimated RY and the population size is estimated to be greater than 70% of K, indicating that current harvests should allow the population to increase, based on this single-species approach to assessment.
